includes the snail *Sublimina octona* and a crustacean (wood louse) as intermediate hosts and certain lizards as paratenic hosts. Cats acquire the parasite by feeding on infected lizards. In mild cases, nonspecific chronic signs of unthriftiness may be seen. Severe infections, however, may cause the "lizard poisoning" syndrome, which is characterized by anorexia, lethargy, depression, persistent vomiting, diarrhea, jaundice, and an enlarged abdomen, leading to death. Treatment with praziquantel (20 mg/kg/day, PO, for 3–5 days, ideally, repeated 12 wk later), or nitroscanate (100 mg/kg, PO, once) has been successful, although these drugs are not approved for this use. Praziquantel appears to be the most effective agent. Bile duct surgery may also be required.

Metorchis albidus and *M. conjunctus* are two small flukes (5 × 1.5 mm) that have been found in the bile ducts and gallbladder of dogs, cats, and other carnivores in North America, Europe, and the former USSR. They seldom cause any recognizable

clinical signs. Their eggs are small (24–30 × 13–16 µm), and the life cycle includes certain freshwater snails and fish as intermediate hosts. Treatment of *Metorchis* spp infections in dogs may be attempted with praziquantel (20 mg/kg, PO, once), although this is an extra-label use.

Eurytrema procyonis is a small fluke (2.1 × 1 mm) commonly seen in the pancreatic duct of raccoons in the eastern USA and occasionally found in the pancreatic duct, bile duct, and gallbladder of domestic cats. Infection may be associated with weight loss and intermittent vomiting. The eggs are medium sized (45–53 × 29–36 µm), and the life cycle involves a land snail and a second intermediate host thought to be an arthropod. Treatment may be attempted with fenbendazole (30 mg/kg/day, PO, for 6 days) or praziquantel/pyrantel/febantel (praziquantel and pyrantel each at 5.8 mg/kg/day and febantel at 28.8 mg/kg/day, PO, for 5 days), although these drugs are not approved for this use.

HEPATIC DISEASE IN SMALL ANIMALS

The liver performs numerous functions, including but not limited to lipid, carbohydrate, and protein metabolism; storage, metabolism, and activation of vitamins; storage of minerals, glycogen, and triglycerides; extramedullary hematopoiesis; and synthesis of coagulant, anticoagulant, and several acute phase proteins. It also influences immunologic responses and contributes to digestion through synthesis and enterohepatic circulation of bile acids and detoxification of many endogenous and exogenous compounds, toxins, and xenobiotics. Because the liver has a large functional reserve and the ability to regenerate, hepatic injury must be considerable or chronic and recurrent to cause overt hepatic dysfunction or failure.

Active liver injury is accompanied by increased liver enzyme activity, with cytosolic transaminases (ALT, AST) acutely reflecting altered membrane permeability or viability or the phenomenon of membrane blebbing, and membrane-affiliated enzyme induction (alkaline phosphatase [ALP], γ-glutamyl transferase

[GGT]) reflecting cholestasis and increased protein transcription (enzyme induction). The liver is predisposed to secondary injury owing to its sentinel position between the systemic circulation and GI tract and because it contains the largest population of fixed macrophages (Kupffer cells) in the body. Macrophage phagocytosis can initiate release of a cascade of inflammatory cytokines, leading to local cellular damage and recruitment of inflammatory infiltrates. The considerable metabolic activity of the liver exaggerates its exposure to noxious products, particularly in the centrilobular region, where high cytochrome p450 activity produces noxious products and adducts. Hepatocytes in this region also are more easily injured by hypoxia. The accumulation of hepatic copper and/or iron can initiate and augment liver injury through oxidative mechanisms.

Clinical signs of liver injury vary depending on the type, mechanism, and chronicity of the insult. Common clinical features may include anorexia, vomiting,

diarrhea, weight loss, and fever. With severe, diffuse liver injury, animals may become jaundiced and demonstrate polyuria and polydipsia (PU/PD), coagulation abnormalities, and ascites. Ascites indicates development of portal hypertension and is typically associated with formation of acquired portosystemic shunts (APSSs) and concurrent hypoalbuminemia. Hepatic encephalopathy (HE) develops in acquired liver disease only when diffuse fibrosis and APSSs have developed, in acute fulminant liver failure, or secondary to congenital portosystemic shunts (congenital malformations of the portal vein that shunt portal blood directly to the systemic circulation). Fecal color may change with complete occlusion of bile ducts (acholic or pale-colored feces) or because of increased enteric bilirubin elimination (green fecal color). Hepatomegaly is found with diffuse infiltrative or storage disorders, acute extrahepatic bile duct obstruction (EHBDO), congenital biliary cystic malformations, or passive congestion, whereas microhepatica (small liver) usually reflects portal venous hypoperfusion, diversion of enteric hepatotrophic factors normally delivered in the portal circulation, or the presence of chronic hepatic fibrosis in dogs.

LABORATORY ANALYSES AND IMAGING

HEMATOLOGY

Depending on the severity and underlying cause of liver disease, a nonregenerative or regenerative anemia may develop. Severe or acute anemia can impact the liver as a result of hypoxia, causing alterations in hepatocyte membranes, leading to release of transaminases and induction of ALP. Altered RBC morphology (poikilocytes, irregularly irregular RBCs) is common in cats with cholangiohepatitis and hepatic lipidosis (HL). Cats with HL, severe cholangiohepatitis, and EHBDO also may develop Heinz bodies, reflecting oxidative injury that may lead to hemolysis. Severe hypophosphatemia in HL may develop secondary to a re-feeding syndrome and cause hemolysis severe enough to require a blood transfusion; this can be avoided by providing fluid therapy supplemented with potassium phosphate when nutritional support is implemented. In dogs with diffuse necroinflammatory liver disease (altered sinusoidal perfusion), RBCs with

microvascular shearing (eg, schistocytes, acanthocytes) may be seen. RBC microcytosis is common in congenital or acquired portosystemic shunting, although the pathologic mechanism remains unclear.

Change in WBC count or distribution are variable. Leukocytosis may reflect inflammatory, infectious, necrolytic, or diffuse infiltrative hepatic disorders, or release of endogenous glucocorticoids or administration of glucocorticoids. Leukopenia can reflect sepsis or toxicosis. In severe diffuse necroinflammatory liver injury, damaged sinusoidal microvasculature can provoke platelet aggregation, contributing to thrombocytopenia and disseminated intravascular coagulation.

COAGULATION TESTS

Coagulation abnormalities can develop as a result of decreased synthesis or activation of coagulation factors and anticoagulant proteins produced in the liver (ie, factors V, VII, IX, X, XI, XII, fibrinogen, prothrombin, antithrombin, protein C, plasminogen, α_2 -macroglobulin, and α_1 -antitrypsin). Decreased enteric absorption of fat-soluble vitamins can lead to vitamin K-responsive bleeding in animals with EHBDO or bile duct immunoinjury (feline sclerosing cholangitis), or in cats with HL. Cats with liver disease appear predisposed to vitamin K-responsive coagulopathies. Conventional coagulation assessments may not reflect impending coagulopathies that remain unsuspected after physical examination, analysis of urine or feces, or mucosal bleeding time test. Dogs with congenital or acquired portosystemic shunting usually develop low protein C activity (<70% activity) that seemingly reflects the severity of portosystemic shunting. Although coagulation factors may be significantly lower in some of these dogs than in age-matched control groups, symptomatic coagulopathy is rare.

ENZYME ACTIVITY

Liver disease is often first suspected based on increased liver enzyme activity. However, abnormally increased liver enzyme activity is considerably more common than the prevalence of liver disease. A wide spectrum of nonhepatic disorders may influence liver enzyme activity. It is important to recognize that liver enzyme measurements are not liver function tests but rather reflect hepatocyte membrane integrity, hepatocyte or biliary epithelial necrosis, cholestasis, or induction phenomenon.

The pattern of liver enzyme abnormalities in relation to the signalment, history, total bilirubin concentration, serum bile acid values, and comorbid conditions/medications provides the first indication of a liver-specific disorder. A full assessment of liver enzyme aberration considers: 1) the predominant pattern of enzyme change (hepatocellular leakage enzymes vs cholestatic enzymes), 2) the magnitude of increase of enzyme activity above the normal reference range (mild is <3 times the upper reference range, moderate is $3-9$ times, marked is >10 times), 3) the rate of change (increase or resolution) with sequential sampling, and 4) the nature of the course of change (fluctuation vs progressive increase or decrement). Up to 2.5% of clinically "normal" animals can have borderline abnormal enzyme values.

Recognizing whether enzyme abnormalities are persistent or cyclic helps categorize likely causes. Investigating liver function with paired fasting and postprandial total serum bile acids (TSBAs) or urine bile acid/creatinine measurements (urine collected 4-8 hr after meal ingestion) may expedite a decision to pursue liver biopsy when clinical signs remain vague and enzymes are only mildly increased. Imaging studies help detect primary underlying disorders that have secondarily influenced the liver, causing increased enzyme activity. Ultrasonographic assessment may help determine the method of liver biopsy; needle biopsies are ill advised in animals with microhepatica, ascites, or difficult-to-sample focal liver lesions.

Age-appropriate reference ranges for serum liver enzyme activity are essential to interpret laboratory values in puppies and kittens. Plasma enzyme activities of ALP and GGT in neonatal dogs and cats are remarkably higher than those of adults. Differences reflect physiologic adaptations during the transition from fetal and neonatal life stages, colostrum ingestion, maturation of metabolic pathways, growth effects, differences in volume of distribution and body composition, and nutritional intake. Serum activities of ALP, AST, CK, and LDH in neonates usually increase greatly during the first 24 hr of life. In kittens, serum activities of ALP, CK, and LDH exceed adult values through 8 wk of age. Serum ALP increases remarkably in day-old puppies and kittens after colostrum ingestion, as also observed in neonatal calves, lambs, pigs, and foals.

Aminotransferases: AST and ALT are commonly measured to detect liver injury;

however, both enzymes are present in high concentrations in liver and several other tissues. AST activity is higher in kidney, heart, and skeletal muscle than liver, whereas ALT activity is highest in liver. Because hepatic ALT activity is 10,000-fold greater than plasma enzyme activity in healthy animals, it has high diagnostic utility to detect "liver lesions." The cytosolic location of transaminases allows their immediate release with even minor change in hepatocellular membrane integrity. Unfortunately, indiscriminate leakage limits their diagnostic utility. Nonetheless, duration and magnitude of transaminase activities measured sequentially can predict disease activity and severity and roughly estimate the number of involved cells.

Hepatic transaminases increase with muscle injury as well as vigorous physical activity in dogs. Persistence of transaminases in plasma contributes to their sustained high activities in certain disorders. Because transaminase catabolism occurs by absorptive endocytosis at the hepatocyte sinusoidal border, slow enzyme clearance may sustain plasma enzyme activity in hepatic insufficiency associated with liver fibrosis, nodular regeneration, and development of APSSs.

Alanine Aminotransferase: The largest increases in ALT develop with hepatocellular necrosis and inflammation. After acute severe hepatocyte necrosis, serum ALT activity increases sharply within 24-48 hr to values often >100 -fold normal, peaking during the first 5 days of injury. If the injurious event resolves, ALT activity gradually declines to normal over 2-3 wk. Although this pattern is considered classic, some severe hepatotoxins are not associated with increased ALT activity, because they inhibit gene transcription or interfere with ALT biosynthesis (eg, aflatoxin B1 hepatotoxicity, microcystin hepatotoxicity). A declining ALT also may represent a paucity of viable hepatocytes in end-stage chronic hepatitis or severe acute liver disease.

Examples of classic necrotizing hepatotoxins are carbon tetrachloride, acetaminophen, and nitrosamine. A single exposure to carbon tetrachloride causes an acute sharp increase in ALT that resolves over the ensuing week. Hepatotoxicity induced by acetaminophen causes a marked increase in ALT and AST within 24 hr that may decline within 72 hr to near normal values. This toxin is highly dose dependent in dogs and cats. Cats are exceedingly susceptible, with hematologic signs

dominating after ingestion of as little as 125 mg. However, in dogs, a dosage of 200 mg/kg may be life-threatening, with susceptibility heightened by antecedent exposure to phenobarbital. Hepatocellular necrosis induced by nitrosamines increases plasma ALT activity, but not significantly, until after 1 wk of intermittent chronic exposure. The ALT activity persists for weeks until necrosis resolves. Low-grade hepatocellular degeneration, observed in some dogs with congenital portosystemic shunts, reflects delayed enzyme clearance and low-grade hepatocyte dropout; most of these dogs have small lipogranulomas reflecting single hepatocyte dropout/necrosis in the absence of an inflammatory response.

Acute hepatic necrosis caused by infectious canine hepatitis increases plasma ALT activity by 30-fold, peaking within 4 days. Thereafter, chronic sustained ALT activity persists as chronic hepatitis develops in dogs unable to clear the virus. Hepatic injury induced by toxins usually causes plasma ALT activity to increase, peak, and return to normal sooner than it does in infectious viral hepatitis. Chronic hepatitis, an idiopathic or copper-associated persistent or cyclic necroinflammatory liver injury in dogs is associated with varying severities of necrosis and fibrosis. Cyclic disease activity is reflected by plasma enzyme "flares." At times, plasma ALT activity is >10-fold normal. Enzyme fluctuations contrast with profiles associated with single injurious events. In dogs with hepatitis, serum ALT activity declines as injury resolves, but serum ALP activity may increase as a result of regenerative responses (progenitor cell proliferation, ductal or oval cell response). Dogs treated with glucocorticoids may develop mildly increased ALT activity that resolves within several weeks of glucocorticoid withdrawal.

Despite high sensitivity of ALT to identify liver disorders, its lack of specificity to differentiate clinically significant liver disease, specific histologic abnormalities, or hepatic dysfunction requires that it be interpreted in conjunction with other diagnostic tests.

Aspartate Aminotransferase: AST is present in substantial concentrations in a wide variety of tissues, especially muscle. Increased AST activity can reflect reversible or irreversible changes in hepatocellular membrane permeability, cell necrosis, hepatic inflammation, and in dogs, microsomal enzyme induction. After acute diffuse severe hepatic necrosis, serum AST

sharply increases during the first 3 days to values 10- to 30-fold above normal in dogs and up to 50-fold above normal in cats. If necrosis resolves, AST activity gradually declines over 2-3 wk. In most cases, AST parallels changes in ALT activity.

Although increased AST activity in the absence of abnormal ALT activity implicates an extrahepatic enzyme source (notably in muscle injury), there are clinical exceptions that may relate to severity and zonal location of hepatic damage. In some cats with liver disease, AST is a more sensitive marker of liver injury than ALT (eg, hepatic necrosis, cholangiohepatitis, myeloproliferative disease, hepatic infiltrative lymphoma, and EHBDO). A similar trend is evident in some dogs. Because AST is located within the mitochondria and free within the cytosol of hepatocytes, AST in fold increases greater than those of ALT may reflect mitochondrial injury. Dogs treated with glucocorticoids may develop mildly increased AST activity that resolves within several weeks of glucocorticoid withdrawal.

Alkaline Phosphatase: Increased ALP activity in dogs is the most common abnormality on routine biochemical testing; its high sensitivity and low specificity can defy diagnostic interpretation without a liver biopsy. ALP activity in dogs has the lowest specificity of routinely used liver enzymes as a result of its complexity associated with induction of different isozymes.

In dogs and cats, tissues containing highest ALP activity (in descending order) are intestine, kidney (cortex), placenta (dogs only), liver, and bone. Distinct serum ALP isozymes can be extracted from some of these tissues in each species; eg, bone (B-ALP), liver (L-ALP), and glucocorticoid-induced (G-ALP) isoenzymes in canine serum. In dogs, L-ALP and G-ALP are primarily responsible for high serum ALP activity, whereas L-ALP is primarily responsible in cats. Increased ALP activity develops in up to 75% of hyperthyroid cats, depending on the chronicity of the condition, with B-ALP substantially contributing.

The comparably small magnitudes of ALP activity in cats with liver disease (2- to 3-fold normal) relative to dogs (usually >4- to 5-fold) reflect the lower specific activity of ALP in feline liver and its shorter half-life. Nevertheless, ALP activity remains clinically useful in the diagnosis of feline liver disease when the species-appropriate perspective is maintained.

The utility of serum ALP activity as a diagnostic indicator in dogs is complicated by the common accumulation of L-ALP and G-ALP isozymes, which can both be induced by steroidogenic hormones.

Because the B-ALP isozyme increases secondary to osteoblast activity, it is detected in young growing animals and in animals with bone tumors, secondary renal hyperparathyroidism, and osteomyelitis. However, the minor contribution of B-ALP to total serum ALP activity usually does not lead to an erroneous diagnosis of cholestatic liver disease. Bone remodeling secondary to neoplasia may not substantially affect serum ALP activity or may cause only a trivial increase (2- to 3-fold) in dogs. In young growing cats, increased B-ALP activity may simulate enzyme activity seen in hepatobiliary disease.

Although ALT is immediately released from the hepatocellular cytosol in acute hepatic necrosis, the small quantities of membrane-bound ALP are not. It takes several days for induction of membrane-associated enzyme to "gear up" and spill into the systemic circulation. Increased serum ALP reflects enhanced *de novo* hepatic synthesis, canalicular injury, cholestasis, and solubilization of its membrane anchor (by bile salts). The largest increases in serum ALP activity (L-ALP and/or G-ALP ≥ 100 -fold normal) develop in dogs with diffuse or focal cholestatic disorders, massive hepatocellular carcinoma, bile duct carcinoma, and those exposed to steroidogenic hormones.

Although serum activity of ALP may be normal or only modestly increased in dogs with metastatic neoplasia involving the liver, it may also increase dramatically in dogs with mammary neoplasia. High serum ALP activity develops in ~55% of dogs with malignant and 47% with benign mammary tumors, with highest ALP activity seen in dogs with malignant mixed tumors. Nevertheless, serum ALP has no value as a diagnostic or prognostic marker in mammary cancer; it remains unclear whether disease remission (surgical, chemotherapy) is followed by a regression in serum ALP activity or whether serum ALP activity functions as a paraneoplastic marker.

After acute severe hepatic necrosis, ALP activity increases 2- to 5-fold in dogs and cats, stabilizes, and then gradually declines over 2-3 wk. Sustained ALP activity usually correlates with a reparative ductal response (progenitor or oval cell hyperplasia). In cats, EHBDO results in a 2-fold increase in ALP within 2 days, as much as a 4-fold

increase within 1 wk, and up to a 9-fold increase within 2-3 wk. Thereafter, activity stabilizes and gradually declines but usually not into the normal range; the declining enzyme activity coordinates with developing biliary cirrhosis (see EXTRAHEPATIC BILE DUCT OBSTRUCTION, p 478). Inflammatory disorders involving biliary or canalicular structures or disorders compromising bile flow increase serum ALP activity secondary to membrane inflammation/disruption and local bile acid accumulation. In both dogs and cats, similar increases in serum ALP activity develop in intrahepatic (metabolic, biochemical, sepsis) associated cholestasis or obstruction involving the extrahepatic biliary structures. Consequently, ALP activity cannot differentiate between intra- and extrahepatic cholestatic disorders.

Many extrahepatic and primary hepatic conditions are associated with increased L-ALP. In cats, HL (see p 456) is associated with marked increase in ALP activity and jaundice. The increased ALP seemingly reflects canalicular dysfunction or compression. Although ALP in cats is rarely affected by anticonvulsants or glucocorticoids, it can increase with diabetes mellitus, hyperthyroidism, and pancreatitis.

In dogs, primary hepatic inflammation as well as systemic infection or inflammation and exposure to steroidogenic hormones may induce a glycogen-associated vacuolar hepatopathy (VH). When severe, VH has a cholestatic effect that seemingly causes canalicular compression. Although glycogen-associated VH was initially characterized as a glucocorticoid-initiated lesion, it is now established that nearly 50% of dogs with glycogen-associated VH lack overt exposure to steroidogenic substances. Chronically ill dogs may produce the G-ALP isozymes secondary to stress-induced glucocorticoid release. Such dogs with glycogen-associated VH (lacking exogenous glucocorticoid exposure) may demonstrate normal dexamethasone suppression and adrenocorticotrophic hormone (ACTH) response tests. However, in some dogs, high ALP with a glycogen-associated VH signals the presence of atypical adrenal hyperplasia associated with abnormal sex hormone production. There is no consistent relationship between the magnitude of serum ALP activity, the presence of high G-ALP activity, or histologic lesions. Unfortunately, G-ALP is not useful for syndrome characterization because it can become the predominant ALP isoenzyme in dogs treated with glucocorticoids and in dogs with spontaneous or iatrogenic

hyperadrenocorticism, hepatic or nonhepatic neoplasia, hepatic inflammation, or numerous diverse chronic illnesses, including primary liver disease.

The magnitude of ALP activity induced by glucocorticoid administration depends on the type of drug and dose given, as well as the individual's response. The production of G-ALP does not imply that a dog treated with cortisone has iatrogenic hyperadrenocorticism, a suppressed pituitary-adrenal axis, or a clinically important glycogen-associated VII. By comparison, the feline liver is relatively insensitive to glucocorticoids, with rare development of a glycogen-associated VH or acceleration of hepatocyte lipid vacuole accumulation.

In dogs, serum total ALP activity and L-ALP isozyme also may be induced by administration of certain anticonvulsants (phenobarbital, primidone, and phenytoin) and other drugs; in this circumstance, the ALP activity usually increases 2- to 6-fold normal. In contrast, serum ALP and L-ALP did not increase in cats after administration of phenobarbital (0.25 grain, bid) for 30 days.

Gamma-Glutamyl Transferase:

Gammaglutamyl transferase (GGT) is a membrane-bound glycoprotein that plays a critical role in cellular detoxification (involved with glutathione availability), conferring resistance against a number of toxins and drugs. Tissue concentrations of GGT in dogs and cats are highest in the kidney and pancreas, with lesser amounts in the liver, gallbladder, intestines, spleen, heart, lungs, skeletal muscle, and erythrocytes. However, serum GGT activity is largely derived from the liver, although there is considerable species variation in its localization within this organ.

Acute, severe, diffuse necrosis is associated with either no change or only mild increases (1- to 3-fold normal) in GGT activity that resolve in ~10 days. In dogs with EHBDO, serum GGT activity increases 1- to 4-fold above normal within 4 days, and 10- to 50-fold within 1-2 wk. Thereafter, values may plateau or continue to increase as high as 100-fold. In cats with EHBDO, serum GGT activity may increase up to 2-fold within 3 days, 2- to 6-fold within 5 days, 3- to 12-fold within 1 wk, and 4- to 16-fold within 2 wk. Glucocorticoids and certain other microsomal enzyme inducers may stimulate GGT production in dogs, similar to their influence on ALP. Administration of dexamethasone (3 mg/kg/day)

or prednisone (4.4 mg/kg/day, IM) may increase GGT activity within 1 wk to 4- to 7-fold above normal and up to 10-fold within 2 wk. Dogs treated with phenytoin or primidone develop only a modest increase in serum GGT activity (up to 2- to 3-fold), unless they develop anticonvulsant hepatotoxicosis that is often associated with marked enzyme activity.

Cats with advanced necroinflammatory liver disease, EHBDO, or inflammatory intrahepatic cholestasis can develop a larger increase in GGT activity relative to ALP. Glucocorticoids and other enzyme inducers in dogs do not clinically influence serum GGT in cats. The normal range for serum GGT activity in cats is much narrower and lower than that in dogs; therefore, assays must be sensitive enough to detect low GGT activity.

GGT values can be markedly increased in dogs and cats with primary hepatic or pancreatic neoplasia. However, GGT does not appear to be suitable for surveillance of hepatic metastasis in either species.

Like ALP, GGT lacks specificity in differentiating between parenchymal hepatic disease and obstructive biliary disease. It is not as sensitive in dogs as ALP but does have higher specificity. In cats with inflammatory liver disease, it is more sensitive but less specific than ALP; these two enzymes should be interpreted simultaneously. The likelihood that HL has developed secondary to necroinflammatory liver disease, EHBDO, or pancreatic disease can be predicted by examining the relative increases in GGT and ALP. Necroinflammatory disorders involving biliary structures, the portal triad, or pancreas are often associated with a greater fold increase in GGT than in ALP. With the exclusion of these underlying disorders, cats with HL usually have a higher fold increase in ALP relative to GGT; this has important diagnostic utility in discerning the underlying cause of HL.

Neonatal animals of several species, including dogs but not cats, develop high serum GGT activity secondary to colostrum ingestion.

OTHER SERUM BIOCHEMICAL MEASURES

Albumin: Albumin is produced exclusively by the liver and has a half-life in healthy dogs estimated at ~8 days. Because the healthy liver is estimated to maintain albumin synthesis at 33% maximal capacity, it has a large reserve capability for albumin

synthesis. Albumin functions as an essential transport molecule, maintaining normal drug-receptor interactions. In liver disease, decline in albumin concentration compromises its transport functions, increasing risk of adverse drug reactions (more free or unbound drug). Albumin's large role in maintaining colloid osmotic pressure reflects its lower molecular weight compared with other plasma proteins and its higher intravascular concentration. In inflammatory disease or during malnutrition, albumin may increase its transcapillary escape rate, augmenting distribution into the interstitial space. This phenomenon hastens onset of hypoalbuminemia in animals with necroinflammatory liver disease, long before development of ascites. Concurrent hypoalbuminemia and development of hepatic presinusoidal, sinusoidal, or postsinusoidal portal hypertension is commonly associated with ascites in animals with chronic severe liver disease.

Albumin also functions as a scavenger of oxygen radicals and other oxidizing agents. These antioxidant effects may be compromised in necroinflammatory liver disease and fulminant hepatic failure. Any disease processes promoting an oxidative environment (eg, diabetes mellitus, renal disease, hepatic insufficiency, hyperthyroidism) can irreparably damage the albumin molecule, accelerating its turnover (synthesis and catabolism).

In many animals with liver disease, an early trend toward hypoalbuminemia often reflects systemic inflammation (negative acute phase effect). Only in severe hepatic insufficiency (eg, chronic progressive hepatitis) is synthetic failure a driving cause of hypoalbuminemia. Protein-losing nephropathy (glomerular disease) or protein-losing enteropathy must be excluded as underlying causes of hypoalbuminemia. Glomerular causes are associated with a urine protein:creatinine ratio >3 and hypercholesterolemia, whereas protein-losing enteropathy is associated with panhypoproteinemia and hypocholesterolemia.

Bilirubin: Total bilirubin >2.5 – 3 mg/dL results in clinical icterus. Hyperbilirubinemia can reflect prehepatic (eg, hemolysis), hepatic (impaired uptake, intracellular transport, glucuronide conjugation, or canalicular elimination), or posthepatic/extrahepatic causes (EHBD, biliary tree rupture). Total bilirubin concentrations vary markedly with different disease processes. Concentrations are highest in dogs with hemolytic disorders and in cats with HL and

EHBD. Bilirubinuria can be detected in healthy dogs because of their ability to conjugate bilirubin in renal tubules (low renal threshold). However, bilirubinuria in cats is always abnormal and should be investigated. Fractionation of total bilirubin into direct (conjugated) and indirect (unconjugated) moieties offers little diagnostic utility. Bilirubin covalently bound to albumin (biliprotein complexes) remains in the circulation and is not excreted in urine. Chronic retention can impart tissue jaundice in the absence of bilirubinuria long after a cholestatic disorder has resolved.

Common causes of hyperbilirubinemia include increased hemoprotein liberation (eg, hemolytic anemia, ineffective erythropoiesis, body cavity hemorrhage), bile duct occlusion, ruptured biliary tract, intrahepatic cholestasis, impaired hepatobiliary bilirubin processing, and sepsis. Jaundiced dogs and cats presenting with regenerative anemia should be tested for hemolytic disorders, including immune-mediated hemolytic anemia, Heinz body hemolysis, zinc toxicity, and erythroparasites (including hemotropic *Mycoplasma* [cats, dogs] and *Babesia* [dogs]).

BUN and Creatinine: There are no characteristic changes in BUN or creatinine concentrations with liver disorders except that low values are associated with portosystemic shunting and feeding of a restricted protein diet (only BUN, not creatinine) formulated to reduce signs of HE. The concentration of BUN reflects numerous variables, including hydration status, nutritional support, enteric bleeding, tissue catabolism, and the hepatic capacity to detoxify ammonia. Anorexia, feeding a low-protein diet, or hepatic insufficiency can result in low normal to subnormal concentration of BUN, whereas increased values relative to creatinine (discordant BUN:creatinine ratio) may reflect dehydration, enteric bleeding, or consumption of a high-protein diet. Compared with BUN, serum creatinine concentrations are less affected by dietary protein intake. The low BUN and low normal or low creatinine concentration often seen in animals with portosystemic shunting reflect increased water turnover that increases glomerular filtration rate (up to 2-fold), contributing to PU/PD. Reduced hepatic synthesis of creatinine also contributes to low creatinine concentrations in animals with hepatic insufficiency, considering that creatinine depends on hepatic synthesis of creatine in the transmethylation pathway.

Glucose: Hypoglycemia is uncommon in acquired liver disease except end-stage cirrhosis or fulminant liver failure. The inability to store hepatic glycogen or convert glycogen to glucose is more common in neonates and juvenile small-breed dogs with congenital portosystemic shunts. Other causes of hypoglycemia, including sepsis, insulinoma, iatrogenic insulin overdose, rare glycogen storage disorders, or paraneoplastic effects of large primary hepatic neoplasia (canine hepatocellular carcinoma or adenoma) or other tumors should be considered in an animal with suspected liver disease.

Cholesterol: All cells in the body except RBCs synthesize cholesterol for intracellular use. Cholesterol incorporated in plasma lipoproteins is synthesized only in the liver and distal small intestine. Bile provides the major excretory pathway for cholesterol. Hypocholesterolemia may reflect endocrine, metabolic, and nutritional factors as well as hepatic insufficiency and portosystemic shunting. Nonhepatic disorders associated with hypocholesterolemia include hypoadrenocorticism, maldigestion/malabsorption, pancreatic exocrine insufficiency, severe starvation, cachexia, sepsis, and hyperthyroidism (cats); hepatic causes include portosystemic shunting (congenital or acquired) and severe hepatic insufficiency (eg, end-stage cirrhosis, fulminant hepatic failure). Hypercholesterolemia is more common in ill animals and requires careful consideration of potential nonhepatic disorders, including hypothyroidism, diabetes mellitus, pancreatitis, nephrotic syndrome, hyperadrenocorticism or treatment with glucocorticoids, idiopathic dyslipidemias, and rarely a postprandial effect. Hypercholesterolemia is usually seen in EHBDO and in some animals with diffuse intrahepatic cholestasis, destructive cholangitis, and marked hepatic regeneration.

HEPATIC FUNCTION TESTS

Total Serum Bile Acids: TSBA concentrations sensitively detect cholestatic disorders and conditions associated with portosystemic shunting. TSBA concentration should be measured before and 2 hr after meal ingestion; fasting is not required. Insufficient hepatic mass or deviated portal circulation to the systemic circulation via extrahepatic portosystemic shunts (congenital or acquired) or

microscopic shunts within the liver (congenital microvascular dysplasia) cause high TSBA concentrations, particularly in postprandial samples. TSBA concentrations are usually lower before a meal than 2 hr after a meal. However, ~15%–20% of dogs and 5% of cats have higher TSBA concentrations before a meal than after, likely reflecting physiologic variables influencing the enterohepatic circulation of bile acids (ie, the rate of gallbladder contraction, gastric emptying, and intestinal transit of bile acids to the ileum where they are actively resorbed). TSBA concentrations in dogs $>25 \mu\text{M/L}$ or in cats $>20 \mu\text{M/L}$ are abnormal either before or after a meal (fasting ranges should not be applied because of the variables influencing the TSBA enterohepatic circulation). Collecting a single sample for TSBA measurement (random fasting or a single postprandial sample) can miss detection of abnormal values. Because TSBA concentrations are a more sensitive indicator of cholestasis than total bilirubin, measuring TSBA concentration is redundant in animals with nonhemolytic jaundice. Use of TSBA as a liver function test can indicate need for a liver biopsy. TSBA concentrations should be routinely measured in all young (6 mo), small, "terrier-like breeds" to detect dogs with microvascular dysplasia (MVD). Finding increased TSBA concentrations in apparently healthy, young, terrier-like breeds, including but not restricted to Yorkshire Terriers, Maltese, Shih Tzus, Miniature Schnauzers, Cairn Terriers, Norfolk Terriers, Havanese, Papillons, Tibetan Spaniels, and Pugs, allows detection of dogs in which TSBA concentration will be misleading if discovered in later life during evaluation of illness.

Ammonia: Measurement of blood ammonia can detect hepatic disorders associated with HE. Ammonia is derived predominantly from protein degradation, with most generated in the intestines from consumed food and enteric bacterial ureases that catabolize urea into ammonia and carbon dioxide. Portal transport of ammonia from the intestines to the liver results in a direct 85% detoxification to urea. Ammonia intolerance (impaired clearance) occurs in any disorder associated with portosystemic shunting and in acute fulminant hepatic failure. Ammonia is not influenced by cholestasis or liver disorders that do not deviate the portosystemic circulation or extensively reduce hepatic parenchymal mass.

Although ammonia is regarded as a pivotal cause of HE, animals with overt HE may have normal blood ammonia concentrations owing to complicated pathologic mechanisms driving HE. A single normal ammonia value cannot discount HE in an animal with suspected chronic liver disease, and serial ammonia measurements may not correlate with an evolving clinical scenario of HE. Thus, ammonia measurements cannot reliably diagnose HE.

Measurement of blood ammonia is complicated. Spurious hyperammonemia can reflect slow blood collection, tight tourniquet technique, conditions promoting ammonia liberation from muscle (seizures, crush injuries), sample contamination (human sweat, cigarette smoke, open urine vials), and spontaneous generation in samples not immediately cooled on collection or not promptly analyzed. Ammonia is highly volatile, and samples cannot be mailed for analyses. Blood samples should be collected into pre-cooled tubes and transported on melting ice to the laboratory for analysis within 20 min. Enzymatic-based methodologies are difficult to standardize. Nonhepatic causes of hyperammonemia also exist, with the most common disorders involving bacterial infection of the urinary tract with a urease-producing organism associated either with uroabdomen or obstructive uropathy.

If a random blood ammonia concentration is within normal limits but hepatic insufficiency and portosystemic shunting suspected, an ammonia tolerance test can be conducted. Ammonium chloride is given at 100 mg/kg in a 5% solution orally (can induce vomiting) or at 2 mL/kg of a 5% solution administered rectally (instilled 30 cm deep) after a cleansing enema, with blood ammonia measured at baseline and then at 20, 30, 40, or 60 min later. Unfortunately, an ammonia tolerance test may induce iatrogenic HE in susceptible animals.

The presence of ammonium biurate crystalluria in an animal with high TSBA is pathognomonic for hyperammonemia and portosystemic shunting. A minimum of three urine samples collected at separate daily intervals should be inspected to optimize surveillance for crystal discovery. In animals on restricted protein intake using diets specifically formulated for hepatic insufficiency, finding ammonium biurates may be difficult because of the high efficacy of such diets to control hyperammonemia.

IMAGING

Radiography: Routine abdominal radiographs are useful to determine liver size and may detect irregular liver borders. Mineralized densities that involve parenchyma or the biliary tree can reflect stasis of bile flow, dystrophic mineralization associated with congenital malformations, acquired duct "sacculation," chronic duct inflammation, or choleliths. Choleliths that contain enough calcium bilirubinate or calcium carbonate are radiographically visible. A mass effect in the right cranial quadrant in suspected EHBDO may represent an engorged gallbladder, pancreatitis, neoplasia, or focal bile peritonitis. Radiographic suspicion of abdominal effusion (poor abdominal detail) may prompt diagnosis of bile peritonitis and ascitic effusion. Gas within hepatic parenchyma or biliary structures indicates an emphysematous process (eg, cholecystitis, choledochitis, infected biliary cyst, hepatic abscess, necrotic tumor mass) and warrants prompt antimicrobial therapy and either surgical intervention or percutaneous, ultrasound-guided aspiration/lavage. Thoracic radiography can indicate signs of systemic disease (eg, metastatic lesions, pleural fluid). Finding sternal lymphadenopathy is common in cats with the cholangitis/cholangiohepatitis syndrome, in which it reflects hepatic inflammation.

Although cholecystography can be accomplished with iodinated contrast given PO or IV, contrast radiographic imaging of the biliary system is rarely pursued. Distribution and concentration of contrast agents within biliary structures is influenced by numerous variables, including hyperbilirubinemia and major duct occlusion. At best, these agents may disclose choleliths, polyps, or sludged bile but are insufficient to confirm bile peritonitis or to localize the site of leakage. Multisector CT and/or hepatic ultrasonography are more useful to discern these processes.

Contrast studies of the portal vasculature are the gold standard for confirmation of a congenital portosystemic shunt. Radiographs should be taken in right and left lateral and ventrodorsal positions for best test sensitivity. Multisector CT imaging produces exceptional images and has replaced radiographic portography for diagnosis of congenital portosystemic shunts because it allows contrast injection into a peripheral vessel, can capture numerous images per second, and allows three-dimensional anatomic reconstruction.

Ultrasonography: There are many diagnostic applications of hepatic ultrasonography: 1) identify distention and determine thickness of biliary structures; 2) verify common bile duct obstruction; 3) detect gallbladder mucoceles and cholelithiasis; 4) differentiate between diffuse and focal hepatic abnormalities; 5) identify and determine dimensions of "mass lesions"; 6) identify pancreatic, mesenteric, and perihepatic lymphadenomegaly; 7) in conjunction with vascular studies, identify congenital intrahepatic and extrahepatic portosystemic vascular anomalies (PSVAs), APSSs, arteriovenous malformations, and hepatic venule distention reflecting passive congestion; and 8) detect small volume abdominal effusion and small volume of fluid surrounding the gallbladder. However, although abdominal ultrasonography has become an indispensable diagnostic tool to assess the liver and biliary system, its use is highly operator dependent, and findings must always be reconciled with the history, physical examination findings, and clinicopathologic data. Reconciliation of data is best done by the principal clinician managing the case, who has the most knowledge of the animal's management and prognosis.

Computed Tomography: Multisector CT imaging, available in specialty referral practices and university teaching hospitals, can distinguish mass lesions, detect changes in structure of hepatic parenchyma and the biliary system, identify choleliths, detect abnormal hepatic perfusion (involving the portal vein, hepatic artery, or hepatic vein), and portal thrombi, and can detail the extent of traumatic hepatobiliary injuries.

CHOLECYSTOCENTESIS

Cholecystocentesis is the aspiration sampling of gallbladder bile; this can be completed using a percutaneous transhepatic ultrasound-guided approach, by laparoscopic assistance, or during exploratory abdominal surgery. Samples of bile are collected for cytologic investigation and culture of aerobic and anaerobic bacteria and fungi; collection of bile that contains particulate debris or sediment has the highest yield to find microorganisms (cytologically, by culture). Complications of cholecystocentesis may include intraperitoneal bile leakage (reduced by using a transhepatic approach), hemorrhage,

hemobilia, bacteremia, and vasovagal reaction, especially in cats, that may result in ventilatory arrest, severe bradycardia, and death. If a gallbladder mucocele or EHBDO is suspected, cholecystocentesis is contraindicated. It is better to perform a cholecystectomy for gallbladder mucocele and surgically decompress EHBDO (relieve or bypass the obstruction).

LIVER CYTOLOGY

Ultrasonographic-guided fine-needle aspirates are routinely used to confirm a diagnosis of HL in cats and to identify suppurative septic inflammation, neoplasia, and glycogen-like VH. However, definitive diagnosis of hepatic disease is otherwise impossible with liver aspirates because the absence of acinar architecture compromises anatomic orientation and correct interpretation. Cytologic interpretation of liver aspirates are notoriously discordant with histologic findings on biopsy specimens. Neither neoplasia nor sepsis can be definitively excluded using cytology, and inflammatory disease is too often suspected. Cytology should not be the basis to recommend immunomodulatory or antifibrotic medications or long-term chelation therapy for copper-associated hepatopathy. Rather, liver biopsy remains the standard for diagnoses of most hepatic disorders.

LIVER BIOPSY

Hepatic needle true-cut biopsies (especially 18-gauge) collected under ultrasonographic guidance may yield samples too small and fragmented for accurate diagnosis because of a lack of representative acinar units (at least 15 portal triads should be sampled). Furthermore, needle biopsies are usually only collected from the more safely sampled left-side lobes, which may miss lesions differentially affecting liver lobes (eg, cholangiohepatitis in cats). Blind-needle biopsies done without ultrasonographic guidance are hazardous and ill advised in animals with suspected hepatic hilar or mesenteric lymphadenomegaly; involvement of the common bile duct, gallbladder, intestines (eg, inflammatory bowel disease, infiltrative disease), or pancreas; or multiple organ abnormalities. An exploratory laparotomy is more appropriate. When possible, wedge biopsies or laparoscopic cup forcep biopsies are preferred, because samples of adequate size can be easily and safely acquired from multiple liver lobes, ensuring accurate disease representation.

These methods also permit assessment of the gross appearance of the liver. Notably, laparoscopic methods are not recommended when disease of the common bile duct or gallbladder is suspected that may necessitate a decompressive biliary procedure, cholecystectomy, or cholectomy. Liver biopsy should always be done even if an obvious biliary abnormality is the predominant disease process, because underlying histologic liver lesions may indicate another primary disease process. It is also important to biopsy grossly normal liver when focal lesions are identified. This practice ensures 1) characterization of "normal" liver histology, 2) determines whether an underlying liver disease coexists, 3) investigates histology of liver distant to the gallbladder in animals undergoing cholecystectomy, and 4) provides multiple liver lobe samples needed to confirm suspected MVD (because this lesion is variable among liver lobes).

Routine biopsy evaluation should include examination of a cytologic imprint, Gram stain (if suppurative or pyogranulomatous inflammation is cytologically detected), routine H&E staining and interpretation, as well as staining with a reticulin stain (discloses sinusoidal collapse of the supporting scaffolding of the liver), Masson's trichrome (to confirm presence and severity of fibrillar connective tissue deposition), Prussian blue to identify iron retention in Kupffer cells (fixed macrophages) and hepatocytes (helps confirm lobular involvement in inflammation, Kupffer cell activation, presence of rare hemochromatosis), rhodanine stain for copper (confirms and can be used to quantify copper with digital scanning of the rhodanine-stained section), aerobic and anaerobic bacterial cultures of liver and bile, and quantification of liver metals (copper, iron, and zinc concentrations because these values can help evaluate risk of oxidative injury and need for zinc supplementation). A tissue sample (formalin fixed) should also be reserved for other special case-specific studies such as special immunohistochemical stains or for PCR testing for infectious agents.

Before biopsy, bleeding tendencies should be evaluated by careful review of the history, physical examination, blood smear (to confirm platelets $\geq 100,000/\mu\text{L}$), routine coagulation profile (prothrombin time [PT], activated partial thromboplastin time [APTT]), von Willebrand factor (vWF) activity in high-risk breeds, and a buccal mucosal bleeding time. Routine coagulation assessments have low reliability to detect bleeding risk. The buccal mucosal bleeding

time is more relevant when performed immediately before the procedure. Animals suspected to have bleeding tendencies should be treated with vitamin K₁ (0.5–1 mg/kg, SC or IM) at 0, 12, and 24 hr before tissue sampling. If buccal mucosal bleeding time is >5 min, a fresh frozen plasma transfusion is indicated, as is administration of desmopressin acetate (DDAVP, 0.3–1 mcg/kg diluted in saline), which increases plasma vWF 2-fold over baseline within 1 hr as well as plasma activity of Factor VIII. DDAVP can initiate a hemostatic effect in dogs with type 1 vWF (partial quantitative deficiency) but not in dogs with qualitative defects or complete vWF deficiency. In many people with liver disease, DDAVP has improved coagulation ability, although the exact mechanisms remain incompletely clarified.

PATHOLOGIC CHANGES IN BILE

(White bile syndrome, inspissated bile syndrome, Bilirubin deconjugation)

In animals with bile stasis, nonabsorbable bile constituents (bile salts, phospholipids, glycoproteins, and cholesterol) are subject to concentration or dilution when water and inorganic electrolytes (sodium, chloride, bicarbonate) are resorbed or added by the biliary epithelium. EHBDO can produce a "white bile" syndrome reflecting the absence of bilirubin pigments; this usually is found in animals with an obstructed gallbladder at the level of the cystic duct or in animals with obstruction of the hepatic ducts. Stasis of bile flow also may cause bile dehydration, promoting a pathologically thickened or sludged bile typically dark green to black in color. Formation of a gallbladder mucocele involves the entrapment, retention, dehydration, and local overproduction of mucin that lends a rubbery viscosity to bile. Bile stasis in obstructed ducts can lead to bilirubin deconjugation, which reduces bilirubin solubility and favors cholelith precipitation. Cholestasis (enhanced bile flow) produces "watery," dilute bile and is a therapeutic goal in disorders associated with bile stasis.

NUTRITION

Nutritional support has a pivotal influence in cats with HL and is an important component of at-home treatment in animals with slowly progressive hepatobiliary disorders. Proper nutritional support improves quality of life in animals with hepatic insufficiency prone to HE. Diets for

animals with hepatobiliary disease should be easily digestible, highly palatable, calorically dense, easy for the owner to prepare and feed, and fed frequently as small meals. Objectives are to optimize food digestion and assimilation and to achieve voluntary food consumption.

If animals are anorectic, tube feeding should be considered. Nasogastric tubes are inexpensive, easily placed, and recommended as a short-term solution. Esophagostomy tubes are preferred in cats with HL for longer dietary support. Use of appetite stimulants remains controversial, because they may delay institution of regimented nutritional support. In addition, some commonly used drugs are metabolized in the liver. Diazepam and oxazepam may rarely lead to idiopathic fulminant hepatic failure in cats.

Dietary modification for animals with liver disease depends on their clinical status, the definitive diagnosis, and assessment of liver function. Diets should be balanced and supplemented with water-soluble vitamins. In severe cholestatic disorders that impede enteric access of bile (eg, EHBD, advanced sclerosing cholangitis in cats), fat-soluble vitamins may become depleted. Vitamin K₁ can be supplemented via parenteral injection of 0.5–1.5 mg/kg every week (titrated against a thrombotest [PIVKA assay] or PT). If vitamin K₁ depletion is confirmed, vitamin E also likely needs supplementation. Because vitamin E is a fat-soluble vitamin, a unique, water-soluble form may be necessary for oral administration: polyethylene glycol α -tocopherol succinate (10 IU/kg/day, PO). It is important to follow dosing recommendations, because excessive vitamin K can lead to hemolytic anemia (in cats), and excessive vitamin E can interfere with vitamin K function.

Liver function also has considerable influence on glucose homeostasis (glycogenolysis or gluconeogenesis from amino acids and lactate), detoxification of nitrogen (urea cycle), and ketogenesis (from fatty acids). In rare circumstances, in animals prone to hypoglycemia, low-dose IV glucose may be transiently needed. Protein modification and restriction is used to address insufficient nitrogen detoxification (see below).

Energy Allowance: Energy allocation should be estimated based on ideal body weight, with modified diets gradually introduced. Initial intake should be no greater than 50% of the calculated daily energy requirement on day 1, increased to 75% on day 2, and then to 100% by day 3–5.

Energy allowances may require adjustment after the diet is accepted, the animal is stable, and weight and body condition reassessments confirm a need for higher or lower intake. Estimation of initial energy intake is calculated using formulas that predict resting energy requirements in healthy animals. Formulas for estimation of initial energy allocations for dogs are $30 \times \text{body wt (kg)} + 70$ (for dogs 2–16 kg); $70 \times \text{body wt (kg)}^{0.75}$ (for dogs <2 or >16 kg); or $99 \times \text{body wt (kg)}^{0.67}$ (safe initial intake for a healthy dog).

For cats, $60 \times \text{body wt (kg)}$ is often used, unless the cat is markedly overconditioned or has a subnormal metabolic rate or activity level. Frequent reassessment is necessary with energy allowances tailored to response.

Dietary Protein Allowance: A diagnosis of liver disease should not automatically dictate a need for protein restriction. In fact, protein restriction can be detrimental in some animals, eg, cats with HL or animals with chronic but stable necroinflammatory liver disease that do not have APSSs or HE. Unfortunately, altering nutritional support can be difficult and challenging in animals that reject novel diet modifications. Protein restriction is appropriate when HE is suspected, ammonium biurate crystalluria is observed in an animal with suspected hepatic insufficiency, or portosystemic shunting (congenital or acquired) is either confirmed by imaging studies or suggested by protein C assessments.

The protein allowance for an animal with HE should maintain a positive nitrogen balance, avoiding tissue catabolism. Because maintenance of lean body mass (muscle) provides a temporary respite from ammonia toxicity, body condition should be monitored regularly for comparative estimates, with the goal being to maintain muscle mass.

When protein restriction is deemed necessary, initial restriction to 2.5 g protein/kg body wt (<5 g protein/100 kcal diet) for dogs and 3.5 g protein/kg body wt (<7 g protein/100 kcal) for cats is advised. Sequential historical, physical, and clinicopathologic assessments judge treatment response and guide further tailoring of these recommendations.

Most protein-restricted diets are used in dogs with chronic, severe liver disease or that have PSVA. If a dog responds well to an initial protein restriction, ~0.25–0.5 g/kg/day can be added, using a tofu or dairy-based protein source. Animals should be monitored every 1–2 wk for signs of HE and alterations in albumin, BUN, and appear-

ance of ammonium biurate crystalluria during dietary protein titration. Three urine samples should be collected: first thing in the morning, 4–8 hr after feeding, and late in the evening to optimize scrutiny for ammonium biurate crystalluria.

Dietary protein should not be restricted in cats with HL, because protein restriction compromises survival. Protein should not be restricted in most dogs and cats with chronic necroinflammatory liver disorders at the time of diagnosis, because many of these animals may have higher protein requirements than a comparably sized, healthy, age-matched control for tissue repair and cell replication. In people with similar health status, nitrogen requirements increase as needed for increased nitrogen utilization (tissue repair and regeneration).

Modified Protein Quality/Source:

Altering the type and quality of protein intake for dogs with HE can help achieve good life quality. A high energy:nitrogen ratio should be maintained, because this optimizes use of dietary protein. In dogs, dairy and vegetable quality protein (soy) sources work best. Dairy quality protein (amount per 8 oz) can be found in the following products: whole milk (8 g in 157 cal), yogurt (8 g in 139 cal), cottage cheese (28–31 g in 200–250 cal), and cheddar cheese (57 g in 800–900 cal). Alternatively, in dogs, calcium caseinate can provide 88 g protein, 2 g fat, and 370 kcal/100 g portion. Using dairy quality and vegetable-derived protein can be estimated using the Nutritional Analysis Tool 2.0 (human nutrition). In cats, which are pure carnivores, a meat-based protein source is recommended in a balanced diet that contains adequate arginine (~250 mg/100 kcal diet) and taurine for feline metabolism (several commercial prescription foods meet these requirements).

Dietary Fat: There is no need to restrict dietary fat in most animals with hepatobiliary disease, because these animals typically have no problems with fat digestion or assimilation. Fat ingestion is important to provide essential fatty acids and fat-soluble vitamins. One exception is animals with chronic EHBDO or cats with sclerosing cholangitis (destructive cholangitis) with symptomatic “ductopenia” (pale acholic feces, bleeding tendencies, marked jaundice). These animals have reduced entry of bile into the alimentary canal and impaired enterohepatic circulation of bile acids, limiting emulsification, digestion, and assimilation of ingested fat. Another

exception is dogs with gallbladder mucoceles, some of which have idiopathic hyperlipidemia; in these, feeding a high-fat diet can facilitate rapid maturation of the gallbladder mucocele.

Micronutrients and Vitamins: **Water-soluble vitamins** should be supplemented (via IV fluids) in animals with chronic liver disease and cats with HL (see TABLE 12). Cats are especially susceptible to thiamine (B_1), cobalamin (B_{12}), and vitamin K_1 deficiency when they are chronically inappetent, treated with antimicrobials, have severe intestinal or pancreatic disease, or demonstrate chronic cholestasis. Hyperthyroid cats may develop malabsorptive problems and may be more prone to these complications when also affected with cholangiohepatitis or HL. Vitamin C is not recognized as a commonly depleted micronutrient in either dogs or cats. Dogs with copper storage hepatopathy and animals with large hepatic iron stores should probably not receive vitamin C supplements, because this may augment oxidative injury associated with transition metal accumulation.

Supplementation of **fat-soluble vitamins** is important in animals with fat malabsorption and obstructed bile flow. Vitamin K_1 depletion develops when the enterohepatic bile acid cycle is interrupted in animals demonstrating acholic feces (eg, EHBDO, severe destructive [sclerosing ductopenic] cholangiohepatitis in cats), HL (cats), exocrine pancreatic insufficiency, severe malabsorptive intestinal disease, after feeding a vitamin K-deficient diet, animals chronically treated with oral antimicrobials, and in animals with severe liver disease causing insufficiency. Vitamin K should be administered to any jaundiced animal with suspected liver disease as early as possible (0.5–1.5 mg/kg, SC or IM, three times at 12-hr intervals) before invasive procedures (insertion of catheters in large veins, cystocentesis, insertion of feeding tubes, hepatic aspiration sampling, or liver biopsy). In ductopenic feline sclerosing cholangitis or chronic EHBDO, animals require intermittent vitamin K_1 injections (eg, every 7–21 days), monitored by PIVKA or PT clotting tests. Overdosing with vitamin K_1 can lead to symptomatic Heinz body hemolytic anemia in cats.

Vitamin E is an important antioxidant, antiinflammatory, and antifibrotic used in necroinflammatory and cholestatic liver disorders. Oral α -tocopherol acetate is given at 10 IU/kg/day. Higher dosages (100 IU/kg/day) are needed in animals with

TABLE 12

FORMULATION OF A FORTIFIED, WATER-SOLUBLE VITAMIN SUPPLEMENT^a FOR DOGS AND CATS WITH LIVER DISEASE

Vitamin Supplement	Concentration per mL
Thiamine hydrochloride (vitamin B ₁)	50 mg
Riboflavin 5' phosphate sodium (vitamin B ₂)	2–2.5 mg
Niacinamide (vitamin B ₃)	50–100 mg
D-Panthenol (vitamin B ₅)	5–10 mg
Pyridoxine HCl (vitamin B ₆)	2–5 mg
Cyanocobalamin (vitamin B ₁₂)	Variable; 0.4–50 mcg (low B ₁₂ values necessitate additional supplementation in deficient cats, SC or IM)
Benzyl alcohol (preservative)	1.5%

^a 2 mL/L of IV fluid

chronic EHBDO or feline destructive cholangitis (ductopenic sclerosing cholangitis). Alternatively, α -tocopherol polyethylene glycol succinate (water-soluble vitamin E) can be used at 10 IU/kg/day. Dosing of vitamin E should not exceed recommended amounts, because too much vitamin E can interfere with vitamin K activity, provoking coagulopathies. Too much vitamin E also can impart oxidant injury secondary to accumulation of the tocopheroxy radical.

DISEASES OF THE LIVER

FULMINANT HEPATIC FAILURE

Fulminant hepatic failure is a syndrome defined by the abrupt loss of liver function, associated with hepatic encephalopathy (HE) and coagulopathy. Early, appropriate therapy is critical. In chronic or end-stage liver disease with an acute or chronic insult and in acute liver injury with no apparent underlying cause, treatment provides supportive care to allow time for hepatic regeneration and compensation.

Specific treatment should be administered if an underlying cause is determined. Decontamination of oral, dermal, and enteric surfaces is mandatory if toxin exposure has occurred within 36 hr. If an adverse drug reaction is implicated, the drug in question must be discontinued and antidotes investigated. Life-threatening infection, cerebral edema, and coagulopathies are major complications.

Attention to fluid, electrolyte, and acid-base balance, glycemic status, and nutritional support optimizes chance of survival. Restoration of intravascular

volume and systemic perfusion may prevent or mitigate the severity of organ failure that often accompanies fulminant hepatic failure (eg, renal, cardiac, adrenal, pancreatic dysfunction). Lactated Ringer's solution should be avoided in animals with compromised lactate metabolism, leading to lactic acidosis. Chronic vomiting and diarrhea often accompany fulminant hepatic failure and can lead to dehydration, hypokalemia, hypochloremia, and metabolic alkalosis. Alkalosis and hypokalemia can each escalate renal ammonia production, contributing to hyperammonemia and HE. Neuroglycopenia can induce neurologic signs that can be confused with and augment HE. Administration of 0.9% NaCl with supplemental vitamins and glucose is usually a safe first option unless portal hypertension and ascites complicate the syndrome. Dextrose (2.5%) and potassium (sliding scale) should be judiciously added to IV fluids, as well as water-soluble vitamins (fortified B-soluble vitamins at 2 mL of fluid). Ascites may develop in animals with an acute sinusoidal collapse or acute or chronic fibrosing hepatic injury.

In cats, a B₁₂ injection (250–1,000 mcg total dose, IM or SC) should be considered if severe gut disease, pancreatic disease, or starvation are suspected; a plasma sample for assessment of B₁₂ should be collected before treatment. Definitive assessment of methylmalonic acidemia defines B₁₂ adequacy but cannot be completed in a timely manner for clinical application in emergent liver failure. Thiamine deficiency (B₁) can also complicate clinical status, producing neurobehavioral signs overlap-

ping with HE. Although hyperglycemia must be avoided because it can worsen cerebral edema, euglycemia must be established before thiamine administration; otherwise, thiamine-provoked neuroglycopenia may aggravate neurologic injury and clinical signs. Thiamine is especially important in cats and can be supplemented PO or slowly with IV fluids (fortified B-soluble vitamin solution); 25–100 mg/day is recommended.

Animals with acute liver failure have high energy expenditure and protein catabolism. Nutritional support should be attempted enterically with protein intake initially restricted to 2.5 g/kg body wt in dogs and 3.5 g/kg body wt in cats, with overt HE. If neurologic signs are inapparent, protein restriction is not advised.

Broad-spectrum antibiotics should be given empirically if HE, renal failure, or components of the systemic inflammatory response syndrome (SIRS) are identified. As for other suspected bacterial infections involving the liver, a combination of ticarcillin, metronidazole (7.5 mg/kg, bid, PO or IV), and enrofloxacin are advised.

In most cases, N-acetylcysteine is administered for the first 2 days to provide cysteine for glutathione synthesis, to improve microcirculatory perfusion, and to protect against development of SIRS. A loading dose (140 mg/kg) is initially administered through a 0.25 μ M filter and given over 20 min; prolonged infusion can precipitate hyperanionemia. Thereafter, 70 mg/kg is given IV at intervals of 6–8 hr for 2 days. Rarely, an adverse reaction develops, manifesting as urticaria, pruritic rash, vomiting, and most severely as angioneurotic edema.

When oral medications can be tolerated, biologically available S-adenosylmethionine (SAME) is recommended at 20–40 mg/kg/day, PO, given on an empty stomach to sustain hepatic glutathione adequacy.

Initially, vitamin K₁ (0.5–1.5 mg/kg, IM or SC) is given in three doses at 12-hr intervals. Repeated dosing may be necessary in animals with overt coagulopathies. However, a balanced hemostatic defect with loss of hepatic procoagulant synthesis paralleled by the loss of hepatically derived anticoagulants results in the lack of an overt coagulopathy. Inhibition of gastric acid secretion with an H₂-receptor antagonist (eg, famotidine, faster onset) or HCl pump inhibitor (eg omeprazole, slower onset) is advised. Omeperazole inhibits certain p450 cytochromes and may result in polypharmacy drug interactions. If overt hemorrhagic tendencies are seen, fresh frozen plasma or cryoprecipitate (for vWF and fibrinogen) may be needed. Desmopressin

acetate (DDAVP, 0.3 mcg/kg, IV, diluted to 10% in saline) can sometimes arrest serious clinical hemorrhage by improving primary hemostasis. With acute portal hypertension, diapedesis of blood into the enteric lumen may develop before opening of APSSs; this can lead to lethal blood loss and/or aggravate HE. In this scenario, only a whole blood transfusion or administration of packed RBCs and species-specific plasma can replace extracorporeal losses. Concurrent propranolol administration may reduce portal hypertension, which may lessen the rate of blood loss.

The goal of therapeutic strategies in fulminant hepatic failure is to prevent the onset of encephalopathy, limit its severity, and reduce the risk of cerebral edema. Development of cerebral edema is multifactorial, complex, and incompletely understood. Mediators of systemic and local inflammation and circulating neurotoxins (especially ammonia) contribute to its development. HE also can be precipitated by systemic infection, hypotension, and systemic vasodilatation. Altered cerebral endothelial permeability in response to neurotoxins (eg, ammonia) and inflammatory mediators, inflammatory responses, and altered cerebral blood flow are also recognized to trigger or worsen HE.

The head and neck should be maintained in a neutral position, avoiding compression of jugular blood flow; elevation of the head and neck can reduce intracranial pressure and decrease CSF hydrostatic pressure. Central venous lines increase risk of serious iatrogenic hemorrhage, which may require use of compression bandaging. Spontaneous hyperventilation sustains a mild respiratory alkalosis that promotes cerebral arterial vasoconstriction, which tends to reduce intracerebral pressure. Hypoxia must be avoided because of its associated cerebral vasodilatory effect. Mannitol (0.25–0.5 g/kg, given as an IV bolus) can help reduce cerebral edema; boluses can be repeated if serum osmolality has not increased. Furosemide (0.5–1 mg/kg, every 6–8 hr) has been used to increase renal elimination of sodium and water. Use of hypothermia, barbiturate coma, hypertonic saline, or flumazenil infusions are not recommended.

HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy (HE) develops in liver disorders associated with portosystemic shunting, fulminant hepatic failure, or cirrhosis (acquired portosystemic shunts, reduced functional hepatic mass, intrahe-

patic shunting of blood around regenerative nodules). Clinical signs vary but involve disturbed sensorium ranging from mild dullness and an inability to respond to basic commands to overt abnormalities, including propulsive circling, head pressing, aimless wandering, weakness, ataxia, amaurosis (unexplained blindness), ptialism, dementia, behavior change (eg, aggression), collapse, seizures, and coma. Although the pathophysiologic mechanisms of HE are not completely known, synergistic effects between the failure of the liver to detoxify ammonia and other endogenous substances, increased cerebral inflammatory cytokines, impaired brain perfusion, development of neuronal edema, hypoxia, mitochondrial dysfunction, neuroglycopenia, and oxidative injury are important interdependent mechanisms. Increased production of reactive oxygen and nitrogen oxide species are thought to trigger protein and RNA modifications that deleteriously influence brain function. The integrated concept of HE explains episodic variability and heterogeneous precipitating factors that correlate with diverse clinical scenarios.

Ammonia plays a key role in HE and is thought to sensitize the brain to numerous other precipitating factors/mediators. However, blood and cerebral ammonia concentrations are often discordant, disqualifying blood ammonia as a simplistic measure of HE. In healthy animals, most ammonia is removed by hepatocytes, converted into amino acids or urea, and excreted via kidneys in urine. In liver failure or portosystemic shunting, blood ammonia concentrations increase because of inadequate hepatic detoxification. In the circulation, ammonia can also be excreted by the kidneys (tubular secretion) and used for glutamine synthesis in skeletal muscle (temporary ammonia detoxification). This latter mechanism is why maintenance of lean body mass (muscle) is essential in animals with hepatic insufficiency that are susceptible to hyperammonemia and HE. A number of clinical scenarios and mechanisms can augment blood ammonia concentrations and precipitate HE, including dehydration (prerenal/renal azotemia), alkalemia, hypokalemia, hypoglycemia, catabolism, infection, PU/PD, anorexia, constipation, hemolysis, blood transfusion, GI hemorrhage, high dietary protein, and various drugs (eg, benzodiazepines, tetracyclines, antihistamines, methionine, barbiturates, organophosphates, phenothiazines, diuretics [overdosage], metronidazole [overdosage], and certain anesthetics).

Ammonia can influence multiple neurotransmitter systems directly (chemical influence) and indirectly (altered substrate availability for transmitters). There is substantial evidence that astrocytes play an important role in the pathogenesis of HE. Ammonia and other endogenous products, inflammatory cytokines, and hyponatremia (associated with portal hypertension) induce astrocyte swelling that can lead to brain edema and herniation most common in acute liver failure and acute severe HE.

Treatment of acute HE is aimed at providing supportive care and rapidly reducing neurotoxins produced in the GI tract. Severely encephalopathic animals may be semicomatose or comatose. Benzodiazepines and other sedatives should not be administered. Food should be withheld until neurologic status improves. Fluids (2.5% dextrose and 0.45% saline with potassium chloride and vitamin B complex added) should be administered to correct dehydration, electrolyte, and acid-base imbalances, but monitoring of plasma osmolality is essential to avoid hyposmolality. Lactated Ringer's solution should be avoided, because hepatic failure may thwart lactose metabolism and cause lactic acidosis. Cleansing enemas of warm soapy water are followed by retention enemas of either lactulose or lactitol (3 parts lactulose or lactitol to 7 parts water at 20 mL/kg), 10% povidone-iodine solution (20 mL/kg, rinsed well after 10–15 min dwell), neomycin (22 mg/kg mixed with water), or diluted metronidazole (7.5 mg/kg suspended in water at 10–20 mL/kg) given every 8 hr until the animal is neurologically responsive. Retention enemas should be maintained for 15–20 min by use of a Foley catheter. Administration (oral or rectal) of live *Lactobacillus* and *Bifidobacillus* organisms (live yogurt cultures or probiotic products) also can assist in displacing ammonia-producing microbes but remains a controversial intervention. Metronidazole, neomycin, and povidone-iodine solutions can directly alter colonic bacterial flora, decreasing populations of ammonia-producing organisms. However, care is warranted in using neomycin with concurrent inflammatory bowel disease because increased systemic uptake can increase potential for renal and otic (cochlear) toxicity. Metronidazole must be restricted to ≤ 7.5 mg/kg every 8 hr (combined oral and rectal dosing); higher dosages confer risk of iatrogenic neurotoxicity (vestibular signs initially).

Once the animal is stabilized, treatment is aimed at preventing recurrence. Protein-modified restricted diets should be fed (*see* p 439). Oral probiotic yogurt and lactulose (0.1–0.5 mL/kg, PO, bid-tid, initial dose) can be used, with initial dose titrated to achieve several soft, pudding-like stools per day. Feeding milk may achieve a similar effect in some animals. The goal of administration of nondigestible carbohydrate is to promote fermentation in the gut. Concentrated probiotic organisms can prevent other bacteria from growing and replicating through substrate competition and pH-related (acid) growth inhibition or mechanical cleansing (catharsis) induced by fermentation products. These effects diminish uptake of ammonia, inflammatory and oxidative substrates, lipopolysaccharide, and other toxic enteric products contributing to HE. Unfortunately, the efficacy of probiotics remains unestablished for this purpose.

In recalcitrant HE, antibiotic therapy, preferably metronidazole (7.5 mg/kg, PO, bid) or amoxicillin (13–15 mg/kg, PO, bid) rather than neomycin, is recommended. Antibiotic therapy works synergistically to reduce enteric toxins along with indigestible carbohydrates. Rifaximin (approved for treatment of HE in people in 2010 because of its few adverse effects and pharmacologic benefits) is a semisynthetic, gut-selective, nonabsorbable oral antibiotic derived from rifamycin and a structural analogue of rifampin. It acts locally in the GI tract, with systemic adverse effects similar to those of placebo in people. It is active against a variety of aerobic and anaerobic gram-positive and gram-negative organisms, as well as protozoal infections. *In vitro* data indicate that the susceptibility of gram-positive organisms to rifaximin is greater than that of gram-negative organisms. Dosing at 5 mg/kg, once to twice daily, has been used in a small number of dogs and cats with recalcitrant HE with apparent positive response. Optimal dosing has not been determined.

Clinical signs of HE can be exacerbated by GI bleeding, infection, glucocorticoid use (enhanced catabolism of tissue protein), hypoglycemia, neoplasia, fever, azotemia or dehydration (increased BUN increases enteric ammonia production), constipation (increased generation and absorption of colonic neurotoxins), metabolic alkalosis (favoring both production of ammonia by the kidneys and uptake of ammonia across the blood-brain barrier), and use of diazepam and barbiturates (synergistic neuroinhibitors). Use of H₂-receptor

antagonists and sucralfate, control of fever and infection, proper hydration, and minimal (if any) use of anticonvulsant medications can help alleviate HE complications. For additional considerations, *see* p 442.)

PORTAL HYPERTENSION AND ASCITES

Ascites develops secondary to portal hypertension and low albumin concentrations. Physiologic responses triggered to maintain euolemia and splanchnic perfusion pressure signal systemic conservation of sodium and water.

Portal hypertension represents circulatory dynamics thwarting cranial flow of blood through the liver. Prehepatic causes include stenosis, stricture, or thrombi involving the extrahepatic portal vein. Intrahepatic causes include the sequela of chronic hepatitis resulting in collagenization and capillarization of hepatic sinusoids, accumulation of connective tissue encircling portal triads or the hepatic venule (centrilobular area), architectural remodeling of the liver by formation of regenerative nodules (cirrhosis), vascular occlusion of hepatic or portal veins (eg, thrombi, neoplasia, vasculitis), or diffuse dissemination of neoplastic cells within sinusoids or storage materials (amyloid within the space of Disse, fat or glycogen within hepatocytes). Rarely, arterIALIZATION of the hepatic parenchyma by an intrahepatic arteriovenous malformation leads to arterIALIZATION of the intrahepatic circulation and causes portal hypertension and ascites. Intrahepatic causes of portal hypertension are categorized as presinusoidal, sinusoidal, and postsinusoidal. Post-hepatic causes of portal hypertension include obstruction of blood flow from the liver through the hepatic vein; this can begin at the level of the heart (eg, right heart failure, cor triatriatum dexter, hemangiosarcoma involving the right atrium), pericardium (eg, restrictive pericarditis, pericardial tamponade), or vena cava (eg, thrombi, congenital or acquired “kink,” heartworm-associated vena caval syndrome).

In all cases of hepatic portal hypertension, intrahepatic portal hypoperfusion (portal perfusion pressure is ~5–8 mmHg) is compensated by an increase in hepatic arterial perfusion that maintains organ circulation. This causes hepatofugal (backward) flow of blood into the valveless portal system and formation of acquired portosystemic shunts (APSSs).

Compensatory imbalance of sodium and water homeostasis becomes clinically apparent at the onset of portal hypertension and is typically associated with a subnormal albumin concentration. Ascitic effusion associated with hepatic disease is usually a modified or pure transudate (serum albumin <1.8 g/dL). Consequences of portal hypertension include development of ascitic effusion, splanchnic vasodilation, risk of bleeding from APSSs, development of a portal-enteric vasculopathy, and increased risk of septic abdominal effusion.

The standard treatment to reduce splanchnic portal hypertension in people is nonselective β -blockade using propranolol, administered to control or reduce risk of spontaneous bleeding from APSSs. Other pharmacologic interventions remain controversial and have not been shown in placebo-controlled trials to provide greater benefit. Therapeutic strategies for control of ascites include dietary sodium restriction, administration of diuretics to increase urinary sodium elimination, and therapeutic abdominocentesis (when necessary). The first step is dietary sodium restriction to an intake of ≤ 100 mg sodium/100 kcal diet (25 mg/kg/day; $<0.1\%$ dry-matter basis in food). However, sodium-restriction alone is often insufficient and too slow in onset for efficient management. Thus, diuretics are usually also recommended. Diuretic therapy should slowly reduce ascites without causing dehydration, metabolic alkalosis, or hypokalemia. Reducing ascites by $\leq 1\%$ – 1.5% of total body wt/day is recommended by initially using combined treatment with furosemide (1–2 mg/kg, PO, bid) and spironolactone (loading dosage 2–4 mg/kg $\times$ 2–3 doses, then 1–2 mg/kg, PO, bid). Reevaluation every 7–10 days allows for careful upward titration of diuretic dosages. Combining a loop diuretic (furosemide) with spironolactone (aldosterone antagonist) reduces risk of iatrogenic hypokalemia.

If ascites is slow to mobilize, measuring the urinary fractional excretion of sodium can help determine whether dietary restriction and diuretic dosing are adequate. If ascites causes tense abdominal distention compromising ventilation, appetite, or patient comfort, therapeutic abdominocentesis may be undertaken. In people, 8 g of human albumin is administered for every 5 L of effusion removed to offset the development of postdiuresis circulatory dysfunction developing ~ 12 hr after effusion removal. Postdiuresis circulatory dysfunction reflects reequilibration of body fluids and worsened hypoalbuminemia (removed by abdominocentesis), leading to systemic

hypotension (response to redistribution of removed ascitic fluid) and splanchnic and renal vasoconstriction. The latter responses increase risk of development of the hepatorenal syndrome (reversible renal vasoconstriction associated with liver failure complicated by ascites). Because there is no access to species-specific albumin for dogs and cats, polyionic fluids may be used when therapeutic abdominocentesis to remove large amounts of ascitic fluid is performed. Large-volume abdominocentesis should never be performed without concurrent diuretic administration. In removing ascitic effusion, the goal is to remove enough volume to improve patient comfort. Rational use of therapeutic abdominocentesis reduces abdominal pressure, improves renal perfusion and cardiac output, and improves response to diuretic therapy. Once ascitic effusion is mobilized, diuretics can often be used intermittently with concurrent dietary sodium restriction.

PORTOSYSTEMIC VASCULAR MALFORMATIONS

The most common circulatory anomalies of the liver in dogs are microvascular dysplasia (MVD) and portosystemic vascular anomalies (PSVAs, also referred to as portosystemic shunts or portocaval shunts). Cats also are affected with PSVAs but less commonly than dogs. MVD and PSVAs are related polygenic disorders affecting small-breed dogs. PSVAs may be extrahepatic (more common in small-breed dogs) or intrahepatic (more common in large-breed dogs). MVD has not been characterized in large-breed dogs or in cats.

Microvascular Dysplasia

MVD is far more common than PSVAs in affected kindreds of small “terrier” type dogs. A diagnosis of MVD denotes abnormal development of the fine (tertiary) branches of the intrahepatic portal veins and is associated with lobular atrophy and a compensatory increase in arterial perfusion (hepatic arterial buffer response), which manifests as coiling of hepatic arteriole branches and development of arterial twigs. The arteriolar response results in increased numbers of thick-walled arterial cross-sections in portal tracts and orphaned random arterioles within the hepatic parenchyma. Other additional MVD microanatomic abnormalities variably include large numbers of binucleate hepatocytes (especially adjacent to the portal tract), merging of hepatic venules

with portal tracts, abnormal sinusoidal organization and expansion, thickening of the throttling muscle of the hepatic venule in dogs, and formation of random foci of lipogranulomas. A diagnosis of "portal hypoplasia" cannot be made on the basis of a liver biopsy, because any reduction in hepatic portal venous perfusion causes identical microanatomic changes. Rather, this histologic pattern is better termed "portal hypoperfusion." Dogs with MVD have high TSBA concentrations but do not demonstrate clinical illness or other laboratory abnormalities found in dogs with PSVAs. They do not demonstrate HE, do not develop ammonium biurate crystalluria, and typically have a normal protein C activity. A normal lifespan should be expected in dogs with MVD. This diagnosis does not warrant feeding a special diet or liver-specific medications (eg, lactulose, SAME, milk thistle). However, because dogs with MVD may have trouble metabolizing drugs that require rapid hepatic delivery and extraction, care is necessary when prescribing certain medications. Because MVD is genetically linked with PSVAs, TSBA should be measured in all young puppies of predisposed breeds for future health care considerations; discovery of high TSBA concentrations during an illness may lead to inappropriate, invasive, and expensive diagnostic testing. Selection of breeding stock in affected kindreds should target dogs with normal TSBA concentrations. However, because the trait is polygenic, breeding dogs with normal TSBA may result in puppies affected with MVD and PSVAs. Once high TSBA concentrations are detected in young (<6 mo) small terrier-type breeds lacking clinical signs of PSVA, repeated bile acid measurements are not warranted; TSBA concentrations will remain variably increased for the animal's life. Knowing that a dog has high bile acids likely caused by MVD will define utility of the TSBA test for future health care assessments.

Definitive diagnosis of MVD is possible only by consideration of the liver biopsy and vascular imaging studies. Liver biopsy demonstrates lesions identical to those of PSVAs. The severity of MVD lesions varies among liver lobes, necessitating collection of samples from three different lobes for definitive characterization. Liver biopsy by the tru-cut method is strongly discouraged for diagnosis of portal hypoperfusion (PSVAs, MVD) because this diagnosis is based on examination of multiple acinar units to detect lobular atrophy, portal triad arteriolarization, and other characteristic

features. Needle biopsies restrict the number of acinar units sampled. However, steps to pursue a definitive diagnosis *are not* recommended in most dogs with suspected MVD (no clinical signs, no hematologic or biochemical markers typical of PSVA). Instead, it is prudent to consider that a dog at risk of hepatic vascular malformations has MVD as the underlying cause of high TSBA unless it exhibits clinical (HE) or clinicopathologic features (RBC microcytosis, low BUN, creatinine, and cholesterol concentrations, low protein C activity) associated with PSVAs.

Portosystemic Vascular Anomalies

A portosystemic vascular anomaly (PSVA) is a grossly apparent aberrant connection between the extrahepatic portal vasculature and the systemic circulation (connecting a branch of the portal vein to the vena cava or azygous vein) that diverts blood to the systemic circulation, bypassing the liver. Reduced portal flow to the liver causes hepatic lobular atrophy. Because the portal circulation transports microorganisms, toxins, nutrients, and other materials from the intestines to the liver, detoured blood is not cleansed or processed before circulation to the brain and systemic circulation. Consequently, neurotoxic substances that can provoke encephalopathic effects can be circulated directly to the brain, causing HE. Other noxious products and infectious agents inefficiently removed by the liver in animals with PSVAs result in a more severe clinical challenge to what should be mild health concerns (eg, infectious diarrhea, infected wounds, dermatitis, tick bites, other).

Congenital PSVAs are seen primarily in purebred dogs with extrahepatic PSVAs, predominantly in small purebred terrier-type dogs (eg, Yorkshire Terriers, Maltese, Shih Tzu, Havanese, Papillon, Miniature Schnauzers, Pugs, Cairn Terriers, Norfolk Terriers, Tibetan Spaniels, and others). Intrahepatic PSVAs predominate in large-breed dogs, including (but not exclusively) Irish Wolfhounds, Old English Sheepdogs, Labrador Retrievers, and Golden Retrievers. Extrahepatic PSVAs usually arise from the portal vein, left gastric vein, or splenic vein and connect to the caudal vena cava (most common), the azygous vein, or rarely another systemic vessel. An intrahepatic PSVA represents the retention of an embryonic vessel that carries fetal blood from the placenta to the heart, through the middle of the liver but bypassing the hepatic circulation (ductus

venous). This malformation is only occasionally seen in small-breed dogs and cats.

Congenital PSVAs in cats are seen more frequently in mixed breeds, but the prevalence may be increased in purebred Himalayans and Persians. However, the higher prevalence of polycystic liver disease and associated portal hypertension and acquired portosystemic shunts in these breeds complicates diagnosis of PSVAs. In cats, extrahepatic PSVAs involving the left gastric vein are most common.

Animals with PSVAs are often smaller than littermates, fail to thrive, and can have other congenital abnormalities (eg, cryptorchidism in dogs and cats, heart murmurs in cats). Clinical signs are highly variable, and 10%–20% of affected animals may be asymptomatic. The presence of clinical signs depends on the severity of portosystemic shunting. In symptomatic animals, clinical signs are usually evident by 6 mo of age in cats and before 1 yr in dogs. Clinical signs include nausea, ptyalism (especially cats), vomiting, diarrhea, pica, intermittent anorexia, PU/PD, amaurosis (unexplained blindness), excessive vocalization, hallucinations, apparent neck or spinal pain, hematuria, pollakiuria, stranguria, urethral obstruction associated with formation of ammonia biurate uroliths, and additional neurobehavioral signs reflecting HE. Signs referable to urinary tract calculi may be the only presenting complaint. Cats with PSVAs have a unique, homogenous, copper-colored iris that appears to be genetically linked with the disorder; the exception is blue-eyed cats. However, because a copper-colored iris is typical for Persians and Russian blue cats that do not have a PSVA, it is important to consider this observation in perspective of clinical signs and finding high TSBA concentrations.

Laboratory abnormalities may include microcytic RBCs (low MCV), mild nonregenerative anemia, poikilocytosis (cats), target cells (dogs), mild hypoproteinemia and hypoalbuminemia, hypoglycemia (rare, primarily young to yb breed dogs), low BUN and creatinine, hypocholesterolemia, normal to mildly increased liver enzyme activity (ALT, AST, and ALP), normal bilirubin, dilute urine (hyposthenuria or isosthenuria), and ammonia biurate crystalluria. Fasting and postprandial TSBA concentrations are usually markedly increased; however, measurement of TSBA or ammonia after a prolonged fast may yield normal values. Postprandial TSBA and ammonia (after NH_4Cl administration) are

markedly abnormal. Routine coagulation assessments are usually within normal limits, but protein C activity is usually <70%. The protein C test is valid for use in dogs. This test reflects the severity of shunting; the lower the value, seemingly the more severe the shunt. In asymptomatic PSVA dogs with a protein C >70%, surgical ligation has been very successful. Those with a protein C <70% may not tolerate complete shunt attenuation.

Abdominal radiographs reveal microhepatica and “plump” kidneys. Ammonium biurate uroliths are radiolucent and thus not detected with radiographic imaging. Ultrasonography can noninvasively identify a PSVA if done by an experienced operator using color-flow Doppler in a fasted, cooperative patient. However, extrahepatic PSVAs can be missed on ultrasonographic imaging and even falsely identified in animals with MVD. Although discovery of intrahepatic PSVAs is relatively easy using ultrasonography, identification of extrahepatic PSVAs can be challenging because bowel gas and animal cooperation may limit imaging in critical regions. Ultrasonographic examination can identify radiolucent uroliths in the renal pelvis or urinary bladder. Colorectal portal scintigraphy or splenoportal scintigraphy, available in specialty clinics or teaching hospitals, can clearly determine the presence of portosystemic shunting. However, scintigraphy is unable to identify the anatomic location of involved shunting vasculature with certainty. Splenoportal scintigraphy requires percutaneous injection of isotope into the spleen, is considered an invasive test, and does not provide better resolution, specificity, or sensitivity over routine colorectal scintigraphy to determine the presence of portosystemic shunting or definitively identify the involved vasculature. Contrast radiographic portography, the traditional gold standard test to confirm PSVAs, requires catheterization of a branch of the portal vein and injection of radio-dense iodinated contrast to illustrate portal vascular anatomy. Noninvasive multisector CT has replaced simple contrast radiographic portography, providing better anatomic mapping of portal vasculature. This imaging modality requires short-term anesthesia with contrast injected into a peripheral vessel and permits 3-dimensional anatomic reconstruction of the splanchnic circulation, vascular anomaly, and adjacent viscera. A liver biopsy is always indicated in PSVA patients during surgical shunt ligation, or if multiple shunts are noted, to determine primary underlying disorders or

acquired liver diseases that may coexist and require specific intervention.

Although the treatment of choice for symptomatic PSVAs is surgical attenuation or ligation, not all dogs can tolerate shunt attenuation, and a subset of dogs (asymptomatic, minimally symptomatic) survive with good quality of life with medical management only. Surgical management of PSVAs may include direct shunt ligation at surgery to the animal's tolerance (judged by measurements of portal pressure, vital signs, local visceral response) or application of an ameroid ring (inner lining gradually expands over a few days to slowly occlude the shunting vasculature). The most common postsurgical complication of PSVA attenuation is short-term benign abdominal effusion that typically resolves within a few days. The most serious postsurgical complication is acute portal hypertension, characterized by development of abdominal effusion, bloody diarrhea, abdominal pain, ileus, endotoxic shock, and cardiovascular collapse. This complication requires immediate removal of the shunt ligature. Other complications include seizures (rare) and formation of blood clots within the portal vein. Unfortunately, in some dogs, acquired portosystemic shunts silently develop at varying intervals after surgery for a PSVA. The ligation site also may be circumvented by formation of a medusa of vessels around the ligated site or recanalization of the PSVA that reestablishes portosystemic shunting several years after initial surgery. The greatest risk of insidious postoperative complications is associated with ameroid constrictors, because the extent of vessel occlusion remains ill defined unless repeat imaging studies are undertaken. In rare cases, ameroids have eroded through the shunting vasculature, causing acute collapse, hemoabdomen, and death that may occur months after their application. Excellent outcomes have been observed with careful intraoperative graded ligation of extrahepatic PSVAs (observing portal pressure and visceral response, systemic blood pressure, and heart rate) as well as with application of ameroid rings. Surgical intervention for intrahepatic shunts is more complicated and less successful. Coil embolization of intrahepatic shunting vessels by interventional radiographic technique is an alternative procedure but can be associated with adverse effects (portal hypertension, portal or vena caval clot formation) and can be prohibitively expensive; in addition, more than a single intervention may be needed to substantially reduce portosys-

temic shunting. Survival analyses of >450 dogs with PSVAs managed with surgical versus long-term medical management estimated a median survival time of 11 yr for dogs with extrahepatic PSVAs treated surgically, with no significant difference for dogs treated solely by medical management. However, this result is biased, because owners of the population of dogs optimally responding to medical management were more inclined to decline surgical intervention. Median survival time in dogs with intrahepatic PSVAs ($n=34$) treated surgically was estimated as 5 yr and was not significantly different from a larger population of dogs treated by medical management alone. In a report of 96 dogs with intrahepatic shunts treated by one or more coil embolization procedures, the estimated median survival time was 6 yr.

Male dogs with repeated bouts of ammonium biurate urolithiasis requiring medical or surgical resolution (those undergoing surgical correction of PSVAs in which the shunt could not be fully attenuated as in those on medical management) should have a permanent prescrotal urethrostomy created to allow passage of small calculi. This will avert subsequent development of an obstructive uropathy.

Overall, prognosis after surgical ligation of a single extrahepatic PSVA is usually good. Prognosis is less favorable in dogs with multiple acquired shunts secondary to severe intrahepatic portal vein atresia and in those with intrahepatic shunts. Surgery is less successful in cats than in dogs, with cats more likely to develop multiple acquired portosystemic shunts after PSVA ligation. Staging surgeries to gradually attenuate PSVAs in dogs or cats has not improved outcomes.

Dogs with relatively asymptomatic PSVAs can often be managed with special diets indicated for hepatic insufficiency. Lifelong dietary support is required, but good health and normal lifespan can be achieved. However, dogs managed medically are always at risk of more severe effects from health issues involving other organ systems, infections, or GI signs. The best protein sources for dogs are soy and dairy quality protein with a protein intake starting at 2.5 g/kg/day. Red meat, fish, and organ meats must be avoided. Additional dairy quality protein is usually easily tolerated and can be used to increase protein, phosphate, and fermentable carbohydrate intake. Treats of raw vegetables (eg, broccoli, carrots), cheese, probiotic yogurt, popcorn, modest numbers of dog biscuits, animal crackers, and limited supervised activity with rawhide

bones can be offered without adverse consequences. If rawhide chews result in oral hemorrhage, they should be avoided because swallowed blood can provoke encephalopathic signs. Variation in the need for daily lactulose and metronidazole administration (see p 443) is broad, such that individualization of treatments is advised. Medically managed dogs remain at risk of developing HE. Owners should be educated to recognize early signs of HE and complicating health issues, how to administer cleansing and retention enemas, and how to administer subcutaneous fluids. This training allows early intervention of HE episodes and reduces the number of emergency veterinary visits.

ACQUIRED PORTOSYSTEMIC SHUNTS

Acquired portosystemic shunts (APSSs) form secondary to portal hypertension caused by 1) chronic liver disease (fibrosis, regenerative nodules), 2) congenital severe portal vein atresia, 3) acquired damage to the fine branches of the intrahepatic portal vein (noncirrhotic portal hypertension), 4) hepatic arteriovenous malformations, 5) congenital hepatic fibrosis associated with polycystic liver malformations (ductal plate malformations), 6) portal vein thrombosis or stricture, or 7) outflow obstruction through the hepatic vein/venules (thrombosis [Budd-Chiari syndrome], hepatic vein injury [veno-occlusive syndrome]). The main body of the portal vein lacks valves and maintains a blood pressure of <8 mmHg. Any disorder diminishing hepatic portal perfusion results in a hepatic arterial buffer response that increases hepatic arterial perfusion. High-pressure retrograde arterial flow into portal vasculature leads to formation of APSSs as blood follows the path of least resistance to the vena cava. In animals with extrahepatic portal atresia or portal thrombi, splanchnic circulatory hypertension leads to an APSS. In animals with occluded hepatic venular outflow or fibrotic hepatic remodeling, sinusoidal and postsinusoidal hypertension also results in retrograde flow of blood into the valveless portal system. APSSs represent nests of tortuous veins uniting portal vasculature with the abdominal vena cava.

The most common sites of APSSs are caudal to the left kidney, in the region of the colorectal vasculature, and associated with vessels of the spleen. Nests of small tortuous vessels can usually be identified during ultrasound examination using

Doppler color flow. Although esophageal varicoceles are most common in people, this location does not predominate in animals. Surgical exploration for shunt ligation should not be done in animals with suspected PSVAs associated with APSSs, because finding an APSS confirms the presence of portal hypertension. Liver biopsies are needed to determine the underlying cause of portal hypertension.

Clinical signs of APSSs include episodic HE, PU/PD, vomiting, diarrhea (sometimes bloody), and abdominal effusion. Laboratory abnormalities consistent with a primary underlying hepatic disease can be seen in addition to markers of shunting (RBC microcytosis, low BUN and creatinine, hypocholesterolemia, anionium biurate crystalluria, and subnormal protein C activity). Hyperbilirubinemia may be present, depending on the underlying cause. Ligation of multiple APSSs is contraindicated, because this is a compensatory response to portal hypertension. Banding of the vena cava to reduce the extent of shunting is ill advised. Medical treatment to minimize signs of HE along with sodium restriction and combination diuretic therapy are used to control abdominal effusion. Dogs and cats with APSSs can live several years without clinical signs, some having a normal lifespan uneventfully when provided with appropriate medical and nutritional support.

OTHER HEPATIC VASCULAR DISORDERS

Other vascular abnormalities seen in dogs and cats include hepatic arteriovenous "fistulas," hepatic venous outflow obstruction, (veno-occlusive disease, Budd-Chiari syndrome), and portal venous thromboembolism. These are relatively uncommon compared with PSVAs and MVD and other acquired hepatic disorders.

Hepatic Arteriovenous Malformation

A hepatic arteriovenous (AV) malformation is a direct intrahepatic connection between the high-pressure hepatic arterial system and the low-pressure portal venous system. High-pressure arterialized blood flows retrograde into the portal vasculature, causing intrahepatic and extrahepatic portal hypertension, ascites, and APSS formation. These may be congenital or, less commonly, acquired from trauma, biopsy lesions, or neoplasia. Clinical signs of a congenital AV malformation initially

manifest in young animals and include HE, abdominal effusion, inappetence, vomiting, and diarrhea (often bloody). A murmur or bruit associated with turbulent blood flow may be audible over the affected liver lobe. Rarely, an intrahepatic AV malformation represents a variant of an intrahepatic PSVA.

Laboratory abnormalities are identical to those associated with more common PSVAs (see p 447) and additionally may disclose erythrocyte changes reflecting turbulence or a shearing effect (ie, schistocytes). Although ascites is a feature distinguishing an AV malformation from a PSVA, dogs with severe congenital portal atresia also may develop abdominal effusion (if they do not manifest a PSVA). Abdominal ultrasonography can easily identify an intrahepatic AV malformation (pulsing flow) and the associated APSS on color-flow Doppler interrogation. Definitive imaging requires contrast angiography via the celiac or anterior mesenteric artery (former "gold standard") or multisector contrast angiographic CT (current "gold standard").

Multiple AV connections are often evident within an affected liver lobe. Although surgical lobectomy or ligation of the nutrient artery is the conventional treatment, many affected dogs have other microvascular malformations causing intrahepatic shunting along with APSSs thwarting efficacy of lesion ablation. Biopsy of the liver from sites distant to the AV malformation (other liver lobes) is imperative to detect other intrahepatic vascular malformations. Surgical management has a dismal prognosis for cure because of the widespread intrahepatic distribution of microscopic vascular malformations and the presence of functional APSSs. Intravascular acrylamide injection using an interventional radiographic approach is an alternative salvage procedure. Unfortunately, this also cannot guarantee clinical cure because of the complex effect of this malformation on hepatic microvasculature. Limited outcome data for this approach describes treatment failures, some procedural complications (unintended embolization of nontargeted vasculature), and need for chronic medical management of HE.

Hepatic Vein Outflow Obstruction

Hepatic venous outflow obstruction can result from cardiac or pericardial disorders causing passive congestion of the caudal vena cava (eg, right heart failure, pericardial disease causing tamponade, congenital

defects [cor triatriatum dexter], cardiac tumors), obstruction of the caudal vena cava (eg, postcaval syndrome associated with heartworm disease, congenital "kinking" of the caudal vena cava, vascular or neoplastic thrombosis of the caudal vena cava, diaphragmatic hernia compressing the caudal vena cava), or obstruction of the efferent hepatic venous system (eg, liver lobe torsion, compression by a hepatic mass, idiopathic postsinusoidal venous obstruction secondary to acquired fibrosis or hepatic venular destruction, severe occlusive or obstructive extramedullary hematopoiesis, or hepatic venule obstruction by occlusive lipogranulomas (subset of dogs with extrahepatic PSVAs or MVD)).

Clinical features of occlusive disorders include hepatomegaly (unless cause is associated with PSVAs or MVD), ascites, formation of APSSs, and signs suggestive of the underlying primary disorders. Simple passive congestion leads to hepatomegaly, modest increases in liver enzymes, normal bile acid concentrations, and an abdominal effusion characterized as a modified transudate. Laboratory abnormalities of veno-occlusive disease (hepatic venule occlusion) or a Budd-Chiari syndrome (thrombosis of the hepatic vein or vena cava) reflect portosystemic shunting (eg, high TSBA concentrations, hypocholesterolemia, and usually low protein C activity), mild to moderate increases in hepatic transaminases, and variable total bilirubin and albumin concentrations. A modified transudate abdominal effusion is common.

Thoracic and abdominal radiographs help distinguish cardiac from other causal disorders; these may disclose kinking or impingement of the caudal diaphragmatic region of the vena cava. Cardiac ultrasonography helps identify causes of passive congestion (eg, differentiate between pericardial disease, cardiac tumors, congenital malformations, or intrathoracic masses compressing the caudal vena cava). Abdominal ultrasonography discloses hepatic venular distention in passive congestion and diminished hepatic venule size in veno-occlusive or Budd-Chiari syndromes associated with hepatic dysfunction and APSSs. Treatment and prognosis depend on the underlying disease.

HEPATOTOXINS

Although many drugs have been associated with hepatic dysfunction, their influence on liver pathology varies depending on the pathomechanism of liver injury and the

acinar zone of metabolic or circulatory disturbance.

Primidone, phenytoin, and phenobarbital can cause acute fulminant liver failure, chronic cholestatic liver disease, or a diffuse progressive degenerative vacuolar hepatopathy (VH) leading to metabolic epidermal necrosis (also known as necrolytic migratory erythema or hepatocutaneous syndrome). Although a diffuse glycogen-like VH (steroid hepatopathy) is usually a benign, reversible change associated with high-dose, long-term glucocorticoid administration, longer-term administration of high doses can cause a diffuse, severe degenerative VH leading to jaundice (in dogs) and hepatic lipidosis (in cats). Increases in ALP and, to a lesser extent, ALT are seen as early as 2 days after glucocorticoid administration in dogs.

Lomustine, a chemotherapeutic agent used mostly in dogs, causes an idiosyncratic unpredictable and progressive hepatitis culminating in cirrhosis. Oxidative injury secondary to drug metabolite accumulation is a suspected pathomechanism of liver injury, because treatment with biologically available SAME before lomustine administration is seemingly protective.

Danazol, an impeded androgen, can cause idiosyncratic reversible jaundice in dogs.

Androgenic anabolics can induce hepatic lipidosis in inappetent cats or in cats fed a protein-restricted diet. Androgenic anabolics also increase risk of hepatocellular carcinoma.

Thiacetarsamide, previously used to treat dirofilariasis, causes hepatotoxicity owing to its arsenical content.

Toxicity is associated with increased ALT activity and, in some dogs, jaundice. High liver enzymes were used as an indication to suspend therapy; thereafter, hepatic injury resolved. Mebendazole-associated idiosyncratic hepatotoxicity caused fatal acute hepatic necrosis or chronic hepatitis in some dogs. Chronic oxi-bendazole-diethylcarbamazine administration in dogs was shown to cause increased ALT and ALP activity, hyperbilirubinemia, periportal hepatitis, and fibrosis. Progressive injury and clinical signs resolved in many but not all dogs after drug discontinuation.

Many NSAIDs are mitochondrial toxins, and some are associated with idiosyncratic acute hepatocellular toxicity. In particular, carprofen was shown to cause idiosyncratic hepatic necrosis in some dogs, particularly Labrador Retrievers. Dogs may recover fully if toxicity is recognized early and drug administration suspended. Based on retrospective liver biopsy inspection, the

concurrent presence of excessive hepatocellular copper seemingly augmented NSAID toxicity in Labrador Retrievers. In dogs, trimethoprim-sulfadiazine also can cause idiosyncratic hepatotoxicity that may involve an immune-mediated component. A reversible cholestatic hepatopathy or acute/subacute massive fatal hepatic necrosis has been observed, sometimes after only a few treatments using a conventional dose. Halothane and methoxyflurane can be associated with a sensitization reaction leading to hepatic necrosis in dogs. Xylitol, a commonly used artificial sweetener in human foods, may be an intrinsic hepatotoxin for dogs, with ingestion of small doses leading to intractable hypoglycemia and lethal hepatic failure. Toxicity may lead to death before liver enzyme activity increases. However, there is some evidence suggesting a breadth of individual responses to this toxin.

Tetracyclines can rarely lead to idiosyncratic necrosis in dogs and cats and have been shown to augment hepatocellular lipid accumulation in many species. Itraconazole and ketoconazole in dogs and cats can cause idiosyncratic hepatotoxicity associated with high liver enzyme activity and jaundice. Clinical signs resolve with drug withdrawal.

Acetaminophen predictably causes centrilobular hepatic necrosis in dogs at dosages >200 mg/kg. Methemoglobinemia is also seen. Toxicity in cats is seen acutely at a much lower dosage (56 mg/kg), with hematologic signs predominating (eg, methemoglobinemia and Heinz body hemolysis). (See also p 3029.)

Methimazole hepatotoxicity in cats causing hepatic degeneration and necrosis appears to be idiosyncratic but also may involve immune-mediated mechanisms. Clinical features include inappetence, jaundice, and increased liver enzyme (ALT, AST) activity that resolve after drug discontinuation.

In cats, griseofulvin-associated hyperbilirubinemia with increased ALT appears to be idiosyncratic. Clinical signs and liver injury are reversible upon drug discontinuation. Idiopathic diazepam toxicity in cats causes fulminant hepatic failure associated with panlobular necrosis; signs of toxicity are evident within several days of initial drug administration. Toxicity has mainly been seen with medication given PO for behavior modification or to treat feline lower urinary tract disease. Unfortunately, idiosyncratic diazepam hepatotoxicity is usually fatal in cats. Proactive monitoring of liver enzymes can identify adverse reactions early in their

course, allowing for prompt drug discontinuation. Similar toxicity has also been seen with oxazepam.

Other specific hepatotoxins include aflatoxins, toxins derived from amanita mushroom (amanitin), blue-green algae (microcystin), cycad-associated (Sago palm) cycasin, and β -methylamino L-alanine, a neurotoxic amino acid. There are many plants in the Sago palm family, which are used as yard ornamentals in temperate climates in North America and also are commonly sold as bonsai plants in large retail stores.) Each of these toxins can cause lethal hepatic necrosis. Other chemicals reported to be hepatotoxic include heavy metals, certain herbicides, fungicides, insecticides, and rodenticides. (See also TOXICOLOGY, p 2948, et seq.)

Important steps to minimize absorption of ingested toxins or overdose of oral drugs include vigorous decontamination of the stomach and intestines by gastric lavage, induced vomiting, and decreasing enteric toxin absorption. Vomiting can be induced within 30 min up to 2 hr after ingestion by oral administration of 3% hydrogen peroxide (2.2 mL/kg [1 mL/lb] to a maximum of 45 mL/dog, repeated once after 10–15 min if vomiting does not occur) or administration of apomorphine hydrochloride (0.03 mg/kg [0.014 mL/lb], IV, once; or a crushed tablet dissolved in saline [0.9% NaCl] solution instilled into the conjunctival sac and rinsed away with water or saline solution after emesis) or syrup of ipecac given orally (1–2 mL/kg).

Activated charcoal without sorbitol (2 g/kg, PO, repeated every 6–8 hr) may be administered to reduce absorption of toxins if the animal is conscious. Activated charcoal may also be administered as a high-retention enema. Gastric lavage is important to prevent absorption in unconscious animals. High-cleansing colonic enemas should also be given, using polyionic warmed fluids in dehydrated animals. Clinical observation suggests that cholestyranine might provide benefit for dogs after acute cycad ingestion if given after initial enteric decontamination steps (induced vomiting, gastric lavage). If there is no specific treatment for a hepatotoxin, judicious, supportive care should be provided.

INFECTIOUS DISEASES OF THE LIVER

Viral Diseases

Viral diseases associated with liver dysfunction include infectious canine hepatitis,

canine herpesvirus, inadvertent parenteral injection of an intranasal *Bordetella bronchiseptica* vaccine in dogs, feline infectious peritonitis, and virulent systemic calicivirus infection in cats. Rarely, canine parvovirus can lead to hepatic injury as a result of portal systemic sepsis.

Infectious canine hepatitis is caused by canine adenovirus 1. In addition to acute hepatic necrosis, chronic hepatitis and hepatic fibrosis can be sequelae if neutralizing antibody is inadequate to eliminate the infection during the active phase. See p 798 for clinical findings, diagnosis, treatment, and control.

Canine herpesvirus affects neonatal puppies, causing hepatic necrosis as well as other systemic changes. It is usually fatal in puppies.

Accidental parenteral injection of intranasal *B. bronchiseptica* vaccine in dogs can cause both a local inflammatory reaction at the injection site and acute, nonseptic hepatocellular degeneration and necrosis that evolves into chronic hepatitis. There is no known treatment other than symptomatic therapy for chronic inflammatory liver disease.

Feline infectious peritonitis virus is a coronavirus that causes diffuse pyogranulomatous inflammation and vasculitis. Icterus, abdominal effusion, vomiting, diarrhea, and fever are common clinical signs. See p 780 for clinical findings, diagnosis, treatment, and control.

Virulent systemic calicivirus, a recently emerged variant of feline calicivirus, can have mortality rates of 33%–60% in adult cats. Primarily identified in shelter or cattery populations, this virus causes profound fever, anorexia, marked subcutaneous edema (limbs and face especially), jaundice, alopecia, and crusting and ulceration of the nose, lips, ears, and feet. Adult cats are most severely affected. Individual hepatocyte necrosis ranging to centrilobular or more extensive necrosis is associated with neutrophilic inflammatory foci and intrasinusoidal fibrin deposits.

Bacterial Diseases

Leptospirosis: Infections with *Leptospira interrogans* serovars Icterohemorrhagiae and Pomona and chronic infections with Grippotyphosa have been associated with liver disease in dogs. Other serotypes may also involve the liver. No specific histologic lesions are pathognomonic. Markedly increased liver enzyme activity and hyperbilirubinemia indicate hepatic involvement. However, these parameters

may reflect hepatic response to a sepsis syndrome rather than specific organ invasion in acutely ill dogs. Clinical and clinicopathologic features of liver involvement may worsen initially with treatment (fever, liver enzymes, hyperbilirubinemia), a Jarisch-Herxheimer reaction. Diagnosis depends on demonstrating a rise in convalescent titer or PCR detection of leptospiral DNA in blood or urine. Identification of organisms in stained liver specimens is difficult. Treatment includes supportive care and specific antimicrobial therapy. Penicillins are used initially for the acute phase, (eg, ampicillin [22 mg/kg, IV, qid] or amoxicillin [22 mg/kg, PO, bid]). Aminoglycosides (dose depends on drug used; streptomycin was historically used to clear leptospirosis) or doxycycline (5 mg/kg, PO, bid for 4 wk) are recommended to treat the carrier phase. Aminoglycosides are currently not recommended for treatment of leptospirosis owing to the high risk of causing nephrotoxicity. Special precautions are recommended when handling animals suspected of having leptospirosis (and their urine specimens) because of the zoonotic potential. (See also LEPTOSPIROSIS, p 646.)

Tyzzar Disease: Tyzzar disease (see p 199) is a rare but fatal condition caused by *Clostridium piliforme*. Infections in dogs or cats most commonly occur in immunocompromised hosts, either neonatal animals or adults affected with other conditions. Because *C piliforme* is a commensal organism in the intestines of laboratory rodents, infection is acquired by contact with or ingestion of rodent feces transporting bacterial spores. Clinical signs (lethargy, anorexia, abdominal discomfort) are acute in onset, and illness rapidly progresses to death within 24–48 hr. Marked increase in ALT activity immediately precedes death. Special stains are needed to identify organisms in liver tissue because organisms do not grow in routine bacterial culture media. Although there is no effective treatment, a vaccine has been developed for research colony animals.

Mycobacterium avium Infection:

Hepatic infection with disseminated *M avium* has been described in young Abyssinian and Somali cats that had an apparent innate immunodeficiency (unknown cause). The clinical course included vague illness characterized by a several month history of weight loss in the face of polyphagia. Marked diffuse interstitial pulmonary infiltrates developed

in cats with and without respiratory signs. Hepatomegaly and increased ALT and AST activities were notable. Liver samples revealed granulomatous inflammation. Treatment with clarithromycin (62.4 mg/cat, PO) combined with either clofazimine (25 mg/cat/day, PO, or 50 mg/cat, PO, every other day) or rifampicin (5–10 mg/kg, bid, PO) and a fluoroquinolone or doxycycline (5–10 mg/kg, bid, PO) achieved remission in affected cats. Relapse should be expected because of the immunocompromised status of these cats.

Systemic infections, including granulomatous hepatitis due to *Mycobacterium* spp has been reported by several investigators in Basset Hounds, Miniature Schnauzers, and additional dogs. Affected dogs are suspected to have some form of cell-mediated immunodeficiency (Basset Hounds) or unique exposure to another infected animal or person. Susceptibility to various *Mycobacterium* spp vary among mammals. *M tuberculosis* can induce progressive disease in people, nonhuman primates, dogs, and swine. Clinical signs in animals infected with *M tuberculosis* depend on the route of exposure and degree of localization of the infection or its systemic dissemination. Early infection is subclinical, leading to cachexia, weakness, anorexia, dyspnea, and a low-grade, fluctuating fever. Hepatic involvement caused increased transaminase activity, reflecting pyogranulomatous hepatitis. Many animals infected with *Mycobacterium* spp are euthanized because of the severity of organ involvement at the time of diagnosis and because of zoonotic concerns. Diagnosis of *M tuberculosis* in an animal should be reported to local health officials. At least 6–9 mo of treatment using a multidrug regimen is advised; single-agent treatment is not advised owing to concern for emergence of resistant strains. Treatment recommendations include combined administration of isoniazid, ethambutol, and rifampin, with pyrazinamide sometimes substituted for ethambutol. However, experience in longterm treatment of dogs is lacking.

Diagnosis of *Mycobacterium* can be difficult because many of these organisms are slow growing (requires >1 mo), acid-fast organisms may not be found in tissue sections, and PCR from formalin-fixed tissue may be falsely negative. However, *Mycobacterium* sp have also been detected by both histologic staining and by PCR from formalin-fixed liver specimens from dogs with pyogranulomatous hepatitis.

Extrahepatic and Intrahepatic Bacterial Infections and Sepsis:

Extrahepatic infection and sepsis can cause cholestasis and hyperbilirubinemia. Increases in serum bilirubin may range from moderate to marked, while increases in liver enzyme activity remain modest. This type of jaundice has been seen in dogs with leptospirosis and in dogs and cats with ill-defined sepsis syndromes. Appropriate treatment targets the underlying organism causing infection. Increased liver enzyme activity in septicemia/sepsis also can reflect bacterial invasion of the liver or hepatocellular damage by associated cytokine release or hypoxia.

Animals with acute hepatic failure, chronic hepatobiliary disease, and cholestatic disorders are predisposed to systemic bacterial infection and endotoxemia due to diminished function of hepatic reticuloendothelial cells (hepatic Kupffer cells comprise the largest fixed macrophage population in the body) and reduced biliary elimination of bacteria derived from the enterohepatic circulation in bile. In acute fulminant hepatic failure, sepsis or septicemia may be masked by fever, hypoglycemia, and leukocytosis that might also represent clinical manifestations of hepatic injury.

Animals with chronic disorders causing stasis of bile flow or with chronic hepatic neoplasia are more likely to develop intrahepatic infections. Risk factors associated with biliary tract infection include advanced age, recent episodes of cholangitis, acute cholecystitis, cholelithiasis, and obstructive jaundice.

Treatments that reduce susceptibility to infection and liver injury during fulminant hepatic failure and extrahepatic bile duct occlusion include administration of N-acetylcysteine, α -tocopherol, glutamine, oral bile acids, and enteric and systemic antibiotics. These strategies increase microvascular perfusion, reduce enteric bacterial translocation, augment innate immunity, and protect against oxidant injury. While awaiting results of culture and sensitivity (tissue, abdominal effusion, bile), antibiotics against enteric opportunists should be administered empirically, avoiding drugs extensively metabolized in the liver. Combination of a β -lactamase-resistant penicillin, metronidazole (7.5 mg/kg, PO, bid), and enrofloxacin (2.5–5 mg/kg, PO, IM, or IV, bid), may be beneficial during initial treatment when the underlying infectious cause remains unclear.

Mycotic Diseases

The most common mycotic infections associated with liver dysfunction are coccidioidomycosis (see p 637) and histoplasmosis (see p 639). In severely affected animals, clinical signs include ascites, jaundice, and hepatomegaly, in addition to signs associated with other involved organ systems. Antifungal treatment is variable, determined by the severity of infection, organ involvement, and individual clinical response. Because liver involvement in histoplasmosis is seen with disseminated disease, aggressive chemotherapy (including combinations of either itraconazole or ketoconazole and amphotericin B) are recommended. Debilitated animals have a poor prognosis. Coccidioidomycosis can be treated successfully with several antifungal medications (itraconazole and fluconazole are preferred to ketoconazole). Chronic treatment (6–12 mo) is required, and relapses may occur. Treatment efficacy is determined based on resolution of clinical signs and radiographic lesions and reduction in serologic titers. Termination of treatment should not be based on serologic titers alone, because these stabilize and persist in many dogs after clinical recovery. Owners must be informed that discontinuing medication may result in relapse. Animals recovering from CNS infection should receive lifelong treatment. Similarly, animals with disseminated disease suffering infection relapse after treatment discontinuation should continue on longterm or lifetime treatment with an azole antifungal. For chronic treatment, drug doses that effectively maintain remission may be lower than those needed to induce remission.

Protozoal Diseases

Toxoplasmosis: Toxoplasmosis (see p 685) can cause acute hepatic failure associated with hepatic necrosis. *Toxoplasma gondii* is more commonly seen in cats positive for feline immunodeficiency virus and feline leukemia virus. Icterus, abdominal effusion, fever, lethargy, vomiting, and diarrhea are seen in addition to clinical signs consistent with CNS, ocular, or pulmonary involvement. Liver disease in dogs is rare but when seen is either in an immunocompromised host or in young dogs and also involves systemic infection. Young dogs may be concurrently infected with canine distemper virus; in these, illness is acute in onset and rapidly fatal. Diagnosis of toxoplasmosis can be difficult; while a

positive IgM titer indicates active clinical disease, IgG titers may be found in chronic infections and in animals lacking clinical disease. Clindamycin (12.5 mg/kg, PO or IM, bid for 4 wk) is the drug of choice. Because clindamycin is metabolized in the liver, dosage reduction may be necessary in severe hepatic insufficiency. Oral clindamycin should be followed by a bolus of water or food to prevent esophageal irritation. In some cases, initial treatment is combined with anti-inflammatory glucocorticoids to protect against tissue injury caused by inflammatory responses initiated by protozoal death. Prognosis depends on the degree of debilitation and stage of disease at initial diagnosis and the associated disorder causing immunosuppression. Despite improvement with treatment, animals should be considered chronically infected and thus must undergo surveillance for recrudescent disease.

Leishmaniosis: Canine leishmaniosis (see p 589) is a multisystemic disease caused by protozoan parasites of the genus *Leishmania*, most commonly encountered in animals that have lived in Mediterranean countries, Portugal, the Middle East, and some parts of Africa, India, and Central and South America. It also is occasionally encountered in dogs in the USA (especially Foxhounds). A serosurvey of >12,000 dogs (Foxhounds, other breeds, wild canids) and 185 people in 35 states and 4 Canadian provinces was done to assess geographic distribution prevalence, host range, and modes of transmission within North America and to assess possible infection in people. Findings identified *Leishmania* spp.-infected Foxhounds in 18 states and 2 Canadian provinces but no evidence of human infection. North America leishmaniosis appears widespread in Foxhounds and is limited to dog-to-dog transmission. However, if the organism becomes adapted for vector transmission by indigenous phlebotomines, the probability of human exposure may greatly increase.

Clinical features in dogs with naturally occurring leishmaniosis include nonregenerative anemia, increased enzyme (ALP, ALT, and AST) activity, hypoalbuminemia, and variable bilirubinemia. Histologic response is characterized by a multifocal pyogranulomatous hepatitis associated with hepatocyte vacuolar degeneration with phagocytized organisms seen within macrophages. Severity of liver lesions represents sequential stages of hepatic infection in chronic visceral leishmaniosis.

However, no correlation has been shown between histologic features and breed, sex, age, clinical features, or hepatic parasite load.

Treatment is rarely curative, and prognosis for debilitated animals is poor. Owing to the zoonotic potential of the organism, owners must be informed that their pet will never be completely free of the disease and that relapses may require repeated treatment. This is particularly important if an owner is immunocompromised. In the absence of renal insufficiency, a high-protein diet is recommended. The most common specific treatment recommended in the USA is allopurinol (7–20 mg/kg, PO, once to three times daily) given for 3–24 mo or indefinitely lifelong; other first-line treatments include meglumine antimony (100 mg/kg/day, IV or SC), sodium stibogluconate (30–50 mg/kg/day, IV or SC), or liposomal amphotericin B (0.25–0.5 mg/kg, IV, every other day until a total dose of 5–10 mg/kg is achieved). Numerous other second-line drugs have also helped control infections.

FELINE HEPATIC LIPIDOSIS

Hepatic lipidosis (HL), the most common acquired and potentially lethal feline liver disease, is a multifactorial syndrome. In most cases, a primary disease process causing anorexia sets the stage for HL in overconditioned cats. Peripheral fat mobilization exceeding the hepatic capacity to either redistribute or use fat for β -oxidation (producing energy) leads to profound hepatocyte cytosolic expansion with triglyceride (fat) stores. In fewer cases, inappetence is caused by environmental stresses (eg, forced weight loss with unacceptable food substitutions, moving to a new household, newly introduced or loss of pets or family members, boarding, accidental confinement [eg, locked in a garage, basement, or attic], or an inside-only cat being lost outside). The term “idiopathic HL” is appropriate only when an underlying disease condition or event leading to inappetence cannot be identified.

HL has no necroinflammatory component, and the severe cholestasis is caused by canalicular compression secondary to hepatocyte triglyceride vacuolar distention. The syndrome is associated with a number of metabolic deficits, including low hepatic and RBC glutathione, low plasma taurine, low vitamin K₁ causing coagulopathies in some cats, thiamine and/or cobalamin deficiency and likely other B vitamin depletions, and electrolyte aberrations

(especially low potassium and low phosphorus).

Clinical signs vary but usually include dramatic weight loss (>25%, may include dehydration deficits), lethargy, vomiting, ptyalism, pallor, neck ventroflexion, hepatomegaly, jaundice, gastroparesis and intestinal ileus (due to electrolyte aberrations), and retention of omental and falciform fat despite diminished peripheral fat stores. Diarrhea is common in HL cats with inflammatory bowel disease or enteric lymphoma as primary disease processes. Classic signs of HE are not seen, and ammonium biurate crystalluria is unusual, although bleeding tendencies may develop. Vitamin K₁ deficiency has been confirmed in numerous HL cats by observation that bleeding tendencies and coagulation test abnormalities resolve with vitamin K₁ therapy.

Laboratory results reflect the HL syndrome as well as the primary underlying disease. A nonregenerative anemia, poikilocytosis, increased RBC Heinz bodies, variable WBC count, hyperbilirubinemia and bilirubinuria, mild to marked increases in ALT and AST, and marked increases in ALP are common. In cats with a primary necroinflammatory process involving the pancreas, liver, bile ducts, or gallbladder, GGT activity will be increased, usually exceeding the fold increase in ALP. In all other conditions causing HL, GGT activity is normal or only modestly increased. The GGT:ALP relationship is useful in discerning underlying cholangitis/cholangiohepatitis and other diseases involving biliary structures (including pancreatitis). Finding a high GGT also predicts whether a liver or pancreatic biopsy is indicated. Depending on underlying disorders, hypoalbuminemia and hyperglobulinemia may be found. Prolonged PT or APTT may develop; the PIVKA clotting time is more sensitive for detection of vitamin K₁ sufficiency. In the earliest stages of the HL syndrome, TSBAs are abnormal before onset of jaundice (this circumstance is rarely encountered). Peritoneal effusion is rare but when found represents the primary disease process or iatrogenic fluid overload.

Ultrasonographic evaluation reveals homogeneous hyperechoic hepatic parenchyma and subjective hepatomegaly. Hyperechogenicity is determined by comparing hepatic parenchyma to falciform fat and the spleen (liver is normally hypoechoic vs spleen). Kidneys also may appear hyperechoic because of increased renal tubular fatty vacuolation. Ultrasonographic examination should carefully assess

the entire abdomen for evidence of an underlying disease process and include evaluation of the biliary tree, gallbladder, pancreas, intestinal wall thickness, hepatic and mesenteric lymph nodes, kidneys, and urinary bladder, and scrutiny for uroliths in the kidneys, ureters, or bladder.

Definitive diagnosis is based on the history, physical examination findings, laboratory features, ultrasonographic appearance of the liver, and ultrasound-guided hepatic aspiration cytology. Liver biopsy is not necessary to diagnose HL; however, underlying cholangitis/cholangiohepatitis or hepatic lymphoma may eventually require biopsy for definitive diagnosis. Cytology preparations show profound vacuolar distention of hepatocytes involving >80% of hepatocytes aspirated. Canalicular cholestasis is commonly seen. Mistaken aspiration of omental fat rather than liver is easily deduced by the absence of hepatocytes.

Treatment of HL is aimed at correcting fluid, electrolyte, and metabolic deficits and initiating food intake. Because cats with HL may have high lactate concentrations and may not be able to metabolize acetate, 0.9% NaCl is the fluid of choice. Fluids should not be supplemented with dextrose, because this will reduce utilization of intrahepatic fatty acids for β -oxidation. Because affected cats are usually overconditioned, fluid therapy must be based on ideal body weight. ● Overhydration is common when fluid dosage is based on total overconditioned body weight and can lead to pleural and abdominal effusion and pulmonary edema.

Fluids should be appropriately supplemented with potassium (using the sliding scale) based on electrolyte status. If initial serum phosphate concentration is low (<2 mg/dL), potassium phosphate should be added at a rate of 0.01–0.03 mmol/kg/hr. Potassium chloride supplementation must be judiciously adjusted, considering concurrent potassium phosphate supplements to avoid iatrogenic hyperkalemia. Potassium phosphate supplements (up to 0.06 mmol/kg/hr) are commonly initiated when feeding is started to guard against development of severe hypophosphatemia associated with the “refeeding syndrome.”

A fortified water-soluble vitamin solution (2 mL/L of fluids, see TABLE 12, p 442) should be added to the IV fluids. Thiamine supplements (50–100 mg/day) are specifically indicated in HL and provided in water-soluble fluid supplements or by the oral route. Rare anaphylactoid reactions and neuromuscular paralysis have been seen in a few cats treated with thiamine by SC or IM injection.

A diagnostic blood sample should be collected for B₁₂ determination followed by empirical B₁₂ administration (250–1,000 mcg/cat, SC). Cobalamin deficiency is seemingly common in HL cats and may predispose individuals to this syndrome. When present, B₁₂ deficiency confounds intermediary metabolism; however, this is confirmed only by assessment of methylmalonic acid, which confirms functional B₁₂ insufficiency. Unfortunately, this assessment cannot be promptly completed. Consequently, B₁₂ supplementation (which has no adverse effects) is routinely supplemented with the less exacting measurement of plasma B₁₂ used to determine propriety of long-term supplementation. Treatment with N-acetylcysteine is initiated during the first 2–3 days (140 mg/kg, IV, administered through a 0.25-µm filter over 20 min, then 70 mg/kg, IV, tid-qid; diluted to a 10% solution). N-acetylcysteine should not be given as a prolonged (>1 hr) constant-rate infusion, because it may induce hyperanionemia by deviating substrates from the urea cycle.

Vitamin K₁ is given with a small needle (0.5–1.5 mg/kg, SC or IM, three doses given at 12-hr intervals) before procedures that might provoke bleeding (eg, insertion of a jugular catheter, esophageal feeding tube, cystocentesis, or hepatic aspiration sampling).

Some cats may develop renal potassium wasting as a result of underlying renal disease or lipid accumulation in their renal tubules. The fractional excretion of potassium can be estimated by measuring potassium and creatinine in simultaneously collected baseline serum and urine samples: fractional potassium excretion = $[\text{urine potassium/urine creatinine}] \times [\text{serum creatinine/serum potassium}] \times 100\%$. In a hypokalemic cat, a value <1% is expected. Values >20% represent marked renal potassium wasting and indicate the need for aggressive potassium supplementation. Cats with prodigious potassium needs should have potassium gluconate added to their food as soon as oral intake is established. This will reduce the concentrations of potassium needed in the IV fluids and associated risk of iatrogenic hyperkalemia.

Nutritional support is the cornerstone of recovery (see p 439). Feeding is initiated after the cat is rehydrated and has reasonable electrolyte balance, because these are requisite factors enabling normal enteric motility. Because cats with HL are in metabolic liver failure, appetite stimulants are inappropriate; diazepam, oxazepam, cyproheptidine, and mirtazapine should not be used and will not recover an affected cat.

Occasionally, an appetite stimulant may help initiate feeding early in syndrome development.

A palatable odiferous food should be offered initially. If the cat salivates or objects, all food should be removed because of the risk of inducing a “food aversion syndrome.” If oral feeding is not tolerated, feeding a liquid diet (eg, CliniCare®) with supplements via a nasoesophageal tube is cautiously initiated as a first step. A 5–10 mL volume of tepid water is administered first to assess the cat’s tolerance and response. If no vomiting or signs of discomfort are noted, the process is repeated with liquefied food. After a few days of nasoesophageal feeding, if the cat is judged to be a reasonable anesthetic risk, an esophagostomy tube (E-tube) is placed with the distal tip 2–4 cm cranial to the esophageal-gastric junction. This should be documented with a lateral thoracic radiograph.

A high-protein, calorie-dense, balanced feline diet is recommended for E-tube feeding. Only rarely should a protein-restricted diet be used, because protein restriction can aggravate hepatic lipid accumulation. Rather, use of lactulose and oral amoxicillin or low-dose metronidazole (7.5 mg/kg, bid) can optimize nitrogen tolerance to allow feeding of a normal feline diet (these measures modify enteric flora, substrate utilization, and increase colonic catharsis or cleansing). A number of metabolic supplements have improved recovery of affected cats: taurine (250–500 mg/cat/day), medical grade liquid oral L-carnitine (250–500 mg/cat/day), vitamin E (10 IU/kg/day), and potassium gluconate (if hypokalemia is persistent).

Initial feedings are small and given frequently or by constant-rate infusion. On the first day, one-third to one-half of the cat’s energy requirements are fed; the amount fed is then gradually increased over the next 2–4 days to the ideal intake. If vomiting occurs, electrolytes must be rechecked, feeding tube position verified, and factors relevant to the underlying disease process considered. Metoclopramide (0.05–0.1 mg/kg, IM, up to tid, or 0.25–0.5 mg/kg divided per day as a constant-rate infusion), ondansetron (0.025 mg/kg, IV, up to bid), or maropitant (1 mg/kg/day, no more than 5 days) may be used as antiemetics. Enteric motility may be stimulated by exercise during owner visits.

To avert development of hypophosphatemia induced by re-feeding, which can cause weakness, hemolysis, encephalopathy, and other adverse effects, serum phosphorus concentrations should be

serially monitored and supplemental potassium phosphate judiciously provided. Routine IV potassium phosphate supplementation is administered when feeding is initiated to obviate persistent or feeding-induced hypophosphatemia. If gastritis is suspected, an H_2 -blocker (eg, famotidine or ranitidine) may be used, and carafate administered PO (but not via E-tube). If the cat tolerates oral medications, SAME at 40 mg/kg/day is given between meals once N-acetylcysteine treatment is completed. SAME supplementation must be accompanied by sufficient B_{12} , folate, and other water-soluble vitamins to ensure optimal metabolic benefit (metabolism to glutathione and methyl group donation for transmethylation reactions). Use of ursodeoxycholate in HL may be detrimental because TSBAAs are extraordinarily high in these cats and because bile acid profiles resemble those associated with EHBDO (increased secondary bile acids). All bile acids are toxic to cells in high concentrations and, in HL, bile acids are seemingly trapped by canalicular compression.

In the rare circumstance that signs of HE are encountered, lactulose, amoxicillin, or low-dose metronidazole (≤ 7.5 mg/kg, PO, bid) may be useful. In symptomatic pancreatitis, feeding distal to the pancreas is done using a constant-rate infusion of CliniCare[®] mixed with supplemental pancreatic enzymes through a jejunostomy tube. Alternatively, parenteral nutrition can be provided, although this may delay recovery and provoke hepatic triglyceride retention.

Prognosis for cats with HL is good with early diagnosis, full treatment support, and control of underlying disease. Monitoring liver enzymes has no value in predicting recovery. However, a decline in total bilirubin by 50% within the first 7–10 days portends an excellent chance of full recovery. Concurrent pancreatitis is a poor prognostic indicator. Monitoring ALP of obese cats undergoing weight reduction may identify emerging HL that will allow suspension of the weight loss program and early treatment intervention. Recurrence of HL is rare in recovered cats.

BILIARY CIRRHOSIS

Biliary cirrhosis refers to periportal bridging fibrosis associated with marked hepatic architectural remodeling and biliary hyperplasia subsequent to chronic (months) of EHBDO or years of nonsuppurative cholangiohepatitis. However, it is uncommon in cats with cholangitis/cholangiohepatitis, because these animals usually

succumb before biliary cirrhosis develops. Biliary cirrhosis is misidentified in cats with ductal plate malformations (a form of polycystic liver disease). Clinical features of biliary cirrhosis include variable inappetence, cachexia, jaundice, variable liver size, and ascites. Liver enzymes may be normal. Hypoalbuminemia, hyperglobulinemia, hyperbilirubinemia, and coagulopathies are common. The liver may be considered large on abdominal radiographs and appears nodular on ultrasonographic evaluation. Biopsies are needed for definitive diagnosis. Coagulation deficits complicate tissue sampling and necessitate vitamin K₁ supplementation and fresh frozen plasma transfusions before procedures. Treatment is symptomatic, requiring management of HE, hypoalbuminemia, EHBDO, and ascites. Prognosis is generally poor. Biliary cirrhosis is most commonly seen in animals with chronic EHBDO caused by obstructive neoplasia. Although cholecystoenterostomy or choledochenterostomy can avert progression of EHBDO to biliary cirrhosis, it introduces recurrent retrograde infection through biliary structures causing chronic or recurrent septic cholangitis.

CANINE CHOLANGIOHEPATITIS

Cholangiohepatitis in dogs is rare and usually associated with suppurative inflammation and ascending biliary tree infection with a wide variety of bacterial organisms (both gram-negative and gram-positive enteric bacteria, *Salmonella*, *Campylobacter jejuni*, coccidiosis). Canine cholangiohepatitis is most commonly associated with disorders causing stasis of bile flow, biliary mucocele formation, cholelithiasis, and surgical manipulations of the biliary tree. Clinical signs include anorexia, vomiting, diarrhea, lethargy, PU/PD, fever, and abdominal pain.

Laboratory abnormalities are consistent with hepatic cholestasis and include hyperbilirubinemia and increased activities of ALP, GGT, and transaminases. Ultrasonography may or may not reveal abnormalities involving the biliary tree or gallbladder. In some cases, a coarse hepatic echogenicity is identified, reflecting portal tract inflammatory infiltrates and connective tissue. In some cases, ultrasonographic findings may indicate need for emergency surgical intervention (eg, mature gallbladder mucocele, cholelithiasis associated with EHBDO). Aspirates or impression smears of liver or bile may reveal suppurative septic inflammation. Samples collected from liver, bile, and sections of the biliary tree should

be submitted for aerobic and anaerobic culture and sensitivity. Antibiotic treatment should be based on cultured organisms, and other treatments should target underlying disease processes. Initial treatment with combination of ticarcillin, metronidazole, and enrofloxacin is commonly used before culture and biopsy results are available. For best outcome in animals undergoing surgery, antimicrobials should be started before the surgical procedure.

CANINE CHRONIC HEPATITIS

Chronic hepatitis that does not focus on biliary structures is more common in dogs than cats. Several breeds are predisposed, including Bedlington Terriers, Labrador Retrievers, Cocker Spaniels, Doberman Pinschers, Skye Terriers, Standard Poodles, West Highland White Terriers, Springer Spaniels, Chihuahuas, and Maltese. Although there is an identifiable etiology for some categories of chronic hepatitis, in most cases the cause remains unidentified. Increased hepatocellular copper and Kupffer cell iron stores are common in dogs with chronic hepatitis. The degree of metal accumulation and its acinar location help determine its relevance to tissue injury.

Other associated conditions include infectious canine hepatitis, chronic hepatitis secondary to infectious processes, and chronic exposure to xenobiotics (including certain drugs, biologic toxins, and chemicals). Terminology that reflects specific etiology or breed predilection, such as drug-associated chronic hepatitis, infectious chronic hepatitis, copper-associated hepatitis, etc, is preferred. The term idiopathic chronic hepatitis indicates that an etiology has not been determined.

Histopathologic changes are generally similar in all cases of chronic hepatitis, regardless of the underlying cause, and include a lymphocytic/plasmacytic inflammation with infiltrates extending into hepatic parenchyma, variable single cell or piecemeal necrosis, and in advanced disease, development of bridging fibrosis and nodular regeneration. The acinar zone of involvement varies with the underlying cause.

Copper-associated Hepatopathy

Copper-associated hepatopathy is a leading cause of chronic hepatitis in dogs, increasing in prevalence since 1997 when copper supplements in commercial dog foods were modified to a more bioavailable form. Retrospective evaluation of liver

biopsies from Labrador Retrievers and Doberman Pinschers from 1980 to 2013 indicated that dogs of these breeds, with and without chronic hepatitis, had significantly higher hepatic copper concentrations in the last 10 yr of the study. Management of body copper homeostasis relies on numerous copper transporters, chaperones, and binding proteins, as well as biliary canalicular egress. Copper-associated hepatopathy is best characterized in Bedlington Terriers, which have a mutation (deletion of exon 2) of the COMMD1 copper transporter protein. Careful breeding programs guided by liver biopsy and genetic testing (PCR gene mutation test) have remarkably reduced disease frequency in Bedlington Terriers. However, some Bedlington Terriers with biopsy-confirmed copper-associated hepatopathy lack this specific gene mutation.

Failure to excrete copper into bile leads to chronic hepatitis and, eventually, cirrhosis and liver failure. Affected dogs develop high liver copper concentrations by 1 yr of age (normal: <400 mcg/g dry liver or 400 ppm), which progressively increase during the first 6 yr of life (values may be >12,000 ppm). Liver injury is reflected by increased ALT activity and has been shown in dogs with hepatic copper as low as 600 ppm.

Three disease phases were historically characterized in Bedlington Terriers. Acute hepatic necrosis occurred in dogs <6 yr old, presenting with hepatomegaly, vomiting, lethargy, anorexia, jaundice, copper-induced hemolytic anemia, and hemoglobinuria. Copper-associated hemolytic anemia occurs only with massive hepatic necrosis, which releases large amounts of copper into the systemic circulation. Death usually occurs within 48–72 hr of onset of clinical signs. In this group of dogs, untreated survivors suffered recurrent bouts of critical illness induced by stress (eg, whelping, attending dog shows, traveling). Another clinical presentation involves chronic hepatitis associated with clinical features, including chronic weight loss, HE, ascites, and jaundice. Some dogs develop an acquired Fanconi syndrome (glucosuria, aminoaciduria, metabolic acidosis, inappropriately alkaline urine pH), signaling renal tubular copper toxicity. The last clinical presentation was recognized in young, clinically healthy dogs, simply demonstrating increased ALT activity and increased hepatic copper concentrations (on liver biopsy). This presentation progresses to acute hepatic necrosis or

chronic hepatitis. Rarely, an affected dog remained asymptomatic until another disease process caused liver injury augmented by excessive hepatic copper stores.

Genetic testing is recommended for selection of Bedlington Terrier breeding stock. However, definitive diagnosis of copper-associated hepatopathy requires liver biopsy in adult dogs with qualitative copper stains reconciled with quantitative copper measurements.

Many other purebred and mixed-breed dogs of all ages also may develop copper-associated hepatopathy. More commonly and perhaps more severely affected are Labrador Retrievers; whether the high breed popularity influences this observation remains unclear. Doberman Pinschers, West Highland White Terriers, and some dogs related to Dalmatians also may develop profoundly increased hepatic copper concentrations accompanied by severe liver injury. A genetic cause has not been identified in any of these breeds. It is important to emphasize that copper-associated hepatopathy can be the primary cause of hepatitis in any dog (purebred or mixed breed) and can be definitively diagnosed only by liver biopsy. There is no recognized gender predisposition.

Histologic features of copper-associated hepatopathy include a focus on the centrilobular region (zone 3), finding eosinophilic granules within the cytosolic compartment of hepatocytes and within macrophages in areas of single cell necrosis. Small granulomas develop subsequent to hepatocyte necrosis and release of copper granules into the surrounding parenchyma. Zone 3 lesional-associated parenchymal collapse is verified with reticulin staining (centrilobular collapse) and fibrillar collagen deposition with Masson trichrome staining (centrilobular connective tissue deposition). With advanced injury, regenerative nodules and regions of parenchymal extinction are seen. The prominent role of copper in driving tissue injury is verified by finding copper granules (rhodanine staining) in nearly every hepatocyte within regenerative nodules.

Treatment of copper-associated hepatopathy requires copper chelation with concurrent restriction of copper intake from dietary and water sources. Dietary copper restriction can be achieved by feeding a prescription diet formulated for dogs with HE (delivering 2.2–2.5 g of protein/kg body wt). These low-protein formulas can be supplemented with protein

sources low in copper to raise the dietary protein intake to 3.5 g of protein/kg body wt. Supplementary protein sources are selected using the USDA food tables (sort based on copper concentration), with feeding amounts of selected foods calculated using the Nutritional Analysis Tool 2.0 (human nutrition). Copper in water should contain <0.1 ppm (0.1 mcg copper/L); if copper pipes transport water, flushing the system for 5 min will eliminate any leached copper.

Administration of antioxidants is important, because copper induces liver damage through oxidative injury. Chelation therapy with *D*-penicillamine (15 mg/kg, PO, bid, given 30 min before feeding, for 24–6 mo) is the gold standard treatment. Thereafter, chronic therapy may be instituted by reducing the *D*-penicillamine dosage by half and administering the drug every other day while maintaining dietary copper restriction. Alternatively, the dog may be treated with zinc acetate (see below). Concurrent administration of pyridoxine (25 mg/day) is advised during *D*-penicillamine treatment, because this drug has antipyridoxine (vitamin B₆) effects. If *D*-penicillamine chelation is not tolerated, trientine hydrochloride can be used (5–7 mg/kg, PO, bid, given 30 min before feeding). Caution is warranted with trientine used at the originally higher recommended dose, because this has induced acute renal failure in dogs with severe copper storage hepatopathy.

An alternative approach to manage copper storage hepatopathy is daily administration of oral zinc (acetate, gluconate, sulfate) to inhibit copper uptake from the GI tract (zinc induces enterocyte metallothionein, which irreversibly binds copper and prohibits its absorption; copper is subsequently eliminated with effete enterocytes in feces). Although zinc treatment theoretically increases dietary options, study of the efficacy of zinc treatment in people with Wilson disease confirms unreliable control of dietary copper uptake. Zinc therapy must not be given concurrent with chelation therapy, because this will thwart efficacy of each treatment. Oral zinc is not well tolerated by some dogs, commonly causing vomiting, nausea, and inappetence. If zinc therapy seems more suitable for chronic treatment in a specific dog, a loading phase of elemental zinc at 5–10 mg/kg/day is given in two divided doses, 30 min before meals. Plasma zinc concentrations are monitored to ensure that circulating zinc is not nearing toxic values (>800 ppm). After several

months, the dosage can be reduced to 2–3 mg/kg/day divided bid, but without study of radiolabelled copper uptake the efficacy of treatment in an individual dog remains unknown.

Vitamin E (10 IU/kg/day, PO) and biologically available SAMe (20 mg/kg/day, PO, on an empty stomach) are recommended antioxidants that also have anti-inflammatory and potentially anti-fibrotic effects. Vitamin C is contraindicated in copper storage hepatopathy, because it may foster injurious transition metal effects.

After chelation therapy, it is essential to continue to limit copper ingestion in food and water lifelong. Adherence to a copper-restricted diet and water source may obviate the need for continual chelation or zinc therapy.

Chronic Hepatitis with or without Increased Hepatic Copper in West Highland White Terriers:

Although West Highland White Terriers have been shown to accumulate excessive hepatic copper, not all dogs with high hepatic copper concentrations develop hepatitis. Some dogs with severely increased hepatic copper concentrations die of old age without necroinflammatory liver lesions. Although West Highland White Terriers with chronic hepatitis usually do have high tissue copper concentrations, they differ from Bedlington Terriers with copper storage hepatopathy in that: 1) the mode of inheritance has not been determined, 2) maximal copper accumulation occurs by 6 mo of age and may then decline, 3) overall hepatic copper concentrations are lower than in Bedlington Terriers, and 4) hemolytic anemia has not been reported.

Focal hepatitis may be seen in asymptomatic young adult dogs. Chronic hepatitis is associated with anorexia, nausea, vomiting, diarrhea, jaundice, and later ascites. Increased liver enzymes develop first with focal disease, followed by increased TSBA concentrations and then hyperbilirubinemia as the severity of liver injury advances. Histopathologic changes include multifocal necroinflammatory hepatitis with typical copper-affiliated granulomas and single cell necrosis, with advanced disease culminating in cirrhosis. Treatments target copper primarily if an association between inflammation and copper accumulation is histologically verified. (For treatment recommendations, *see* COPPER-ASSOCIATED HEPATITIS, p 460, and CANINE CHRONIC HEPATITIS, p 460.)

Idiopathic Chronic Hepatitis

Idiopathic chronic hepatitis is defined as chronic necroinflammatory self-perpetuating liver disease associated with a nonsuppurative inflammatory infiltrate. To qualify as an idiopathic syndrome, an underlying cause should have been rigorously pursued yet not discovered. Autoimmune hepatitis is included in this classification. An antinuclear antibody test, testing for endemic infectious diseases (titer or antigen tests), and investigation of drug and toxin exposure, along with dietary, environmental, and family history, must be undertaken. Middle-aged to older adult dogs are more commonly affected; there are no breed or gender predilections.

Clinical features include variable anorexia or hyporexia, lethargy, weakness, vomiting, diarrhea, weight loss, jaundice, PU/PD, and in severe or advanced disease, coagulopathies, ascites, and HE. Earliest laboratory findings are persistent or cyclic increases in activity of ALT, AST, ALP, and GGT. With advancing disease, increased TSBA concentrations are followed by hyperbilirubinemia. Other findings may include a nonregenerative anemia, leukocytosis, and hyperglobulinemia. In late-stage disease, portal hypertension causes development of APSSs and the associated laboratory markers of RBC microcytosis, hypocholesterolemia, hypoalbuminemia, prolonged APTT and/or PT, and ammonium biurate crystalluria. At this stage, overt signs of HE may manifest. In early disease, liver size is normal and there may be no demonstrable ultrasonographic lesions. In late-stage disease, radiographs may demonstrate a small liver with nodular lesions detected on ultrasound examination. Ultrasonographic evaluations also may disclose ascites and APSSs in dogs with advanced liver injury.

Definitive diagnosis requires liver biopsy to detail acinar distribution of liver injury, the type of inflammatory infiltrates, the presence of lobular remodeling and fibrosis, and accumulation of copper and/or iron. Chronic, sustained, unexplained increases in liver enzymes usually indicate liver biopsy. Biopsy specimens should be submitted for both aerobic and anaerobic bacterial cultures and quantification of copper, iron, and zinc. Copper stains must be reconciled with quantitative copper measurements to avoid erroneous interpretations. Liver biopsies must be large enough to detail at least 15 contiguous portal triads, and biopsies must be taken from several different liver lobes. Samples

collected only from apparent "mass lesions" can lead to erroneous diagnoses. Application of special stains will disclose the acinar location of liver injury (reticulin staining); presence of collagen deposition of fibrosis (Masson's trichrome staining); extent of iron accumulation in macrophages, Kupffer cells, and hepatocytes (Prussian blue staining); and the extent and location of hepatocellular copper accumulation (rhodanine staining).

Supportive care (nutritional, vitamin supplementation) and use of specific therapies to slow inflammation and fibroplasia and to restore liver antioxidant status are recommended. Antibiotics are initially prescribed empirically until results of the biopsy and tissue cultures become available, and then adjusted or discontinued based on culture results. Additional treatments include ursodeoxycholic acid as a hepatoprotectant and anti-inflammatory choleretic (15–20 mg/kg, PO, divided bid, given with food), polyunsaturated phosphatidylcholine as an antifibrotic (PhosChol® [the specific source used containing 52% of the active antifibrotic component dilinoleoylphosphatidylcholine] 25–50 mg/kg/day, given PO with food), vitamin E as an antifibrotic and antioxidant (10 IU/kg/day, given with food), and bioavailable SAME as an antioxidant (20–40 mg/kg/day, PO, on an empty stomach).

Immunosuppressive drugs are used only after careful consideration and exclusion of infectious or toxic causes and when an active disease process (nonsuppurative or pyogranulomatous inflammation) is characterized on liver biopsy. Prednisolone or prednisone is usually started at a dosage of 2–4 mg/kg/day, for 7–10 days and titrated downward to a maintenance level of 0.5–1 mg/kg, given every 24 hr or on alternate days, depending on patient response. In the presence of ascites or APSSs, dexamethasone is used instead of prednisone or prednisolone, because it is a synthetic glucocorticoid lacking mineralocorticoid effects. The dose is adjusted considering its longer biologic half-life (72–96 hrs) and higher potency (7–10 fold more than prednisolone or prednisone) such that dexamethasone is used at 0.1–0.2 mg/kg, PO, given every 3 days after a daily loading dose for 3 days. An immunomodulatory agent additional to the glucocorticoid is used to enable titration of the glucocorticoid dosage to the lowest effective dose. This reduces the dose of each immunosuppressive drug, reducing their adverse effects and achieving a multimodal immunosuppressive effect. Adverse effects of glucocorticoids in

chronic hepatobiliary disease include sodium and water retention (which can exacerbate or promote ascites), catabolic effects (which can promote HE), GI ulceration and enteric bleeding (which can precipitate HE), pancreatitis, predisposition to secondary infections, glucose intolerance, and iatrogenic hyperadrenocorticism (glycogen-like VH).

Azathioprine is most commonly used at a dosage of 1–2 mg/kg/day for 3–5 days, then every other day. Beneficial effects may not be seen for up to 8 wk. Because azathioprine can cause bone marrow suppression and gastroenteric, pancreatic, and rarely liver toxicity, frequent follow-up assessments are imperative. If azathioprine causes acute bone marrow suppression (within 1 mo), treatment is discontinued until recovery, then restarted with a 25%–50% reduction in dosage. If bone marrow toxicity is identified only after chronic administration (months), azathioprine should be permanently discontinued. Pancreatitis and idiopathic hepatotoxicity are rare adverse effects that also mandate drug discontinuation. Mycophenolate mofetil is used in dogs that cannot tolerate azathioprine or, alternatively, as an initial immunosuppressant. Recommended dosing is 10–20 mg/kg, PO, bid for 7–10 days, then every 24 hr, followed by dosage titration based on patient response. Cyclosporin is another alternative immunosuppressant used in combination therapy. Some dogs previously managed well on azathioprine have lost remission on conversion to cyclosporin. Other dogs started on cyclosporin as their primary immunosuppressant have responded well. In the absence of placebo-controlled clinical trials for treatment of canine immune-mediated hepatitis, treatment is individualized to each dog based on sequential monitoring and, sometimes, follow-up liver biopsy. Discontinuation of immunosuppressive therapy is not recommended in dogs with chronic hepatitis; if drugs are discontinued, they should be withdrawn gradually, with close monitoring (serum biochemical profiles).

Because complete remission is difficult to evaluate clinically, a follow-up biopsy may be required. In most cases, serum ALT activity serves as a surrogate marker of disease activity. Prognosis is widely variable. Some dogs live ≥5 yr after initial diagnosis. Dogs with ascites require dietary sodium restriction and treatment with furosemide and spironolactone (see p 445). Dogs with HE require dietary protein modification and may benefit

from lactulose and administration of low-dose metronidazole.

If immune-mediated hepatitis is considered the definitive diagnosis, careful consideration should be given before administration of routine vaccinations. Nonspecific immune stimulation may adversely stimulate hepatitis and cause disease flare.

Breed-specific Chronic Hepatitis

Labrador Retrievers: This popular breed is predisposed to chronic hepatitis that is commonly associated with pathological accumulation of hepatocellular copper (*see* COPPER-ASSOCIATED HEPATITIS, p 460). However, this breed also can develop a primary lymphoplasmacytic hepatitis that appears to involve immune-mediated mechanisms. Clinical features at diagnosis (in order of highest frequency) include jaundice, inappetence, vomiting, lethargy, and weight loss, with some dogs demonstrating abdominal discomfort, PU/PD, or no signs relevant to hepatitis. Common laboratory features include a normal PCV, leukocytosis, increased ALT (10-fold), increased ALP (5-fold), modest or no increases in AST and GGT, hyperbilirubinemia, prolonged APTT, and transient glucosuria if severe copper-associated hepatopathy is a concurrent problem. Ultrasonographic imaging often demonstrates hypoechoic and hyperechoic parenchymal nodules, subjective microhepatica, and less frequently, irregular liver margins and ascites. A lymphocytic-plasmacytic hepatitis with single cell necrosis and remodeling may focus on the portal tract or be diffusely disseminated. If pathologic copper accumulation is a leading cause of the liver injury, inflammatory responses are focused in the centrilobular region. When both disorders coexist, marked lymphoplasmacytic infiltrates are seen within sinusoids of all acinar zones. Copper-associated hepatopathy is not typically associated with a marked lymphoplasmacytic infiltrate. In dogs with coexistent lesions, it remains unclear whether sensitization to epitopes on hepatocytes damaged from copper toxicity is the primary underlying etiopathogenesis of the immune-mediated response.

Treatment decisions are based on liver biopsy findings with routine and special liver stains and tissue copper quantification. Copper chelation and restricted copper intake (food and water) establishes complete remission in dogs with overt copper overload (>800 mcg/g dry weight tissue but lacking a nonsuppurative

inflammatory reaction). Response to treatment is rapid and dramatic if diagnosed early but lifelong management of copper-associated hepatopathy (*see* p 460) is required. Labrador Retrievers with chronic nonsuppurative immune-mediated hepatitis not associated with hepatic copper retention are treated lifelong as for idiopathic chronic hepatitis (*see* above). Response to treatment can be dramatic and is especially effective when diagnosis is made early in the disease process.

Doberman Pinschers: An idiopathic, chronic, immune-mediated hepatitis recognized in Doberman Pinschers in the mid 1980s predominantly involved middle-aged adult female dogs. Copper retention appears to play a role in some dogs, which currently contributes to hepatitis seen in this breed.

In dogs with advanced disease, clinical features include cyclic illness involving anorexia, weight loss, vomiting, diarrhea, PU/PD, jaundice, coagulopathies (melena, epistaxis), splenomegaly, microhepatica, ascites, and HE. Laboratory features may include a nonregenerative anemia, leukocytosis, thrombocytopenia, increased ALP and ALT activities, hyperbilirubinemia, hypoalbuminemia, prolonged APTT, and a pure or modified transudative abdominal effusion. Ultrasonography may identify nodular liver lesions.

Liver biopsy is necessary for definitive diagnosis and treatment recommendations.

Treatment in dogs with immune-mediated nonsuppurative hepatitis includes immunomodulation with prednisone (1–2 mg/kg/day for several weeks, slowly titrated to 0.5 mg/kg/day and if possible, to every other day) and antioxidants, with or without azathioprine. In dogs with developing fibrosis, PhosChol[®] polyunsaturated phosphatidylcholine is also recommended (25–50 mg/kg, PO, with food). Nutritional support depends on the presence of HE and the need for copper restriction. Prognosis is poor for dogs diagnosed with advanced nonsuppurative hepatitis. Dogs diagnosed early can achieve remission for several years with prednisone, vitamin E, antioxidants, and ursodeoxycholic acid. Prognosis for dogs with apparent copper-associated hepatopathy can be good if diagnosed early in the disease process (*see* COPPER-ASSOCIATED HEPATITIS, p 460).

Cocker Spaniel Hepatopathy: Chronic Cocker Spaniel hepatopathy is associated with a degenerative vacuolar hepatopathy

(glycogen, lipid, and hydropic degeneration) associated with low-grade nonsuppurative inflammation and sinusoidal myofibrocyte activation that leads to sinusoidal deposition of fine tendrils of fibrillar collagen. Disease is typically advanced at initial presentation. Definitive diagnosis by liver biopsy demonstrates regenerative nodules and marked distortion of the hepatic architecture consistent with micronodular and macronodular cirrhosis. There is no gender predisposition, and most dogs are diagnosed as young adults (4–4.6 yr, range 2–11 yr). Most dogs lack signs of liver disease antecedent to development of portal hypertension, ascites (pure or modified transudate), hypoalbuminemia, abrupt onset of HE, and APSSs. Clinical signs at presentation may include (in declining frequency) inappetence, lethargy, diarrhea, weight loss, melena, vomiting, and amaurosis. In some dogs, hepatopathy is discovered during abdominal ultrasonography for another health problem. Clinicopathologic features include modestly increased to normal liver enzyme activity, hypoalbuminemia, hypocholesterolemia, and increased TSBAs in the absence of hyperbilirubinemia. Normal fibrinogen, clotting times, normal or increased C-reactive protein, and subnormal antithrombin activity argue for a lack of acute phase marker induction and an inflammatory phenotype. Some dogs have moderate to abundant copper (on copper-specific staining), which may represent copper retention secondary to cholestasis (mild copper retention) or a more primary copper-associated injury (copper >800 ppm). In the latter dogs, foci of hepatocellular damage coordinate with regions of dense copper retention.

Strong sinusoidal staining with alpha-smooth muscle actin confirms transformation of resting stellate cells (Ito cells) that normally store retinoic acid (vitamin A) into activated myofibrocytes. Although the lesion has been labeled "lobular dissecting hepatitis" and Cocker Spaniel "hepatitis," the minimal inflammation and necrosis and lack of clinicopathologic markers of inflammation suggest that "hepatopathy" is better terminology. Chronic Cocker Spaniel hepatopathy studied in Sweden nearly 20 yr ago investigated whether a genetic abnormality causing alpha₁-antitrypsin (AAT) deficiency was involved. AAT is an important serum protease inhibitor synthesized in the liver and exported to the systemic circulation. Study of plasma AAT protein configuration and immunohistochemistry of AAT in canine liver biopsies

implicated a unique enzyme phenotype associated with AAT globules evident in hepatocytes of some but not all Cocker Spaniels. Unfortunately, retention of AAT in damaged or dysfunctional hepatocytes may also occur as an epiphenomenon of compromised protein transcription consequent to hepatocellular injury (but usually not retention of globules) as demonstrated in affected dogs. Yet it remains unknown whether AAT plays a role in this breed-related syndrome. In people, treatment for AAT deficiency is liver transplant.

Treatment is supportive and symptomatic using a balanced protocol as described for chronic hepatitis. Early glucocorticoid immunomodulation (eg, before the diagnosis of liver disease, glucocorticoids prescribed for ear or skin disorders) has seemingly prolonged survival in affected dogs. However, in dogs with hypoalbuminemia or ascites, glucocorticoids are poorly tolerated and may cause melena, ascites, HE, etc. If a glucocorticoid trial is undertaken, dexamethasone should be used instead of prednisone to avoid mineralocorticoid effects. Ursodeoxycholic acid, vitamin E, SAME, polyunsaturated phosphatidylcholine (PhosChol®), and individually tailored nutritional support are recommended. A permanent urethrostomy may be necessary in male dogs that develop ammonium biurate calculi. Successful treatment of severely affected dogs has been possible for several years. Need for copper chelation is based on specific stains and copper quantification. Management of HE (dietary modification, lactulose, low-dose metronidazole, or nonabsorbable orally administered antimicrobials), and management of ascites (sodium restriction, diuretics, judicious therapeutic abdominocentesis) as described previously are recommended. Dogs receiving glucocorticoids as treatment for antecedent health issues before hepatopathy diagnosis and dogs treated with glucocorticoids with or without azathioprine after diagnosis may have improved survival. Additional supportive treatments reported include ursodeoxycholic acid, antioxidants, and antifibrotics. Although there was no correction of hypoalbuminemia in most dogs, survival beyond 3 yr of diagnosis was documented.

Skye Terriers: Three reports of hepatitis in Skye Terriers, one characterizing disease in nine related dogs, described no age or gender predilection and clinical signs ranging from asymptomatic to end-stage liver failure at time of initial diagnosis.

Three separate liver disorders were described: mild inflammation with no evidence of cirrhosis or copper accumulation, advanced macronodular cirrhosis with cholestasis, and marked copper accumulation. Treatment is based on liver biopsy, as described previously for these disorders.

Maltese Dog Zone 3 (Centrilobular) Hepatopathy: Maltese dogs have a high prevalence of congenital hepatic vascular malformations (MVD, PSVAs). Dogs with MVD vastly outnumber those with PSVAs. Within kindreds, finding high TSBA in 60%–90% of dogs confirms high trait prevalence. Clinicians and breed enthusiasts have been confused by a published article proposing that TSBA quantification in Maltese dogs is confounded by interfering analytes. Liver biopsies from Maltese dogs with increased TSBA concentrations strongly refute that supposition, with >250 studied cases (60% lacking PSVAs) demonstrating lesions of portal hypoperfusion. An inflammatory and degenerative zone 3 (centrilobular) hepatic lesion develops in a subset of dogs with the MVD/PSVA trait; the lesion often coexists with marked persistent or cyclic increases of serum ALT activity. Histologic lesions vary in severity and may be progressive, eventually culminating in cirrhosis. This hepatopathy is often associated with concurrent inflammatory bowel disease and may derive from splanchnic delivery of inflammatory cytokines and inflammatory cells. Histologic lesions in dogs with increased serum ALT and high TSBA concentrations typically consist of a lymphoplasmacytic infiltrate with or without eosinophils adjacent to and sheathing hepatic venules (centrilobular, zone 3). Dogs develop a degenerative hepatopathy with lipogranulomas (foamy macrophage aggregates) located adjacent to hepatic venules that appear to partially or completely obscure vascular lumen. A spectrum of histologic severities exists within biopsy sections from an individual dog. Severe lesions provoke postsinusoidal intrahepatic portal hypertension and development of APSSs. Although cirrhosis has been confirmed in a small subset of dogs, ascites is detected clinically in nearly 75% of those affected. In dogs with ascites, ultrasonography usually discloses hepatic parenchymal nodules, a nodular liver surface contour consistent with hepatic remodeling, and narrowing of hepatic venules on color-flow vascular interrogation. A small subset of dogs may have copper-associated hepatopathy (rhodanine

staining and quantified tissue copper >1,200 ppm). Dogs with zone 3 degenerative hepatopathy concurrent with a PSVA usually respond poorly to surgical or ameroid shunt attenuation.

Treatment focuses on management of associated inflammatory bowel disease (hypoallergenic diets, home-cooked nutritionist-formulated or commercially available diets), metronidazole (7.5 mg/kg, PO, bid [low dose because of portal hypoperfusion]), and glucocorticoids avoiding use of drugs with mineralocorticoid effects (eg, dexamethasone, every 3 days, anti-inflammatory dose). Vitamin E (10 IU/kg/day) and SAMe (20 mg/kg/day) are recommended for antioxidant and antifibrotic benefits. Because a subset of severely affected dogs have developed thromboemboli involving hepatic venules and/or portal veins, minidose aspirin (0.5 mg/kg, PO, once to twice daily) has been prescribed for some dogs until inflammation abates (assumed based on decline in liver enzyme activity with maintained synthetic markers). Inflammation also has been successfully managed with budenonide in some dogs. In dogs treated with glucocorticoids, dosage is titrated to response (enzymes, clinical features) to minimize undesirable adverse effects. Some dogs require combined immunomodulation to achieve control of inflammation or because of unacceptable glucocorticoid effects. In these, azathioprine or cyclosporine are used in combination with or to replace glucocorticoids. Ascites is managed with sodium restriction and combined furosemide and spironolactone administration. A loading dose of spironolactone (2–4 mg/kg, PO, given once) followed by 1–2 mg/kg, PO, bid. Furosemide is dosed at 1 mg/kg, PO, once to twice daily. Diuretic treatment is suspended when ascites is in remission and reinstituted on recurrence, with continued sodium restriction.

LOBULAR DISSECTING HEPATITIS

Lobular dissecting hepatitis is a unique hepatic reaction pattern rather than a unique hepatic syndrome. The histologic features are typified by liver injury associated with intrasinusoidal nonsuppurative inflammatory infiltrates leading to panlobular sinusoidal fibrosis. Although more commonly described in juvenile to young adult dogs and in a small group of related Standard Poodles, this disorder seemingly has no breed, gender, or age predilection. Weight loss and ascites, with or without jaundice, are common clinical

features. Laboratory abnormalities include hypoalbuminemia, hypocholesterolemia, low BUN, and increased TSBA concentrations in nonjaundiced dogs. Liver enzymes may be normal or mildly or markedly increased. APSSs develop due to acquired intrahepatic sinusoidal portal hypertension. Hepatic copper concentrations are not consistently increased. The syndrome commonly progresses to cirrhosis. Supportive treatment is recommended for HE, ascites, and control of fibroplasia and inflammation as described previously. Colchicine (0.03 mg/kg, PO, daily to every other day) has been used to control fibrosis and sinusoidal inflammation in some dogs. Other dogs have been managed with more conventional immunomodulatory protocols with PhosChol® (polyunsaturated phosphatidylcholine with 52% dilinoleoyl-phosphatidylcholine, 25–50 mg/kg/day), used as an antifibrotic with fewer adverse affects. This is a poorly understood and characterized syndrome and in some cases may reflect hepatotoxin exposure.

CANINE VACUOLAR HEPATOPATHY

Vacuolar hepatopathy (VH) is a commonly diagnosed canine liver syndrome in which hepatocytes become markedly distended with cytosolic glycogen with or without discrete membrane-bound lipid inclusions. Glycogen-like VH is associated with typical or atypical hyperadrenocorticism or endogenous release of corticosteroids in response to chronic stress, illness, inflammation, or neoplasia. Liver biopsy is often pursued because of unexplained increases in serum ALP activity. Transaminase activity may be only modestly increased; GGT may or may not be increased.

Abdominal radiography may reveal hepatomegaly or changes associated with an underlying disease process. Metastatic disease or mineralized airways (chronic hyperadrenocorticism) may be seen on thoracic radiography. Ultrasonography reveals subjective hepatomegaly and hypoechoic hepatic nodules against a hyperechoic parenchymal background, the so-called “Swiss cheese pattern” that cannot be differentiated from infiltrative mass lesions, hepatic fibrosis, nodular hyperplasia, regenerative nodules, or cirrhosis. In some cases, grossly evident hepatic nodules cannot be discerned by ultrasound examination. VH usually is the underlying hepatic lesion in dogs with idiopathic nodular hyperplasia and also is common in

dogs with hepatic adenomas, hepatocellular carcinoma, and gallbladder mucoceles. Progressive VH merges into the classic hepatic syndrome associated with the hepatocutaneous lesion (*see below*). Hepatic biopsy is needed for definitive diagnosis, because glycogen-vacuolated hepatocytes are also seen in necroinflammatory liver disorders. Intrahepatic extramedullary hematopoiesis is common.

It is critical to determine and treat any underlying disease process. Careful scrutiny for adverse drug reactions is also necessary, with a focus on drugs associated with “induction phenomenon.” These should be discontinued and replaced with an alternative therapy. Clinicians should investigate any use of holistic or herbal remedies that may have systemic glucocorticoid or adrenocorticotrophic hormone (ACTH) effects.

Nutritional support is important and must be individualized. In most cases, a normal protein intake is appropriate. VH in dogs with hyperlipidemia requires treatment with a fat-restricted diet (<2 g fat/100 kcal of diet). A protein-restricted diet should not be fed, unless indicated (eg, demonstration of HE or ammonium biurate crystalluria). In fact, protein restriction may augment development of this liver lesion, especially if it is associated with hypoaminoacidemia as in the hepatocutaneous syndrome. A supplemental water-soluble vitamin is recommended for all dogs. Antioxidants should be provided, because some experimental evidence implicates oxidative injury in degenerative VH. Ursodeoxycholic acid is recommended if TSBA concentrations are increased.

Vacuolar Hepatopathy in Scottish

Terriers: VH associated with a progressive increase in ALP activity is common in Scottish Terriers. Studies suggest this syndrome is linked with a breed-related abnormality involving adrenal steroidogenesis, leading to overproduction of progestins and androgens. Severe progressive VH is first noted in middle-aged dogs and can be either slowly progressive or progress rapidly over a few years to liver failure, cirrhosis, APSSs, ascites, and hyperbilirubinemia. Ultrasonographic imaging discloses the typical “Swiss cheese” pattern of VH (described above). High risk of hepatocellular carcinoma is recognized in dogs demonstrating progressive hepatic remodeling. Liver biopsy often discloses dysplastic proliferative lesions antecedent to formation of hepatocellular carcinoma. Adrenomegaly is common and may be

bilateral or unilateral. Treatment with adrenal-modulating drugs can be hazardous and appears ineffective. Supportive care as for dogs with declining hepatic function, monitoring both sequential biochemical profiles for sudden marked increases in ALP or ALT activity that may signal tumor formation, and serial ultrasonographic evaluations for enlarging hepatic mass lesions are recommended. Early surgical excision of enlarging hepatic mass lesions that likely represent hepatocellular carcinomas is recommended to allow complete excision. A subset of dogs studied also have copper-associated liver injury that cannot be inferred on the basis of biochemical assessments but rather require liver biopsy for definitive diagnosis.

METABOLIC DISEASES AFFECTING THE LIVER

Diabetes mellitus, hyperadrenocorticism, hypothyroidism, and hyperthyroidism can cause changes in the liver.

HL can develop secondary to diabetes mellitus because of increased lipid metabolism and mobilization; notable are hepatomegaly and increased liver enzyme activities. Dogs with diabetes mellitus rarely manifest liver dysfunction unless they develop severe progressive VH associated with the hepatocutaneous syndrome (*see below*). Most of these dogs have markedly increased ALP with lesser increases in transaminase activity. Diabetic cats also may develop increased ALT and ALP activities and may become hyperbilirubinemic with onset of HL. Diabetic animals have increased risk of pancreatitis that may progressively lead to EHBDO and cholangitis. These animals have increased risk of bacterial infections involving biliary structures (emphysematous cholecystitis, cholangitis).

Cats with hyperthyroidism usually develop increases in ALP and ALT activities and are rarely hyperbilirubinemic. Liver function is usually normal. The underlying cause of altered enzyme activity is not fully understood but postulated to involve toxic effects of excessive thyroxine, malnutrition, cardiac dysfunction, induction phenomenon, and increased bone turnover (causing increase in the bone isoenzyme of ALP). Liver enzymes return to normal with successful treatment; however, methimazole also can lead to a drug-associated hepatopathy that resolves only after drug discontinuation.

HEPATOCUTANEOUS SYNDROME

(Superficial necrolytic dermatitis, Necrolytic migratory erythema, Glucagonoma syndrome)

Hepatocutaneous syndrome is a rare, chronic, progressive, and usually fatal disorder. Although typically associated with diabetes mellitus, the liver lesion is a severe, degenerative, glycogen-like VH that also can accompany pancreatic or neuroendocrine tumors and severe VH secondary to endogenous steroidogenic hormone release or chronic phenobarbital therapy.

Bilaterally symmetric crusting and ulcerative lesions are found on mucocutaneous junctions and cutaneous regions susceptible to pressure injury (eg, footpads, ears, periorbital regions, and limb pressure points). Skin lesions are characterized by a marked parakeratotic epidermis. Edematous spaces between cells are filled with neutrophils, necrotic cells, and debris that create an "eosinophilic" layer. Mild neutrophilic perivascular inflammation is also seen. Lesions are commonly referred to as "red, white, and blue" on H&E staining (red for parakeratosis, white for edema, and blue for hyperplasia). Skin lesions are seen initially in most affected dogs, but liver lesions may precede cutaneous changes.

Clinical features include anorexia, weight loss, lethargy, PU/PD, mild nonregenerative anemia, marked increases in ALP and moderate increases in ALT and AST, hyperglycemia, decreased plasma amino acid concentrations (by 50% of normal), hypoalbuminemia, and increased TSBA concentrations. High plasma glucagon levels are inconsistent. Liver size is variable. On ultrasound, multiple hypoechoic nodules surrounded by hyperechoic parenchyma are diffusely scattered throughout the liver, described as a "Swiss cheese" pattern. The association between the cutaneous and hepatic lesions is not understood but is speculated to involve hypoaminoacidemia or abnormal zinc metabolism. Liver lesions are not necroinflammatory and are not associated with fibrosis or cirrhosis. The prognosis for recovery from hepatocutaneous syndrome in dogs is poor.

Treatment focuses on correcting amino acid deficiencies and providing symptomatic care for cutaneous lesions and VH. In general, corticosteroids are contraindicated for the skin lesions. A commercial diet high in protein or formulated for dogs with hepatic insufficiency with an added "body-building" amino acid concentrate can

be used. Administration of IV amino acids requires delivery through a catheterized jugular vein. Aminosyn 10% crystalline amino acid solution (100 mL contains 100 g of amino acids) can be given IV, 500 mL/dog, over 8–12 hr. Symptoms from hyperammonemia may develop in susceptible dogs (previously demonstrating HE) but should resolve within 12 hr after completion of the infusion. The IV amino acid infusion is repeated 7–10 days later if skin lesions persist; four cycles can be given. If no response is seen, further amino acid infusions are futile. Amino acid treatment results in regression of skin lesions and hepatopathy in some dogs.

Control of concurrent diabetes mellitus can be challenging, because insulin resistance suggests involvement of counter-regulatory hormones (glucagon, glucocorticoids, others). Supportive care requires use of appropriate broad-spectrum antifungals or antibiotics for superficial secondary bacterial and fungal invaders, zinc methionine supplementation (1.5–2 mg/kg/day, PO), water-soluble vitamins (doubled daily dose), essential fatty acid supplements, and topical lesion cleansing. Some dermatologists also recommend treatment with niacinamide (250–300 mg/dog, PO, bid). Ursodeoxycholic acid (15–20 mg/kg, divided and given bid with food) and antioxidants (vitamin E and SAMe) are recommended. Identification and treatment of underlying metabolic conditions is essential for control. Chronic phenobarbital therapy has been an underlying cause in some dogs. Successful treatment with long-acting somatostatin (octreotide; prohibitively expensive) has been described in a single dog with hepatocutaneous syndrome secondary to metastatic glucagonoma.

NODULAR HYPERPLASIA

Nodular hyperplasia (proliferative hepatocytes maintaining single-celled hepatic cord architecture with normal reticulin support) occurs as a benign, age-related microscopic or grossly apparent small mass lesion in dogs. It is often associated with a VH, lacks a defining remodeled border (as characterizes regenerative nodules), and may be confused histologically with adenomatous hyperplasia or hepatic adenoma (demonstrating proliferative disorganized hepatocytes forming thick hepatic cords with diminished reticulin support). Although nodular hyperplasia does not cause clinical disease, it can be accompanied by increased liver

enzyme activity, particularly ALP. Unless the liver is diffusely remodeled with nodular lesions (secondary to degenerative VH), TSBA concentrations remain normal. Ultrasonographically, nodular hyperplasia is associated with hypoechoic hepatic nodules set against a hyperechoic background (if associated with glycogen-like VH). Cytology of an aspirate may discriminate dysplastic, neoplastic, or inflammatory cells but cannot exclude any of these disorders. Biopsy is necessary to differentiate between nodular hyperplasia, dysplastic microscopic nodules, regenerative nodules, cirrhosis, and neoplasia.

HEPATIC NEOPLASIA

Primary hepatic neoplasms are less common than metastatic neoplasms in the liver and are either carcinomas, carcinoids, sarcomas, or of hemolymphatic origin. Metastatic neoplasia of the liver can originate from multiple visceral organs and can include lymphosarcoma. There may be no clinicopathologic features indicating the presence of metastatic neoplasia within the liver.

Primary tumors are most often found in older animals (<9 yr) and can be malignant or benign. The most common primary hepatic neoplasm in dogs is hepatocellular carcinoma, whereas the most common primary hepatic neoplasms in cats include biliary adenomas and carcinomas and cystadenomas (not considered a neoplasm) most common in older cats. Additional tumor types include hemangiosarcomas, carcinoids, and sarcomas in dogs; lymphomas and myeloproliferative disease in cats; and less frequently, leiomyosarcomas, GI stromal tumors, and myelolipomas.

Hepatocellular Carcinomas: Hepatocellular carcinoma is most common in dogs but also may occur rarely in cats. Diagnosis may be initially pursued because of palpation of an abdominal mass or recognition of serially increasing ALT, ALP, or GGT activities. Less commonly, mass lesions are discovered as the cause of critical abdominal hemorrhage. Radiography may disclose a large mass lesion or emphysematous abscess within a necrotic tumor core. Ultrasonography is more sensitive for detection of mass lesions and can discriminate single from multiple lobe involvement. Small hepatocellular carcinomas may appear hypoechoic, hyperechoic, or heteroechoic. However, the large size of some masses precludes clear

differentiation of tumor impingement on or invasion into adjacent viscera and vasculature. Hepatocellular carcinomas can occur as a single large mass in one liver lobe with or without smaller masses in other lobes (massive), as discrete nodules located in multiple lobes (nodular), or as infiltrative disease throughout the liver without obvious discrete nodularity (diffuse). Nodular and diffuse hepatocellular carcinomas, which account for 29% and 10%, respectively, of all hepatocellular carcinomas, involve multiple liver lobes and are not usually amenable to surgical removal. Single massive hepatocellular carcinomas represent 61% of all canine hepatocellular carcinomas and are potentially resectable with good outcome. Tumors involving the left liver lobes carry the best prognosis. Hepatocellular carcinomas are locally invasive and may spread to local lymph nodes but are slow to metastasize elsewhere. Multiple histologic patterns have been characterized for canine hepatocellular carcinoma, including (but not limited to) solid, clear cell, trabecular, peliod, pseudoglandular, scirrhous, and anaplastic.

Common clinical signs in dogs include weight loss, inappetence, fever, and lethargy; less common signs include vomiting, PU/PD, and seizures (hypoglycemia). However, dogs may be asymptomatic until the tumor reaches massive size or develops a necrotic core leading to critical abdominal hemorrhage. On abdominal palpation, a mass may be detected, and pain notable. Abdominal effusion is uncommon. Laboratory tests may indicate nonregenerative anemia, RBC microcytosis, thrombocytosis, increased serum activity of ALP and AST, and hypercholesterolemia. High ALT and AST concentrations may reflect invasion of adjacent normal tissue or central tumor necrosis and may indicate a poor prognosis. Increased ALP may reflect association with increased steroidogenesis (particularly androgens and progestins). Hypoglycemia may develop either due to large tumor mass or a paraneoplastic effect. Pulmonary metastases are uncommon. Tumor margins should be demarcated on submitted specimens to judge adequacy of mass resection (tumor-free margin). Mass excision with wide margins can be curative in both dogs and cats. Liver biopsies from regions distal to the tumor are recommended in dogs, because antecedent dysplastic foci may portend possible tumor recurrence. Finding dysplastic foci should increase ultrasonographic and clinicopathologic (a sudden peak in ALP or transami-

nase activity) surveillance for tumor recurrence.

Hepatocellular Adenomas and Adenomatous Hyperplasia or Dysplastic Foci:

Differentiation of hepatocellular carcinoma from hepatocellular adenoma can be difficult, involving judgement of the degree of dysplasia and characterization of the histologic features. Like hepatocellular carcinomas, adenomas also may be accompanied by microscopic dysplastic foci in unaffected liver lobes. Hepatocellular adenomas and dysplastic foci are more common in dogs with atypical adrenal hyperplasia associated with increased androgen or progesterone concentrations. Both lesions are often associated with increased liver enzyme activity (ALP primarily, with more modest change in transaminases). Rather than single mass lesions, multiple dysplastic foci are commonly identified within a single biopsy sample and among multiple biopsies from the same animal. Neoplastic transformation of dysplastic foci is suspected.

Similar to hepatocellular carcinomas, hepatocellular adenomas may outgrow their central blood supply, developing a necrotic core that may serve as a nidus for abscess formation. Mass lesions also may rupture and cause critical abdominal hemorrhage. Hepatocellular adenoma is curable by wide resection, although recurrence is possible in dogs with dysplastic foci. Tumor margins should be demarcated on submitted specimens to enable microscopic assessment of the adequacy of mass resection (tumor-free margin).

Biliary Adenocarcinomas: Variably classified as cholangiocellular carcinoma or adenocarcinomas and hepatocellular adenocarcinomas, these tumors are the most common primary malignant hepatic neoplasm in cats and may derive from intrahepatic or extrahepatic bile ducts, pancreas, or gallbladder. Pancreatic adenocarcinomas, invasive into hepatic structures, are also common in cats. Immunohistochemical staining may be necessary to definitively characterize the tissue of origin (biliary epithelium vs hepatocellular). Biliary cysts can be mistaken on gross inspection for primary biliary adenocarcinomas.

Clinical signs usually include anorexia, lethargy, and vomiting, and some cats are jaundiced. Many cats have a history of antecedent liver disease based on historical biochemical profiles; histologically, the chronic liver disease is a nonsuppurative

cholangiohepatitis. A mass or large liver may be palpable. Increased ALT, AST, ALP, and GGT activities and increased cholesterol and bilirubin concentrations are common. However, some cats with biliary adenocarcinomas have no clinical signs or laboratory abnormalities. Biliary tree obstruction is identified in some but not all cats with neoplasia associated with the common bile duct and gallbladder. Abdominal radiographs may disclose mass lesions disrupting the hepatic silhouette. Ultrasonography usually delineates mass lesions, their dimensions, and lobe location and documents the presence or absence of biliary tree and/or gallbladder obstruction. Some cats develop abdominal effusion and carcinomatosis.

Surgical resection of neoplastic lesions associated with biliary structures distal to the porta hepatis and lesions associated with the gallbladder is possible. Neoplasia involving the common duct may be palliated with stent placement through the sphincter of Oddi into the duodenum (poorly tolerated by cats) or surgical creation of a biliary diversion. Some cats survive for months with palliative supportive care (without surgery) despite total bile duct obstruction. However, the long-term prognosis is poor. Metastatic lesions are often found in the local lymph nodes, peritoneum, and lungs.

Lymphoma: The most common hemolymphatic tumor found in the liver in both dogs and cats is lymphoma; this may be primary or metastatic (from primary enteric or multifocal disease). Other myeloproliferative diseases and mast cell neoplasia also can involve the liver, especially in cats. Animals with infiltrative hepatic lymphoma may remain asymptomatic in regard to clinicopathologic features except for hyperbilirubinemia and hepatomegaly. Ultrasonographic imaging may not recognize architectural changes or discover nodules or mass lesions. Abdominal effusion may develop secondary to compressive presinusoidal and sinusoidal intrahepatic portal hypertension. Sampling of the effusion and hepatic aspiration may allow cytologic diagnosis of lymphoma. Circulating blood should first be reviewed for presence of neoplastic lymphocytes.

Myelolipomas: These benign tumors are composed of adipose cells and hematopoietic elements. The cellular composition closely resembles cellular elements found in bone marrow. These tumors are usually serendipitously discovered during

abdominal ultrasonography, appear densely hyperechoic, have a clearly demarcated border, and are usually small. Aspiration cytology can easily characterize the cellular features. Unless large vessels and biliary structures are compressed, these lesions do not require surgical removal.

Metastatic Neoplasia: The most common tumors metastasizing to the liver in dogs include lymphoma, pancreatic carcinoma, mammary carcinoma, pheochromocytoma, intestinal carcinoma, thyroid carcinoma, fibrosarcoma, osteosarcoma, hemangiosarcoma, mast cell tumors, and transitional cell carcinoma. Metastatic tumors of the liver are less common in cats but include pancreatic, intestinal, and renal cell carcinomas; mast cell tumors; and lymphoma. Metastatic tumors are often multifocal but may initially exist only within vascular and lymphatic elements.

Clinical signs can be nonspecific or specific to the liver and resemble features associated with primary hepatobiliary neoplasia, including anorexia, weight loss, vomiting, PU/PD, and variable hyperbilirubinemia. Metastatic hepatic neoplasia is more likely to be associated with a malignant abdominal effusion. Neurologic signs may indicate metastatic lesions within the brain, with associated clinical signs mistaken for HE. Abnormalities on baseline hematologic or chemistry profiles may be minimal. Although a nonregenerative anemia may develop, there are no consistent changes in WBC count or distribution. Schistocytes may be seen when neoplasia invades hepatic sinusoids, creating a shearing effect on RBCs. Eosinophilia can develop with mast cell tumors and lymphoma, especially in cats. Liver enzymes may be normal or variably increased. Hypoglycemia due to large tumor mass (enhanced glucose utilization) or a paraneoplastic effect (insulin-like effect) is sometimes identified. Hyperbilirubinemia and increased AST are more frequent in canine metastatic disease than in primary hepatic neoplasia. Although radiographic findings are variable, ultrasonography can discriminate single vs multiple lobe involvement from diffuse infiltrative disease. However, aspirates of mass lesions or biopsy is needed for definitive diagnosis. If one liver lobe is involved, surgical removal is recommended. If lymphoma or mastocytosis is diagnosed, appropriate chemotherapy may prolong life.

Hepatic hemangiosarcoma is treated by surgical resection as primary therapy if a defined mass lesion is characterized, with

follow-up chemotherapy. There is no specific study of survival expectations of dogs with hepatic hemangiosarcoma, with or without surgical debulking or chemotherapy. Surgery is palliative to arrest active hemorrhage but does not provide longterm survival benefit for most dogs with liver involvement. Survival in dogs with grossly evident metastatic disease have the worst prognosis, with median survival ranging from 68–136 days. A number of combination chemotherapy protocols have been investigated in dogs with hemangiosarcoma, providing median survival ranging from 145 to 250 days in dogs with incisional or excisional biopsies (all sites of tumor not limited to the liver). In a chemotherapy study with doxorubicin (free or pegylated liposome-encapsulated drug) compared with a random prospective clinical trial (n=17 for each group), there was no survival difference between treatments in dogs with splenic hemangiosarcoma. Pegylated liposome-encapsulated doxorubicin was associated with more adverse effects. Another combination protocol for dogs with advanced-stage noncutaneous hemangiosarcoma (doxorubicin, dacarbazine, and vincristine) with nonresectable stage II and stage III hemangiosarcoma (doxorubicin and dacarbazine day 1, vincristine days 8 and 15, protocol repeated every 21 days for a maximum of six cycles or until disease progression) was studied. In this study of 24 dogs, a 47.4% response rate (five complete responses, four partial responses) was realized; median time to tumor progression was 101 days with a median survival of 125 days. Significant toxicities included hematologic and GI adverse effects.

MISCELLANEOUS LIVER DISEASES

Glycogen Storage Disease: Of the four glycogen storage diseases reported in dogs, types I and III directly affect the liver, causing massive hepatomegaly in young puppies. These disorders are characterized by excessive accumulation of glycogen in the liver and other organs. Accumulated glycogen is unavailable for conversion to glucose as a result of defective glycolytic enzyme activity.

Type Ia glycogen storage disease, caused by deficiency of glucose-6-phosphatase¹⁴, has been reported in toy-breed dogs, particularly Maltese. There is no gender predilection, and disease transmission is autosomal recessive. Clinical signs include emaciation, stunted

growth, abdominal distention due to massive hepatomegaly (glycogen and lipid vacuolation of hepatocytes), and lethargy and weakness associated with severe hypoglycemia. Histologic lesions are also seen in renal tubular epithelium. Affected dogs develop lactic acidemia, hypercholesterolemia, hypertriglyceridemia, and hyperuricemia. Clinical signs progress to death or euthanasia by 60 days of age. A genetic test is available for type I disease in Maltese dogs.

Type III glycogen storage disease, caused by a deficiency in glycogen debranching enzymes, has been reported in German Shepherds and Curly Coated Retrievers. There is no gender predilection, and an autosomal recessive transmission has been confirmed. Clinical signs include abdominal distention due to hepatomegaly and mild hypoglycemia. Glycogen stores are notable in both liver and skeletal muscle. In Curly Coated Retrievers, the mutation leads to profound hepatocyte glycogen vacuolation, resulting in progressive hepatic fibrosis and liver failure. Affected dogs also develop a progressive degenerative myopathy. A genetic test is available for type III disease in Curly Coated Retrievers.

Diagnosis of these disorders is based on a high index of suspicion considering breed affiliation and symptomatic hypoglycemia. Abdominal radiography reveals hepatomegaly, and ultrasonography reveals hyperechoic hepatic parenchyma consistent with hepatic glycogen or lipid accumulation. Differential diagnoses include other causes of juvenile hypoglycemia (including malnutrition, endoparasitism, transient fasting hypoglycemia in toy breeds, and PSVAs) and other causes of muscular weakness (including endocrinopathies, immune-mediated disorders, infectious diseases, hypokalemia, and neuromyopathies). Supportive care consists of fluid support, IV dextrose to achieve euglycemia, and frequent feedings of a high-carbohydrate and protein diet. Diagnosis is confirmed by tissue enzyme analyses, confirmation of excess glycogen stores in liver tissue, or genetic testing. Prognosis is poor. Affected dogs and their parents should be eliminated from breeding programs.

Hepatic Amyloidosis: Amyloidosis is a familial disease of Abyssinian, Siamese, and Oriental short-hair cats and Chinese Shar-Pei dogs. Affected Shar-Pei are more

likely to demonstrate episodic fever and swollen hocks (SharPei fever) with or without renal failure, but the liver may also be affected by diffuse amyloid deposition. Affected Abyssinian cats often present with clinical signs related to the kidneys or with complications associated with diffuse hepatic amyloidosis or amyloid deposition in other organs. Oriental short-hair and Siamese cats generally present with amyloid-related hepatic complications. Other conditions associated with hepatic amyloidosis include a diversity of chronic infections or antigen exposures (eg, coccidioidomycosis in dogs, cyclic hematopoiesis in Gray Collies, infusion of porcine insulin in dogs) and hypervitaminosis A in cats.

Although animals may be asymptomatic for long intervals, clinical signs may include fever, lymphadenopathy, vomiting, inappetence, weight loss, PU/PD, jaundice, and hepatomegaly. Acute presentation for severe abdominal hemorrhage subsequent to liver lobe rupture usually leads to the diagnosis in Oriental short-hair and Siamese cats. Ultrasonography can often identify a developing hematoma at the site of liver lobe rupture. Aspiration of abdominal effusion confirms active hemorrhage. Diagnosis can be made by aspiration cytology if amyloid fibrils are retrieved. Otherwise, diagnosis is made by identifying amyloid deposits in a liver biopsy; amyloid is confirmed by tissue staining with Congo red and examination under polarized light.

Because familial amyloidosis is a progressive systemic disorder, prognosis is poor. Cats surviving acute, severe hepatic hemorrhage by aggressive administration of blood component therapy subsequently succumb to renal amyloidosis. (See also AMYLOIDOSES, p 592.) Colchicine and dimethyl sulfoxide have been used to slow progression of systemic amyloidosis in Shar Pei dogs and in cats, with limited success. Anecdotally, hepatic amyloid has regressed in Shar Pei treated with colchicine (0.03 mg/kg/day, daily to every other day). Long-term survival in Shar Pei demonstrating systemic signs of Shar-Pei fever is possible with early institution of colchicine therapy. In predisposed Shar Pei, a duplication mutation upstream of the hyaluronic acid synthase 2 (HAS2) gene amplifies production of hyaluronic acid, which initiates chronic inflammation and amyloid formation. Additional genetic studies have identified complex polygenic modifier genes.

DISEASES OF THE GALLBLADDER AND EXTRAHEPATIC BILIARY SYSTEM

Jaundice is often the primary presenting sign in animals with disorders involving the gallbladder or extrahepatic biliary structures; abdominal effusion may reflect bile peritonitis. Finding a higher bilirubin concentration in an effusion relative to serum (>10-fold difference) confirms leakage of bile into the abdominal cavity and constitutes a surgical emergency.

CHOLECYSTITIS

In **non-necrotizing cholecystitis**, inflammation of the gallbladder may involve nonsuppurative or suppurative inflammation; may be associated with infectious agents, systemic disease, or neoplasia; or may reflect blunt abdominal trauma or gallbladder obstruction by occlusion of the cystic duct (eg, cholelithiasis, neoplasia, or choledochitis). Cystic duct occlusion incites gallbladder inflammation secondary to bile stasis; this process is augmented by mechanical irritation of a cholelith. The gallbladder wall thickens, and the lumen distends with a white, viscid, mucin-laden bile (white bile).

Necrotizing cholecystitis more commonly affects middle-aged to older adult dogs and may develop secondary to thromboembolism, blunt abdominal trauma, bacterial infection, EHBDO (cystic duct obstruction or distal duct obstruction by choleliths, stricture, or neoplasia), or a mature gallbladder mucocele (causing tense gallbladder distention). Extension of an inflammatory or neoplastic process from adjacent hepatic tissue also may be an underlying cause. Necrotizing cholecystitis can present with or without gallbladder rupture, or as a chronic syndrome associated with adhesions between the gallbladder, omentum, and adjacent viscera. Bacteria are commonly cultured from the gallbladder wall.

Necrotizing cholecystitis requires prompt surgical intervention (cholecystectomy and potential biliary diversion). Clinical signs usually develop acutely and include abdominal pain, fever, and increased liver enzyme activity. However, signs may remain vague and episodic, and hyperbilirubinemia is inconsistent.

Clinical Findings and Diagnosis: Signs of acute cholecystitis include abdominal

pain (may only be postprandial), fever, vomiting, ileus, and mild to moderate jaundice. Some animals present in endotoxic shock. The hemogram discloses variable leukocytosis, with or without toxic neutrophils or a left shift. Hyperbilirubinemia and development of jaundice depend on chronicity, involvement of extrahepatic biliary structures, presence or extent of biliary tree occlusion, bile peritonitis, and endotoxemia. Liver enzyme activity is variable, but ALP and GGT are usually moderately to markedly increased. Gallbladder rupture leads to pericholecystic abscess formation (localized by the omentum) or focal or generalized bile peritonitis. Abdominal radiography may reveal indistinct detail in the cranial abdomen consistent with focal peritonitis; a sentinel intestinal loop may implicate focal ileus. Rarely, the gallbladder wall may become radiodense due to dystrophic mineralization secondary to chronic inflammation. Choleliths may be found on ultrasonography. Detection of gas within the biliary tree or gallbladder heralds an emphysematous process associated with sepsis and should prompt antibiotic administration before surgical intervention. Consideration of triage for emergency cholecystectomy is appropriate in some cases. Pericholecystic fluid can be sampled using ultrasonographic guidance to confirm bile leakage and infection. Comparison of total bilirubin concentration in effusion versus serum helps confirm bile leakage.

Diagnosis is based on clinical signs, clinicopathologic features, and ultrasonographic imaging. Ultrasonographic detection of a thickened gallbladder wall or cystic bile duct and tenderness during the imaging procedure or on deep abdominal palpation may be the only evidence of illness. Because necrotizing cholecystitis is often associated with gallbladder mucocele in dogs, early intervention by prophylactic cholecystectomy may reduce need for emergency surgery.

Treatment and Prognosis: Management of cholecystitis focuses on restoration of fluid and electrolyte status, treatment with broad-spectrum antibiotics effective against enteric opportunists, and prompt surgical intervention. In some cases, colloids and plasma transfusion are necessary (plasma preferred to colloids). Because EHBDO is a differential diagnosis, vitamin K₁ should be administered (0.5–1.5 mg/kg, IM or SC, three doses at 12-hr intervals) before surgery to avert hemorrhagic complications. If emergency surgery is necessary, fresh

frozen plasma should be given judiciously based on coagulation tests and a buccal mucosal bleeding time. Careful exploration of all biliary structures is warranted during surgery. Patency of the cystic and common bile ducts must be determined, and viability of the gallbladder ascertained as surgical assessments are made.

Cholecystectomy is the treatment of choice in most cases. However, some animals benefit from a cholecystoenterostomy or choledochointerostomy to circumvent a permanently occluded distal common bile duct. Placement of a temporary biliary stent may be appropriate but should be carefully considered because of the high rate of complications, especially in cats. Cats with EHBDO secondary to pancreatitis demonstrate greater morbidity associated with this technique than dogs. In one case series of seven cats with EHBDO secondary to pancreatitis, after stent insertion, two cats reobstructed within 1 wk, one cat developed ascending cholangitis, two cats suffered chronic intermittent vomiting, and two cats died during the perioperative period.

Samples of bile, gallbladder wall, choleliths, and liver tissue should be submitted for aerobic and anaerobic culture. Cytologic evaluations of tissue imprints and bile help initial selection of antimicrobials (based on bacterial morphology and Gram staining). A combination of metronidazole, ampicillin-clavulanate, and enrofloxacin provides broad protection against commonly encountered enteric opportunists. If only the gallbladder is involved, simple cholecystectomy may be curative. If the common bile, cystic, or hepatic ducts are involved, a more guarded prognosis is warranted, and longterm antibiotic therapy recommended.

There are few adverse consequences of cholecystectomy, although episodic abdominal pain and diarrhea associated with fat malabsorption have been described. Cholecystectomy results in loss of the absorptive and pressure-regulating function of the gallbladder and the fasting reservoir where bile is concentrated. After cholecystectomy, the volume of bile increases because of reduced sodium and water resorption that normally occurs in the gallbladder, the size of the bile acid pool diminishes, and the enterohepatic circulation of bile becomes continuous. Bile composition shifts because of the increased exposure of bile acids to enteric flora with increased formation of secondary bile acids.

Animals undergoing biliary tree decompression by biliary enteric anastomo-

ses are thereafter susceptible to retrograde septic cholangitis and choledochitis. Dogs tolerate this procedure with fewer clinical signs than cats. Animals should be monitored for fever, inappetence, vomiting, and signs of cyclic illness. A hemogram and liver enzymes should be monitored quarterly. Chronic or intermittent antimicrobial administration may be needed to control ascending cholangitis. Fortunately, illness is usually transient and responsive to antibiotics. Longterm survival with good quality of life is expected in the absence of neoplasia. Owners should be instructed to monitor the rectal temperature of animals with cyclic illness to detect episodes of septic cholangitis to enable institution of at-home antimicrobial therapy.

Emphysematous Cholecystitis/Choledochitis

Emphysematous cholecystitis/choledochitis is an uncommon condition associated with gas within the wall or lumen of the gallbladder or segments of the biliary tree. In dogs, it has been associated with diabetes mellitus, acute cholecystitis with or without cholecystolithiasis, traumatic ischemia, mature gallbladder mucocele formation, and neoplasia. Gas within the biliary structure indicates serious septic inflammation associated with a gas-forming bacteria such as *Escherichia coli* or *Clostridium* spp. Treatment requires cholecystectomy and antimicrobial therapy based on culture and sensitivity of bile and involved biliary tissues. Broad-spectrum antibiotic coverage should be initiated before surgical exploration. Use of a β -lactamase-resistant penicillin, with enrofloxacin and metronidazole, is initially indicated until culture and sensitivity results are available.

CANINE GALLBLADDER MUCOCELE

Canine gallbladder mucocele (GBM) is characterized by progressive accumulation of tenacious, pale yellow to dark green, mucin-laden bile, which may extend into the cystic, hepatic, and common bile ducts, resulting in variable degrees of bile duct obstruction. Progressive expansion of a GBM leads to gallbladder ischemia and necrosis, bile peritonitis, and sometimes opportunistic infection. Gallbladder stasis, perhaps reflecting dysmotility, and distention predispose to cholecystitis. A GBM should be considered when sequential ultrasonographic examinations fail to indicate a reduction in gallbladder volume

after feeding, confirming lack of movement of luminal "sludge." Feeding a dog (100 g of food) and recording gallbladder dimensions at 0, 15, 30, 45, 60, 90, and 120 min, recorded in cm ($[\text{width} \times \text{height} \times \text{length}] \times 0.52$) yields the gallbladder volume in mL. Failure to reduce baseline gallbladder volume by at least 25% suggests dysmotility. Erythromycin (0.5–1 mg/kg, PO, one dose) combined with a small meal also may stimulate initiation of gallbladder motility; however, in healthy dogs studied, neither feeding with or without erythromycin was consistently superior to initiate contraction.

Dogs with GBM range in age from 3–14 yr old with no gender predisposition. Incidence is increased in Shetland Sheepdogs, Miniature Schnauzers, and Cocker Spaniels. A genetic mutation in the ABCB4 (MDR3) phospholipase flippase transporter was demonstrated in Shetland Sheepdogs and other dogs with GBM. All affected dogs were heterozygous for this mutation.

Factors predisposing to GBM formation include middle to older age, endocrinopathies (typical and atypical hyperadrenocorticism, hypothyroidism, diabetes mellitus), hyperlipidemia or hypercholesterolemia (idiopathic, nephrotic syndrome, feeding of a high-fat diet, pancreatitis), gallbladder dysmotility, and cystic hyperplasia of the gallbladder mucosa (shown to be inducible by progestins in dogs). The inciting cause of mucus hypersecretion or accumulation is unproved and may be multifactorial. Nevertheless, mucin imparts important viscoelastic properties to bile and likely importantly contributes to GBM formation. Decreased gallbladder motility leads to luminal bile stasis and enhanced absorption of electrolytes and fluid, promoting biliary sludge formation. Dogs with risk factors may rapidly mature a developing mucocele after beginning glucocorticoid therapy or a high-fat diet (eg, some diets for renal disease or hepatic insufficiency). Because concurrent VH is common, associated underlying disorders should be investigated.

Clinical Findings and Diagnosis: Symptomatic illness averages ~5 days, although some dogs have vague episodic signs (ie, inappetence, vomiting, vague abdominal pain) for months. In decreasing order of frequency, clinical signs include vomiting, abdominal discomfort, anorexia or hyporexia, jaundice, tachypnea, tachycardia, PU/PD, fever, diarrhea, and abdominal distention. Dogs progressing to gallbladder rupture usually demonstrate abdominal pain, jaundice, tachycardia, tachypnea, and fever. However, occasionally, ruptured

GBMs asymptomatic with a free-moving congealed mucocele have been imaged in the peritoneal cavity. Typical clinicopathologic indicators include leukocytosis with a mature neutrophilia and monocytosis and sometimes a left shift, high liver enzyme activities (ALP, GGT, ALT, and AST), hyperbilirubinemia, and inconsistent hypercholesterolemia. Aerobic bacteria may be cultured from bile or the gallbladder wall, with a number of enteric organisms identified, including *Escherichia coli*, *Enterobacter* spp, *Enterococcus* spp, *Staphylococcus* spp, *Micrococcus* spp, and *Streptococcus* spp. Transhepatic ultrasound-guided cholecystocentesis should not be performed if a GBM is suspected. Ultrasonography may detect hepatomegaly and either a heterogeneous or hyperechoic hepatic parenchyma. Hypoechoic "nodules" correspond to a severe VH with formation of reticulin-defined nodules and regenerative repair. After gallbladder removal, sequential hepatic ultrasonographic evaluations are necessary to determine whether parenchymal lesions resolve. A liver biopsy should be collected from a liver lobe distant to the gallbladder to evaluate for underlying or coexisting disorders; sections collected adjacent to the gallbladder contain peribiliary glands and numerous ductal elements that may result in erroneous assessments.

Histologically, cystic mucosal hyperplasia of the gallbladder wall is common. All dogs have thick biliary debris; some components may be profoundly viscous and mucin laden, others more liquid, some dark green to black, some with white bile, some contain gritty black material, and some contain a firm, organized gelatinous matrix. Transmural ischemic necrosis may develop and lead to necrotizing cholecystitis and gallbladder rupture. Liver biopsies may disclose a VH or mild to moderate portal hepatitis or periductal fibrosis; the later changes reflect associated cholangitis or transient biliary tree occlusion. Some dogs lack concurrent hepatic lesions, especially when cholecystectomy is done preemptively (before GBM maturation).

Treatment: Dogs without signs of mucocele leakage or biliary tree obstruction at the time of initial diagnosis may benefit from hydrocholeresis induced by administration of ursodeoxycholic acid (15–25 mg/kg, PO, divided bid and given with food), SAME (20–40 mg/kg/day, PO, after an overnight fast; food should also be withheld for 2 hr after dosing), and antimicrobial coverage. Biochemical and

ultrasonographic evaluations every 6 wk are useful to monitor treatment response or syndrome progression. Rarely, an evolving GBM may resolve with medical treatment. However, progression in any clinical, clinicopathologic, or imaging parameter indicates poor control and need for surgical intervention.

Cholecystectomy is the best course of treatment and is essential for most dogs with clinical signs and clinicopathologic findings consistent with biliary tree inflammation, obstruction, or rupture. Because bile stasis predisposes to infection, broad-spectrum antimicrobials should be initiated before surgical intervention. Examination and staining of cytologic preparations of bile and imprints of liver and biliary tree biopsies may be invaluable if antibiotic coverage interferes with submitted cultures. Evidence of bacteria in cytologic samples or histologic confirmation of suppurative cholecystitis or cholangitis indicates a need for chronic postoperative antimicrobial administration. The resected gallbladder should be submitted for histopathology (sectioned before fixation to allow formalin penetration), and a liver biopsy collected distant to the site of surgery. Perioperative mortality is high for symptomatic dogs with a ruptured gallbladder complicated by sepsis. If bile peritonitis is present, the peritoneal cavity must be extensively cleansed with sterile, warm, polyionic fluids to remove debris, bacteria, and injurious bile salts. Abdominal drains may be necessary. Antibiotics should be administered for 4–6 wk after surgery.

Cholecystotomy for removal of gallbladder contents without cholecystectomy is not advised, because GBMs usually recur. Furthermore, necrosis of the gallbladder wall may not be grossly evident at surgery, leading to postoperative gallbladder rupture. After gallbladder resection, chronic cholestatic therapy is recommended, especially for Shetland Sheepdogs in which a genetic risk is surmised for sludged bile. Underlying causes of hyperlipidemia or endocrine disorders should be identified and managed appropriately. Clinicopathologic abnormalities (high ALP usually) normalize after gallbladder removal in most dogs, except those with associated suppurative cholangiohepatitis, unresolved endocrinopathies, persistent hyperlipidemia, or surgical complications of cholecystectomy. Feeding a protein-restricted, high-fat diet to hyperlipidemic animals may be detrimental and is not recommended.

OTHER DISORDERS OF THE GALLBLADDER

Gallbladder agenesis describes the congenital absence of the gallbladder. In the absence of congenital malformations of the intrahepatic biliary structures, this is an inconsequential abnormality.

Biliary atresia describes the congenital maldevelopment of intrahepatic biliary structures and is uncommonly encountered. Affected individuals are jaundiced and unthrifty at a young age. Prognosis is poor.

A bilobed gallbladder is occasionally identified in cats during ultrasonography or at surgery as an inconsequential abnormality.

Cystic mucosal hyperplasia of the gallbladder is also known as cystic mucinous hypertrophy, cystic mucinous hyperplasia, and mucinous cholecystitis (although it is not an inflammatory lesion). The role of steroid hormones in lesion induction remains unclear but is suspected. There is no associated inflammation, and the serosal surface of the gallbladder remains intact. These hyperplastic lesions are routinely identified in dogs with gallbladder mucocele, in which "cystic" structures are filled with tenacious viscoelastic mucin.

Gallbladder dysmotility is proposed as an emerging syndrome in dogs and may precede GBM development. The syndrome may be linked to steroid hormones, based on early observations of an apparent link between mucocele development and treatment with progestational compounds. Sex hormones (progestins, androgens) have been shown experimentally (in vitro) to reduce contractility of gallbladder smooth muscle in experimental animal models.

OTHER DISORDERS OF THE BILE DUCTS

Benign Hepatic or Biliary Cysts: These single cysts are often limited to one liver lobe, usually cause no substantial compressive injury, and are occasionally discovered serendipitously during ultrasonographic examinations for other disorders, at surgery, or at necropsy. They do not expand to damage adjacent tissues, are not associated with increased liver enzyme activity, and are considered inconsequential. However, they may be problematic if they enlarge or interfere with bile flow at the porta hepatis.

Hepatic Fibropolycystic Disorders: Hepatic fibropolycystic disorders are

congenital disorders that have been identified in dogs and cats and reflect embryologic malformations involving the ductal plate (portal triad). Ductal plate malformations (DPMs) reflect embryogenic malformations due to dysfunction of primary cilia causing defective tubulogenesis, affecting formation of bile ducts and renal tubules. Either or both organs may be affected. Fibropolycystic syndromes are divided into six categories in people, and this divisional classification also appears relevant to animals: 1) diffuse DPMs associated with increased deposition of extracellular matrix (congenital hepatic fibrosis) causing intrahepatic presinusoidal portal hypertension, 2) Caroli malformation causing sacculization of large intrahepatic or interlobular bile duct (may be associated with increased deposition of extracellular matrix), 3) von Meyenburg complexes representing microscopic isolated DPMs, 4) simple hepatic cysts, 5) choledochal cysts representing an appendix-like diverticulum from the extrahepatic bile duct that can act as an infection sump, and 6) biliary cystadenomas that likely represent expanding cystic malformations involving large biliary ducts usually located adjacent to the gallbladder and cystic duct. Different malformations can predispose to cholangitis, lead to prehepatic portal hypertension, or evolve into space-occupying cystic lesions. A single genetic mutation in cats (autosomal onset dominant polycystic kidney disease) can lead to biliary ductule malformations and hepatic fibrosis, which are commonly misidentified as advanced biliary cirrhosis subsequent to the feline cholangitis/ cholangiohepatitis syndrome. Most cats with this mutation demonstrate polycystic renal malformations rather than biliary malformations, although a small subset of cats develop diffuse fibropolycystic liver lesions. Multiple mutations have been identified to cause fibropolycystic malformations in people, and it is suspected that a similar spectrum of gene mutations also may underlie similar syndromes in dogs and cats. In some cats, many large hepatic cysts cause profound hepatomegaly, requiring repeated drainage, fenestration, marsupialization, or surgical resection. Uncommonly, cystic structures may become mineralized or complicated by formation of mineralized choleliths.

Cats with diffuse DPMs have islands of normal hepatic parenchyma segregated by bridging portal tracts that represent proliferative malformed bile ductules embedded in a complex of extracellular

matrix (dense fibrillar collagen). Extensive connective tissue causes intrahepatic portal hypertension, a firm large liver, development of APSSs, signs of HE, and ascites. Affected cats may present with increased liver enzyme activity (ALT, AST, ALP) due to low-grade inflammation or development of septic cholangitis or cholelithiasis. Most are not hyperbilirubinemic or jaundiced. Liver enzymes may be within the normal range, with diagnostic biopsy initiated by ultrasonographic findings.

Biliary dysplastic syndromes rarely occur in dogs concurrent with renal cystic malformations. However, DPMs are as commonly identified in dogs as in cats. Affected dogs may develop increased ALP activity and increased TSBA concentrations. As in cats, extensive connective tissue deposition in the portal tract can cause portal-to-portal bridging fibrosis, intrahepatic presinusoidal portal hypertension, APSSs, HE, and ascites.

The only treatment for DPM associated with bridging portal fibrosis is to palliate HE with protein-modified diets and efforts to alter the enteric microbial flora and pH (lactulose, milk, or low-dose metronidazole). Diuretics and dietary sodium restriction are used to control ascites. Similar syndromes in people are managed by liver transplantation.

Choledochal Cyst: Congenital, appendix-like cystic dilation of the extrahepatic bile duct is recognized uncommonly in cats. Clinical signs include fever, abdominal pain, and jaundice, associated with cyst infection, with the amotile cyst functioning as an infected sump. Surgical exploration is usually required for definitive diagnosis. Extirpation of the cystic malformation or its marsupialization into the common bile duct has been a successful treatment. Postoperative long-term antimicrobial therapy is guided by bile culture, cytology, and repeated ultrasonographic imaging.

Biliary Cystadenoma: These lesions, also termed cystadenomas, bile-duct adenomas, cholangiocellular adenomas, cystic cholangiomas, and hepatobiliary cystadenomas, are benign lesions most commonly encountered in older cats. Well-demarcated, single lesions often have a complex internal structure and may invade or compress adjacent hepatic parenchyma, causing compressive atrophy. Cyst contents range from clear, watery fluid to viscous or solid material; typically there are no bile acids or bilirubin. Cyst sizes vary, ranging

from 1 mm to 8 cm, with masses ranging from 5 mm to 12.5 cm. Imaging studies (ultrasonography or CT) are key to diagnosis.

Although surgical excision is the treatment of choice, this may not be possible if the structure integrates into the porta hepatis. However, because these lesions are often discovered serendipitously, surgical excision is commonly not indicated. Prognosis after complete cystadenoma excision is good; however, if surgical intervention is necessary and complete excision is not possible, partial resection may delay complications from mechanical invasion of normal tissue. Repeated aspiration, catheter drainage, marsupialization, and partial excision have been used for palliative management but carry risk of infections. Neoplastic transformation is also possible. Cystadenomas are usually difficult to aspirate owing to their complex internal structure.

EXTRAHEPATIC BILE DUCT OBSTRUCTION

Obstruction of the common bile duct is associated with a number of diverse primary conditions, including inflammation (eg, pancreatitis, duodenitis, duodenal foreign body, etc), cholelithiasis, gallbladder mucocele, choledochitis/cholecystitis, neoplasia, bile duct malformations, parasitic infection, extrinsic compression, fibrosis, and bile duct stricture. Hepatomegaly and distention of intrahepatic bile ducts promptly follow EHBDO. If obstruction resolves within a few weeks, resolution of fibrosis and bile duct distention can follow. However, obstruction for >6 wk results in persistent peribiliary fibrosis, connective tissue bridging between portal tracts, remodeling of the liver consistent with biliary cirrhosis, portal hypertension, and formation of APSSs.

Complete EHBDO may result in development of white bile within the bile duct or gallbladder, reflecting the absence of bilirubin pigments in bile; ie, bile cannot enter the distal "stagnant loop" of the ductal system or gallbladder (cystic duct occlusion). Increased ductal mucin contributes to duct distention and the color of luminal contents. In some cases, the biliary tree becomes colonized by bacteria, which are not cleared because of failed mechanical expulsion of bile and inadequate antibiotic penetration into bile.

Clinical Findings and Diagnosis: Acute complete EHBDO leads to lethargy, cyclic

fever, and prompt development of jaundice; total bilirubin concentration increases within 4 hr. Vomiting may be episodic. Some animals are intermittently inappetent, whereas others become polyphagic, reflecting fat maldigestion due to the lack of enteric bile acids and consequent fat malabsorption. Hepatomegaly, acholic feces, and the absence of urine urobilinogen (inconsistent) usually develop within the first week. Bleeding tendencies may be notable within 2–3 wk and are more common in cats and develop earlier. GI ulceration at the pyloric-duodenal junction is common and can lead to considerable blood loss. Even with miniscule enteric bleeding, bilirubin pigments gain access to the bowel, allowing feces to become brown (stercobilin formation) and urine to test positive for urobilinogen, negating the reliability of finding acholic feces and negative urine urobilinogen for EHBDO diagnosis.

The hemogram may reveal a nonregenerative anemia with chronic obstruction or a strongly regenerative anemia in animals with substantive enteric bleeding. A neutrophilic leukocytosis with or without a left shift is common. As bile stagnates in the biliary tree, serum ALT and AST activities increase. Serum ALP and GGT activities increase within 8–12 hr of obstruction and are substantial within a few days. Parenchymal necrosis, periductal inflammation, and cholestasis sustain serum transaminase and cholestatic enzyme activity. In cats, the magnitude of ALP and GGT are less dramatic than in dogs but nevertheless are useful indicators of biliary tree obstruction, injury, and inflammation. Hypercholesterolemia develops within 10–14 days of complete obstruction, reflecting impaired cholesterol elimination and possibly increased hepatic cholesterol biosynthesis. With chronic obstruction and development of biliary cirrhosis, serum cholesterol declines, reflecting impaired cholesterol synthesis and APSSs. Coagulopathies associated with vitamin K deficiency may develop within 2–3 wk in dogs and earlier (within 1 wk) in cats. Response to vitamin K₁ administration is usually dramatic. EHBDO is confirmed with ultrasonographic imaging and exploratory laparotomy.

Treatment: Surgical inspection of the liver and biliary structures and appropriate biliary decompression are requisites for optimal therapy. Gross inspection of the gallbladder and common bile duct usually reveals the site and cause of obstruction;

duct palpation is essential to identify intramural mass lesions. A grossly distended, tortuous common bile duct makes the diagnosis apparent. Gentle gallbladder compression is used to verify obstruction and the site of restricted bile flow. The most difficult obstructions to confirm and resolve involve hepatic ducts. A duodenotomy, cholecystotomy, or choledochotomy may be necessary for passage of a flexible catheter into the common bile duct to verify the site of obstruction and to allow removal of inspissated biliary sludge or choleliths. Successful treatment of biliary tract sepsis requires mechanical removal of biliary debris and infectious material and a decompressive maneuver often involving a surgical correction. Animals with biliary tree infections tend to become hypotensive and are susceptible to endotoxic shock during surgery and anesthesia, especially cats. Liver biopsy by percutaneous needle or laparoscopic methods does not allow safe biliary decompression and may lacerate distended bile ducts, leading to bile peritonitis; thus, laparotomy is the optimal managerial and assessment approach.

Controversy exists regarding the need for biliary tree decompression in animals with EHBDO secondary to pancreatitis. In most dogs, obstruction resolves spontaneously over several weeks as the inflammation resolves. In animals with obstruction persisting beyond 2–3 wk, temporary (stenting of the bile duct at the sphincter of Oddi) or permanent decompression of the biliary tree is usually considered. The risk of mortality in dogs with pancreatitis undergoing extrahepatic biliary surgery may be as high as 50%. Transhepatic ultrasound-guided aspiration of the gallbladder as a decompressive approach has been successfully completed in some affected animals but has high risk of focal or more generalized bile peritonitis.

CHOLELITHIASIS

Most choleliths in dogs and cats are clinically silent. Diagnosis of this disorder has increased subsequent to routine use of abdominal ultrasound as a diagnostic modality. Choleliths are more common in middle-aged to older animals, and incidence may be higher in small-breed dogs. Most choleliths in dogs and cats contain calcium carbonate and calcium-bilirubinate pigments and are considered “pigment stones.” However, many stones do not contain enough mineral for detection on survey radiographs. Pigment gallstones are

divided into two categories: "black-pigment" stones composed primarily of bilirubin polymers, reflecting prolonged hyperbilirubinemia, and "brown-pigment" stones composed predominantly of calcium bilirubinate, which are associated with bacterial infections and biliary stasis. Mucin production, enhanced by local inflammation and prostaglandins, entangles calcium bilirubinate and bilirubin polymers into cholelith aggregates. This process is augmented by gallbladder dysmotility and bile stasis.

Clinical Findings and Diagnosis: Cholelithiasis may be associated with vomiting, anorexia, jaundice, fever, and abdominal pain. However, many animals remain asymptomatic or display postprandial discomfort (eg, stretching, position of relief, changing postures, wandering, pacing). Laboratory features of cholelithiasis most commonly reflect related cholecystitis or choledochitis, or cholangitis (intrahepatic choleliths or hepatolithiasis). In animals with small duct lithiasis, clinicopathologic features reflect involvement of biliary structures (high ALP and GGT activities). Jaundice is only directly related to cholelithiasis associated with EHBDO or sepsis; thus, many animals with cholelithiasis are not hyperbilirubinemic. Cholelithiasis may develop secondary to infection, or stones may promote infection secondary to amechanical trauma derived from choleliths. Animals with DPMs, especially Caroli malformation (sacculation of large intrahepatic bile ducts) are predisposed to intrahepatic cholelithiasis and infection. High vigilance for signs of sepsis is warranted in any animal with cholelithiasis.

The hemogram may be normal or reflect inflammation or infection. A serum biochemical profile may be normal or reveal high cholestatic enzyme activity or evidence of obstructive jaundice. Ultrasonography can detect stones >2 mm in diameter in the gallbladder; however, both skill and luck are needed to recognize stones lodged in segments of the common bile duct or in the hepatic bile ducts. For animals with small duct cholelithiasis, biopsy and culture of liver tissue is necessary to identify underlying disease processes and associated bacterial infections.

Treatment: Medical treatment of cholelithiasis includes broad-spectrum antibiotics and a choleretic regimen of ursodeoxycholic acid at 15–25 mg/kg, PO, divided bid and given with food, and SAME at 20–40 mg/kg/day, PO, on an empty stomach. Liver biopsy determines whether

immunomodulatory therapy is appropriate. Vitamin E at 10 U/kg/day can be used for its antioxidant and anti-inflammatory effects.

Surgical intervention is necessary if choleliths are associated with cholecystitis, are causing cystic duct obstruction, or are occluding the common bile duct. Successful treatment of cholecystitis and cystic duct occlusion requires cholecystectomy and lavage of the common bile duct. The causal factors of cholelith formation must be carefully considered; retaining a diseased or dysmotile gallbladder imposes risk of recurrent lithiasis or necrotizing cholecystitis. In cases in which obstruction of the common bile duct is irresolvable, a cholecystoenterostomy is necessary, followed by longterm monitoring for septic cholangitis. Chronic pulsatile antimicrobial administration may be needed to control retrograde infections of the biliary tree thereafter. Biopsy of involved biliary structures and liver is essential to determine whether an underlying primary inflammatory, septic, or neoplastic disease is present and predisposing to cholelith formation. Tissue (liver, bile duct, gallbladder), bile, and cholelith nidus should be submitted for aerobic and anaerobic bacterial cultures.

Cholecystoduodenostomy and cholecystojejunostomy are the most common surgical procedures for biliary bypass in small animals. Cystoenteric anastomosis to the proximal duodenum is most physiologic, because it allows bile to enter the duodenum in a position that closely maintains normal physiologic responses in the proximal bowel to allow coordinated mixing of bile acids and pancreatic enzymes necessary for digestion and assimilation.

BILIARY TREE RUPTURE AND BILE PERITONITIS

Rupture of the common bile duct, cystic duct, hepatic ducts, or gallbladder is most often associated with cholelithiasis, necrotizing choledochitis or cholecystitis, blunt abdominal trauma, or neoplasia. In dogs, necrotizing cholecystitis most often occurs as a result of a mature gallbladder mucocele that stretches the gallbladder wall to the extent of causing ischemic necrosis. Regardless of cause, rupture of any portion of the biliary tree can lead to bile peritonitis. Clinical signs may be minimal early in the disease process, consisting only of inappetence and vague abdominal discomfort. With chronicity, free bile initiates an inflammatory reaction (chemical peritonitis), an abdominal effusion accumulates, and vivid jaundice develops.

Ultrasonography should guide collection of abdominal effusion as close to the biliary tree as possible, because this will increase detection of free and phagocytized bilirubin crystals and bacterial organisms. Abdominal adhesions develop with delay in diagnosis and complicate surgical remediation.

Surgical interventions are specific to the causal lesions and may involve biliary tree decompression, cholecystectomy, cholecystotomy, choledochotomy, biliary-enteric anastomosis, or bile duct stent insertion. A liver biopsy should be collected to identify antecedent or coexistent hepatobiliary disease. Portions of the ruptured structure, bile, and abdominal effusion should be sampled and cultured for aerobic and anaerobic bacteria. Affected tissue and adjacent and nonadjacent liver tissue should be biopsied. The abdominal cavity must be thoroughly lavaged with sterile warm saline to remove bile contamination. Antibiotic coverage against likely enteric opportunists (gram-negative bacteria) and anaerobic flora is recommended, eg, ticarcillin, piperacillin, third-generation cephalosporins, or enrofloxacin combined with metronidazole. Antimicrobial therapy should begin before surgery and, if sepsis is confirmed, continued for 4–8 wk. Antimicrobial selection should be guided initially by results of cytology and Gram staining, and adjusted based on results of culture and sensitivity. Animals with chronic jaundice should receive vitamin K₁ (0.5–1.5 mg/kg, IM or SC, bid for up to three doses) before surgical intervention. Fresh frozen plasma may be necessary to abate bleeding tendencies during emergency surgery. Antiemetics are recommended if the animal is vomiting; H₂-receptor antagonists are used if enteric bleeding is identified, because these act quickly. In animals with cholelithiasis and in dogs with gallbladder mucocele, hydrocholeresis (ursodeoxycholic acid and SAME) and antioxidants (vitamin E and SAME) are recommended postoperatively.

FELINE CHOLANGITIS/ CHOLANGIOHEPATITIS SYNDROME

Feline cholangitis/cholangiohepatitis syndrome (CCHS) is the most common acquired inflammatory liver disease in domestic cats. Both cholangitis and cholangiohepatitis are more common in cats than dogs. The anatomic difference between the biliary and pancreatic ducts in cats compared with dogs has long been considered an underlying risk factor. Feline

CCHS coexists with inflammatory processes in the duodenum, pancreas, and kidneys (chronic interstitial nephritis). Numerous concurrent conditions have been identified in cats with CCHS, whether the inflammatory infiltrate is predominantly neutrophilic (suppurative), lymphocytic or lymphoplasmacytic (nonsuppurative), or whether it actively involves bile duct destruction. Disorders associated with feline CCHS include bacterial infections (primary or chronic), septicemia, cholecystitis, cholelithiasis, EHBDO, trematode infestation, toxoplasmosis, inflammatory bowel disease, primary cholangitis, pancreatitis, neoplasia (eg, pancreatic or gallbladder or bile duct adenocarcinoma), biliary cystadenoma, and various ductal malformations (eg, choledochal cyst, diffuse ductal plate malformation [congenital hepatic fibrosis associated with polycystic liver malformation], Caroli malformation).

Liver lobe involvement in feline CCHS is variable, and the extent and severity of histologic lesions may not be fully ascertained on a single liver biopsy or with small tru-cut biopsies (eg, 18 gauge). Some biopsy sections may show modest or moderate periductal inflammation and hepatitis, whereas other liver lobes reveal complete elimination of bile ducts and lack active inflammation owing to loss of bile duct epitopes that may drive the inflammation. Cats with disease in multiple organ systems have significantly shorter survival times if untreated. However, because CCHS is slowly progressive, cats can survive several years beyond initial diagnosis without therapeutic interventions.

Suppurative CCHS causes the most overt clinical illness. These cats have a shorter duration of illness before presentation (<5 days), with young or middle-aged adults predominating (range 3 mo to 16 yr). Clinical signs include pyrexia, lethargy, dehydration, inappetence, vomiting, and variable jaundice. Many cats manifest abdominal pain, and some have palpable hepatomegaly. Clinicopathologic features are similar to those of other forms of CCHS, with moderate to marked increases in transaminases (ALT, AST) and more modest increases in ALP and GGT activities. Surprisingly, some cats lack cholestatic enzyme abnormalities. Most cats are hyperbilirubinemic, some have concurrent renal azotemia, and many demonstrate a left shift and toxic neutrophils on their leukogram. Concurrent HL may confuse initial assessments. Abdominal ultrasonography may reveal EHBDO; abnormalities

consistent with cholecystitis, choledochitis, pancreatitis, or inflammatory bowel disease; diffuse hepatic parenchymal hyperechogenicity consistent with HL; coarse parenchymal echogenicity; or no abnormalities. A coarse or heterogeneous hepatic parenchymal pattern sometimes recognized may reflect parenchymal inflammation and/or periductule or portal tract fibrosis and inflammation. Thoracic radiography often reveals a large sternal lymph node reflecting abdominal inflammation/sepsis.

Medical treatment is usually provided before surgical intervention (biliary decompression surgery for EHBD, cholecystectomy for cholecystitis, cholecystotomy for cholelithiasis) and liver biopsy. Disorders causing stasis of bile flow must be rectified, because they increase risk of opportunistic infection involving the biliary system. Aspiration or biopsy imprint cytology of liver and bile usually reveal bacterial organisms and suppurative inflammation. Gram-stain characterization of bacteria on cytologic specimens assists in selection of antimicrobial agents and may provide the only confirmation of bacterial infection. Cultures may be negative because of prior antibiotic administration or failure to culture for anaerobic bacteria. Commonly isolated bacteria include *Escherichia coli*, *Streptococcus*, *Clostridium*, *Bacteroides*, and *Actinomyces*.

Treatment involves broad-spectrum antimicrobials effective against anaerobic and gram-negative enteric opportunists, ursodeoxycholic acid, SAMe, vitamin E, water-soluble vitamins, enteral alimentation with a maximum-calorie diet formulated for cats, and judicious administration of fluids and electrolyte supplements to correct and maintain hydration and electrolyte status. Antioxidants are provided during critical illness by administration of N-acetylcysteine (140 mg/kg initial dose [10% solution in NaCl], 70 mg/kg thereafter, bid-tid, infused IV over 20 min through a 0.25- μ m filter); when oral administration is possible, SAMe is given by mouth. A combination of enrofloxacin, metronidazole, and ampicillin/sulbactam is often initially administered and adjusted based on culture and sensitivity reports from hepatobiliary or bile aspirates or tissue samples. Antimicrobial treatment should begin before surgical intervention (because sepsis compromises postoperative survival) and continue for 8–12 wk or until liver enzymes normalize. If liver enzymes remain increased, repeat ultrasonographic assessment is warranted to check for abnormalities involving biliary

structures, pancreas, or gut, or development of lymphadenopathy. Repeat aspiration cytology or liver biopsy may be necessary.

Feline lymphocytic portal hepatitis is a diagnosis demonstrating inflammatory infiltrates without tropism for bile ducts but showing single cell hepatocyte necrosis. It is presumed that many of these cats are responding to antigens or debris from the alimentary canal or reflect inflammatory cells delivered in the portal circulation. Otherwise, this diagnosis may represent mild lesions in cats with CCHS when only a few portal triads are sampled from a relatively uninvolved liver lobe. Low-yield needle biopsies from cats with nonsuppurative CCHS may generate this diagnosis. In some cats, however, an inflammatory portal tract infiltrate is associated with single cell hepatocyte necrosis, qualifying as a true portal hepatitis.

Nonsuppurative CCHS without destructive cholangitis is usually a T-cell or mixed T-cell with B-cell mediated inflammatory syndrome affecting middle-aged or older cats. Concurrent infection with feline leukemia virus or feline immunodeficiency virus is uncommon, and there is no gender or breed predisposition. Duration of illness ranges from 2 wk to several years, with most cats demonstrating signs of illness for several months before initial presentation. Clinical signs include intermittent vomiting and diarrhea and episodic illness characterized by anorexia or hyporexia, reclusiveness, or self-resolving jaundice. Hepatomegaly is common. It is uncommon for nonsuppurative CCHS to cause portal hypertension, APSSs, and abdominal effusion, because cats usually succumb to the effects of this syndrome before diffuse fibrosis evolves. Rather, cats with these features more likely have fibropolycystic biliary malformations (see p 477).

The hemogram is variable, commonly demonstrating poikilocytosis and Heinz bodies. The leukogram is variable but typically does not display a left shift or toxic neutrophils. Hyperglobulinemia develops with chronicity; most cats have moderate to marked increases in ALT and AST activities with widely variable ALP and GGT activities depending on cyclic activity of the disease process. Hyperbilirubinemia is inconsistent and also appears cyclic. Some cats are persistently jaundiced secondary to inflammatory obstruction or destruction of small and medium-sized bile ducts (nonsuppurative CCHS with destructive cholangitis); these often develop symptomatic coagulopathies responsive to vitamin

K administration. Abdominal ultrasonographic findings overlap with those of suppurative CCHS; a nonuniform or coarse parenchymal pattern may be identified. However, cats with marked nonsuppurative CCHS may lack ultrasonographic hepatic or biliary abnormalities. Severity of histologic lesions is highly variable within and between liver lobes and between cats.

Initial treatment consists of appropriate antimicrobials (*see above*), SAME, vitamin E, supplementation of B vitamins, enteral alimentation with a maximum-calorie diet formulated for cats, and fluids and electrolyte supplements to correct and maintain hydration and electrolyte abnormalities. Broad-spectrum antimicrobial coverage (against anaerobic and gram-negative enteric opportunists) is recommended pending liver biopsy and culture results. Longterm treatment requires immunomodulation. Ursodeoxycholic acid is used in cats lacking evidence of destructive cholangitis. However, ursodeoxycholic acid is no longer recommended for cats with destructive cholangitis based on evidence (experimental animal models, people with sclerosing cholangitis) that it may provoke small duct injury in destructive cholangiopathies. First-line immunosuppressive therapy is prednisolone, initially administered at 2–4 mg/kg ideal body weight, PO, daily, with the dose titrated to 5–10 mg/day, administered daily to every other day. Glucocorticoid dosing is titrated based on clinical assessments. Metronidazole (7.5 mg/kg, PO, bid) is also recommended to assist with immunomodulation and control of associated inflammatory bowel disease; adding this drug may allow reduction of the glucocorticoid dose. Continued administration of SAME (40–50 mg/kg/day, PO) and vitamin E (10 U/kg/day) is recommended.

As a single agent, SAME has reduced nonsuppurative CCHS-associated inflammation in a few studied cats. Chlorambucil (2 mg/cat/day, titrated to every other or every third day) is used in cats that do not respond to anti-inflammatory glucocorticoid and metronidazole therapy. Treatment usually returns bilirubin concentrations to normal, but cyclic increases in enzyme activity remain although at lower magnitudes.

Cats with **nonsuppurative CCHS with destructive cholangitis (sclerosing cholangitis)** can eventually develop widespread small duct destruction causing permanent hyperbilirubinemia and intermittent acholic feces due to a histologic progressive “ductopenia.” This subset of CCHS is confirmed by finding defining

histologic features that include the following: 1) infiltration of bile ductules with lymphocytes, 2) peripheralization of bile ductules to the margin of portal tracts, 3) evidence of involuting bile ducts, 4) lipogranulomas (when ducts have been eliminated), 5) scant lymphoid nodules (B cells) consistent with an inflammation, and 6) periductular sclerosing fibrosis without other features suggesting EHBDO. In some cases, confirmation of bile duct involution and peripheralization to the edge of portal tracts requires immunohistochemistry using a cytokeratin antibody. Marked differences between liver lobes in status of portal tract inflammation may be seen; in lobes with elimination of biliary ductules, inflammation can be mild or inapparent. Approximately 30% of cats with destructive cholangitis treated with glucocorticoids develop diabetes mellitus. Involvement of pancreatic ducts with the T-cell ductal targeting inflammation may influence this outcome.

Symptomatic ductopenic cats require once or twice weekly vitamin K₁ injections (*see p 439*) and water-soluble vitamin E (polyethylene glycol α -tocopherol succinate, 10 U/kg/day, PO). Overdosing vitamin K₁ can cause serious hemolytic anemia, and overdosing vitamin E can lead to insufficient vitamin K activity. Affected cats should be investigated for severe inflammatory bowel disease and B₁₂ adequacy. Hematology and serum biochemistry features are similar to those of cats with non-duct destructive CCHS. Immunomodulation with prednisolone does little to moderate enzyme activity or hyperbilirubinemia in destructive CCHS when used as monotherapy immunosuppression. Instead, methotrexate or chlorambucil are used initially with glucocorticoids. Pulsatile methotrexate is given at a total daily dose of 0.4 mg/cat divided into three treatments given on a single day (0.13 mg per dose, PO) once every 7–10 days. Alternatively, methotrexate may be given IV or IM with a 50% dose reduction. Folic acid, 0.25 mg/day, PO, is concurrently administered to prevent methotrexate-associated hepatotoxicity, GI toxicity, or hematopoietic effects. The dosage of methotrexate must be reduced in cats with renal azotemia. Methotrexate imposes profound immunosuppression at the recommended dosage, and careful monitoring for complicating infections is essential. Alternatively, treatment with chlorambucil, as described above, can be used instead of methotrexate. Concurrent treatment with SAME is recommended,

along with low-dose prednisolone and metronidazole. Treatment for concurrent inflammatory bowel disease with a hypoallergenic diet also may be beneficial. Cobalamin deficiency must be corrected, with cats chronically supplemented if deficiency is proved through laboratory testing. Low cobalamin concentrations should raise concern for severe small-bowel malabsorption (especially small-cell lymphoma) or severe pancreatic disease.

In lymphoproliferative disease masquerading as lymphocytic CCHS, lesions are characterized by dense portal lymphocyte infiltrates that penetrate hepatic sinusoids. However, involved lymphocytes lack convincing morphology for classification as a neoplastic population; this syndrome may represent a transition phase between conventional inflammatory disease and overt neoplasia. Treatment with chlorambucil has proved beneficial in some cats (2 mg/cat, given every other or every third day), combined with treatments previously described for CCHS. Affected cats may survive for several years with minimal clinical signs. Immunohistochemical staining and other molecular tests (investigation of clonality) may help differentiate this syndrome from lymphoma.

In small-cell lymphoma masquerading as lymphocytic CCHS, dense lymphocytic portal infiltrates penetrate hepatic sinusoids. However, this population of cells has morphology consistent with a diagnosis of small-cell lymphoma. Treatment with chemotherapy protocols for feline lymphoma is recommended, along with judicious administration of nutritional, vitamin, and antioxidant support. Many of these cats respond to chlorambucil, as described above, for several years. Affected cats may have concurrent intestinal involvement, although some cats with overt hepatic lymphosarcoma have inflammatory bowel disease, and some cats with overt enteric lymphosarcoma have non-neoplastic nonsuppurative CCHS. Evolution of chronic inflammation to a neoplastic process is suspected in each organ system.

HEPATOBIILIARY FLUKE INFECTION

Infection with liver flukes in endemic regions can cause acute and chronic cholangitis in cats and less frequently in dogs. The most common fluke infecting cats is *Platyosomum concinnum* in Florida, Hawaii, and other tropical areas. Infestation is acquired by ingesting an infected intermediate host, usually a lizard or frog;

~15%–85% of cats with access to intermediate hosts are infected in endemic areas. After infection, young flukes emerge in the intestines and migrate into the common bile duct, gallbladder, or hepatic ducts, where they mature within 8–12 wk. Embryonated eggs thereafter pass from bile into the alimentary canal, where they may be detected in feces as early as 12 wk after infection (sedimentation, Baermann test).

Clinical signs depend on severity of infection (parasite burden); however, most infested cats remain asymptomatic. Symptomatic cats demonstrate progressive illness characterized by progressive lethargy, fever, hepatomegaly, and abdominal distention. These cats may become jaundiced and emaciated secondary to anorexia, vomiting, and mucoid diarrhea. Chronic fluke infestation can be fatal in severely affected cats. First clinical signs develop between 7 and 16 wk of infection. In some cases, clinical signs resolve by 24 wk after infection without treatment. A circulating eosinophilia may develop 3–14 wk after infection and may persist. In heavily infected cats, ALT and AST activities may increase, while ALP activity may remain normal or only increase mildly. Hyperbilirubinemia may develop within 7–16 wk after infection.

Hepatic histologic lesions develop after 3 wk and are progressive in persistent infections. Inflammation and distention of large bile ducts is associated with mixed neutrophilic and eosinophilic inflammatory infiltrates. By 4 mo, severe adenomatous biliary hyperplasia and peribiliary inflammation are well established. By 6 mo, progressive fibrosis is obvious and evolves into biliary cirrhosis. Regional lymphadenopathy may be notable. Bile duct distention increases with growth of adult flukes, and when flukes become sexually mature, bile ducts become fibrotic. During this time, serum transaminase activities decline and may normalize. Abdominal ultrasonography may reveal apparent biliary obstruction involving the gallbladder, common bile duct, and/or intrahepatic ducts. Gallbladder debris associated with flukes may appear as oval hypoechoic structures having echoic centers. A thickened gallbladder wall associated with a double-rim sign may reflect cholecystitis. Hypoechoic hepatic parenchyma with prominent hyperechoic portal regions (ducts) reflects cholangitis and cholangiohepatitis.

Canine infection with *Heterobilharzia americana*, a schistosomal fluke, has also been characterized in dogs from Texas,

North Carolina, Louisiana, and Florida. Infection is acquired through skin penetration by cercariae released from snails. These forms migrate through the host as schistosomula, reaching the lungs within 5–9 days and liver within 7–45 days. Schistosomes grow and mature in liver, with adults migrating to mesenteric veins, where they release eggs and also proteolytic enzymes upon migration to the bowel lumen. Eggs provoke a granulomatous reaction. Healing of the host leads to scar formation and organ injury that can result in liver failure and GI malabsorption.

Clinical signs of illness in dogs with schistosomiasis may manifest as early as a few days to months after infection. Young adult dogs are more commonly affected. Common clinical features (in descending order) include lethargy, weight loss, vomiting, diarrhea, inappetence, hypercalcemia, PU/PD, and more rarely, melena. The most common hematologic findings are lymphopenia and mild to marked thrombocytopenia, with eosinophilia being uncommon. Schistocytes have been seen in some dogs, reflecting intravascular shearing injury of RBCs. Common serum biochemical features include modest azotemia (BUN and creatinine), hyperglobulinemia, total and ionized hypercalcemia, and hyperglobulinemia. Liver enzyme activity is variable. Hypercalcemia is thought to reflect granulomatous inflammation. Acquired immunodeficiency (neoplasia, drug therapy) may increase susceptibility to infection.

Because fluke-infected cats may remain asymptomatic, diagnosis can be difficult. Eggs may not be detected on fecal examination, because they are only sporadically passed and demonstrate variable morphology (immature and embryonated forms). Furthermore, fluke eggs are small, and

routinely used fecal methods are relatively insensitive for fluke egg detection. In addition, development of bile duct obstruction and fibrosis may impede passage of fluke eggs into bile and feces.

Suspected fluke infestation is treated with praziquantel (based on dosing extrapolated from experimentally infected animals and proved to control schistosome infection in dogs). Praziquantel at 20–25 mg/kg body wt, tid for 3 days, has been effective in some but not all treated animals. Eggs may continue to be passed in feces for up to 2 mo after successful treatment in cats, and reinfection may complicate assessment of treatment response. Some infected dogs have been treated with fenbendazole (50 mg/kg body wt/day, PO, for 10 days) with or without concurrent praziquantel administration. Prednisolone is used to reduce fluke-associated inflammation (2 mg/kg/day for 2–4 wk, tapered in 50% decrements every 2 wk). Ursodeoxycholic acid is recommended for bile duct-associated lesions given at 15–20 mg/kg, PO, divided bid and administered with food to initiate hydrocholeresis. Broad-spectrum antibiotic coverage is recommended to protect against secondary bacterial infections associated with migrating or dying flukes. Vitamin E (10 IU/kg/day, PO) and SAME (20–40 mg/kg/day, PO) are given until liver enzymes normalize. If necessary, an antiemetic can be administered, eg, metoclopramide (0.2–0.5 mg/kg, PO or SC, every 6–8 hr) or maropitant (1 mg/kg/day for no more than 5 consecutive days).

Treatment results are variable, but prognosis is favorable in mild fluke infestation. Other rare parasites of the biliary tract include *Amphimerus pseudofelineus*, *Metorchis conjunctus*, and *Eurytrema procyonis*. (See also HEPATIC FLUKES, p 427.) Similar assessment and treatment strategies are warranted.

OPHTHALMOLOGY

PHYSICAL EXAMINATION OF THE EYE

The initial examination of the eye should assess symmetry, conformation, and gross lesions; the eye should be viewed from 2–3 ft (~1 m) away, in good light, and with minimal restraint of the head. The anterior ocular segment and pupillary light reflexes are examined in detail with a strong light and under magnification in a darkened room. Baseline tests like the Schirmer tear test, fluorescein staining, and tonometry (intraocular pressure measurement) may be followed by ancillary tests such as taking corneal and conjunctival cytology and cultures, everting the eyelids for examination, and flushing the nasolacrimal system to evaluate the external parts of the eye, including the anterior segment. Diseases of the vitreous and ocular fundus are evaluated by direct and indirect ophthalmoscopy (usually performed after inducing mydriasis) and vision testing (menace reflex, obstacle course, dazzle reflex, etc).

Schirmer tear tests and cultures should be performed before topical anesthetic is instilled. Fluorescein staining and eversion of the eyelids do not require topical anesthesia, but tonometry, examination of the bulbar surface of the nictitating membrane, conjunctival and corneal cytology, gonioscopy, and lavage of the

nasolacrimal system usually do. To avoid false-positives, samples for corneal and conjunctival cytology that will be analyzed by fluorescent antibody procedures should be collected before topical fluorescein staining.

Special examinations such as slit-lamp biomicroscopy, ultrasonography, fluorescein angiography, and electroretinography may require sedation or local, regional, or general anesthesia, depending on the species.

EYELIDS

The eyelids consist of four parts: 1) the outer very thin and mobile skin; 2) the strong and encircling orbicularis oculi muscle anchored at the medial canthus; 3) the thin and poorly developed fibrous tarsus, which contains the sebaceous Meibomian glands and attaches the lid to the bony orbital rim; and 4) the thin and flexible palpebral conjunctiva, which continues to the conjunctival fornix or conjunctival cul-de-sac. Eyelid disorders may be associated with facial and orbital abnormalities, specific breeds, and adjunct skin diseases, as well as with many systemic diseases.

Conformational Abnormalities

Entropion is an inversion of all or part of the lid margins that may involve one or both

The eye and eyelids, median section. Illustration by Dr. Gheorghe Constantinescu.

eyelids and the canthi. It is the most frequent inherited eyelid defect in many canine and ovine breeds and may also follow cicatrix formation and severe blepharospasm due to ocular or periocular pain. Inversion of the cilia (or eyelashes) or facial hairs causes further discomfort, conjunctival and corneal irritation, and if protracted, corneal scarring, pigmentation, and possibly ulceration. Early spastic entropion may be reversed if the inciting cause is quickly removed or if pain is alleviated by everting the lid hairs away from the eye with mattress sutures in the lid, by subcutaneous injections (eg, of procaine penicillin) into the lid adjacent to the entropion, or by palpebral nerve blocks. Temporary stay sutures or surgical staples left in place for 2–3 wk may be used to treat entropion in very young puppies. Established entropion usually requires surgical correction.

Ectropion is a slack, everted lid margin, usually with a large palpebral fissure and elongated eyelids. It is a common bilateral conformational abnormality in a number of dog breeds, including the Bloodhound, Bull Mastiff, Great Dane, Newfoundland, St. Bernard, and several Spaniel breeds. Contracting scars in the lid or facial nerve paralysis may produce unilateral ectropion in any species. Conjunctival exposure to

environmental irritants and secondary bacterial infection can result in chronic or recurrent conjunctivitis. Topical antibiotic-corticosteroid preparations may temporarily control intermittent infections, but surgical lid-shortening procedures are often indicated. Mild cases can be controlled by repeated, periodic lavage with mild decongestant solutions.

Lagophthalmos is an inability to fully close the lids and protect the cornea from drying and trauma. It may result from extremely shallow orbits (in brachycephalic breeds), exophthalmia due to a space-occupying orbital lesion, or facial nerve

Bilateral entropion, Shar Pei puppy. Courtesy of K. Gelatt.

paralysis. Corneal scarring, pigmentation, and ulceration usually result. Unless the cause can be corrected, the therapy is frequent topical lubrication and surgical shortening or closure of the lateral canthi either temporarily or permanently. Excessive nasal skin folds and facial hair may aggravate the damage caused by lagophthalmos.

Abnormalities of the cilia include extra (distichia) or misdirected eyelashes on the lid margin. Epiphora, corneal vascularization, and corneal ulceration and scarring may result. In many instances, anomalous cilia are very fine, the same color as the surrounding eyelid hair, and result in neither clinical signs nor damage. However, ectopic cilia protruding through the dorsal palpebral conjunctiva can cause profound pain. If the corneal or conjunctival damage is caused by the extra cilia, excision, cautery, or cryotherapy of the cilia follicles is indicated. Anomalies of the cilia are common and probably inherited in some dog breeds but are rare in other animal species. Distichiasis is not treated unless corneal and/or conjunctival disease results. Successful removal of distichia requires destruction of the follicular base of the eyelids while not injuring the eyelid margin. The most popular method is cryotherapy applied at the base of the cilia beneath the palpebral conjunctiva at the eyelid margin. Depigmentation of the eyelid margin may result after cryotherapy but usually re-pigments in the subsequent months. Inadequate cryotherapy can result in distichia recurrence.

Inflammation

Blepharitis (inflammation of the eyelids) can result from extension of a generalized dermatitis, conjunctivitis, local glandular infections, or irritants such as plant oils or solar exposure. The lids can be the original site of involvement for agents that lead to a generalized dermatitis. Dermatophytes (all species), *Demodex canis* (dogs), *D cati* or *D gatoi* (cats), and bacteria such as staphylococci often are involved. The mucocutaneous junction of the skin and conjunctiva can be the site of lesions of immune-mediated diseases such as pemphigus. Skin scrapings, cultures, and biopsies may be required for an accurate diagnosis. Localized glandular infections may be acute or chronic (stye [glands of Zeis and Moll] and chalazion [Meibomian glands]).

In generalized blepharitis, systemic therapy often is indicated in addition to topical treatment. Supportive therapy of hot packing and frequent cleansing is indicated in acute cases. Nonophthalmic preparations can be used to treat the eyelids, but caution in application is indicated to avoid corneal and conjunctival contact and possible irritation.

NASOLACRIMAL AND LACRIMAL APPARATUS

The tear production and drainage system is vital for health of the outer eye. Tear glands within the orbit (lacrimal and in some species Harder gland) as well as the superficial tear gland of the nictitating membrane (third eyelid) produce the collective precocular or precorneal tear film. This film consists of three layers: outer lipid (from the Meibomian glands), middle aqueous layer (from lacrimal and third eyelid glands), and deep layer (mucus) from the goblet cells within the conjunctiva.

The tear drainage system consists of two lacrimal puncta (except in the rabbit and pig, which have only one punctum), two canaliculi, the lacrimal sac (within the bony lacrimal fossa), and the long and often tortuous lacrimal duct (to empty tears within the forward nasal cavity).

Hypertrophy, inflammation, and prolapse of the gland of the nictitating membrane (**cherry eye**) is common in young dogs and certain breeds (eg, American Cocker Spaniel, Beagle, Lhasa Apso, Pekingese, English Bulldog). In the acute stage, the red glandular mass swells and protrudes over the leading margin of the nictitans, and there is a mucopurulent discharge.

Although the swelling may recede for short periods, the gland eventually often remains prolapsed. Because it is a major tear gland, it should be preserved if possible; the gland should be replaced and anchored with sutures to the orbital rim, periorbital fascia, or nictitans cartilage, or covered with adjacent mucosa (envelope or pocket techniques). Partial excision should be avoided. Complete excision may predispose to keratoconjunctivitis sicca (see p 492) in 30%–40% of dogs in later life. Surgical or medical resolution of cherry eye still predisposes ~20% of these dogs to future keratoconjunctivitis sicca. Therefore, these dogs should be monitored for several years after undergoing surgery.

Lacrimal apparatus, dog. Illustration by Dr. Gheorghe Constantinescu.

Dacryocystitis (inflammation of the lacrimal sac) usually is caused by obstruction of the nasolacrimal sac and proximal nasolacrimal duct by inflammatory debris, foreign bodies, or masses pressing on the duct. It results in epiphora, secondary conjunctivitis refractory to treatment, and occasionally a draining fistula in the medial lower eyelid. Irrigation of the nasolacrimal duct reveals an obstruction of the duct, reflux of mucopurulent discharge from the lacrimal puncta, or both. Radiographs of the skull after injection of contrast material into the duct (dacryocystorhinography) may be necessary to establish the site, cause, and prognosis of chronic

obstructions. Therapy consists of maintaining patency of the duct and instilling topical antibiotic solutions. Tubing (polyethylene or silicone) or 2-0 monofilament nylon suture temporarily catheterized in the duct may be necessary to maintain patency during healing. When the nasolacrimal apparatus has been irreversibly damaged, a new drainage pathway can be constructed surgically (conjunctivorhinostomy or conjunctivoranolostomy) to empty tears into the nasal cavity, sinus, or mouth.

Imperforate lacrimal puncta are an infrequent cause of epiphora in young dogs. In foals, atresia of the nasal (distal) end of the nasolacrimal duct is a common

Bilateral inflammation and prolapse of the nictitating membrane (cherry eye), young Boston Terrier. Courtesy of K. Gelatt.

Exposure of inflamed, prolapsed nictitating membrane using thumb forceps, Boston Terrier. Courtesy of K. Gelatt.

cause of early epiphora and chronic conjunctivitis. In calves, multiple openings of the nasolacrimal duct may empty tears onto the lower eyelid and medial canthus, causing chronic dermatitis. Therapy in dogs and foals consists of surgically opening the blocked orifice and maintaining patency by catheterization for several weeks during healing.

Keratoconjunctivitis sicca (KCS) is due to an aqueous tear deficiency and usually results in persistent, mucopurulent conjunctivitis and corneal ulceration and scarring. KCS occurs in dogs, cats, and horses. In dogs, it is often associated with an autoimmune dacryoadenitis of both the lacrimal and nictitans glands and is the most frequent cause of secondary conjunctivitis. Distemper, systemic sulfonamide and NSAID therapy, heredity, and trauma are less frequent causes of KCS in dogs. KCS occurs infrequently in cats and has been associated with chronic feline herpesvirus 1 infections. In horses, KCS may follow head trauma.

Topical therapy consists of artificial tear solutions, ointments, and, if there is no corneal ulceration, antibiotic-corticosteroid combinations. Lacrimogenics such as topical cyclosporin A (0.2%–2%, bid), tacrolimus (0.02%, bid), or pimecrolimus (1%) may increase tear production; cyclosporine increases tear formation in ~80% of dogs with Schirmer tear test values ≥ 2 mm wetting/min. Ophthalmic pilocarpine mixed in food may be useful for neurogenic KCS (dogs 20–30 lb [10–15 kg] should be started on 2–4 drops of 2% pilocarpine, bid). Mucolytic agents (eg, 10% acetylcysteine) lyse excess mucus and restore the spreading ability of other topical agents. In chronic KCS refractory to medical therapy, parotid duct transplantation is indicated. In general, canine KCS requires longterm (often for life) topical lacrimogenic therapy.

CONJUNCTIVA

The conjunctiva consists of the palpebral conjunctiva (lining the posterior eyelids), the fornix or conjunctival cul-de-sac where the palpebral and bulbar conjunctiva connect, and the bulbar conjunctiva (covering the anterior globe or episclera) and nictitating membrane. The conjunctiva has important roles in tear dynamics, immunologic protection, ocular movement, and corneal healing. Because it is loosely attached to the episclera, the bulbar conjunctiva is a useful tissue to graft to weakened, ulcerated corneas.

Subconjunctival hemorrhage may arise from trauma or blood dyscrasias, von Willebrand factor deficiency, and certain infectious diseases. It does not require therapy, but close inspection is warranted to determine whether more important intraocular alterations have occurred. If definite evidence or history of trauma is not present, then systemic examination is indicated to determine the cause of the spontaneous hemorrhage.

Chemosis, or conjunctival edema, is seen to some degree in all cases of conjunctivitis, but the most dramatic examples are seen with trauma, hypoproteinemia, allergic reactions, and insect bites. The latter are treated with topical corticosteroids and usually resolve rapidly. Specific therapy for the etiologic agent is indicated.

Conjunctivitis is common in all domestic species. Primary infectious conjunctivitis caused by different bacteria, viruses, mycoplasma, fungi, and parasites affect several species. The etiologic agents vary from infectious to environmental irritants. The signs are hyperemia, chemosis, ocular discharge, follicular hyperplasia, and mild ocular discomfort. The appearance of the conjunctiva usually is not sufficiently distinctive to suggest the etiologic agent, and specific diagnosis depends on history, physical examination, conjunctival scrapings and culture, Schirmer tear test, and occasionally biopsy. Unilateral conjunctivitis may result from a foreign body, dacryocystitis, or keratoconjunctivitis sicca (see above). In cats, feline herpesvirus 1 (FHV-1), *Mycoplasma*, or *Chlamydia psittaci* may produce conjunctivitis that begins in one eye and becomes bilateral after ~1 wk. Specific diagnosis is made most rapidly by demonstrating the inclusions or the agent in conjunctival scrapings. Bilateral conjunctivitis is common in viral infections in all species. Herpesviruses produce conjunctivitis in cats, cattle, horses, and pigs. Purulent discharge indicates a bacterial component, but this may be opportunistic because of debilitation of the mucous membrane. Environmental irritants and allergens are common causes of conjunctivitis in all species. If a mucopurulent exudate is present, topical antibiotic therapy is indicated but may not be curative if other predisposing factors are involved. Mechanical factors such as foreign bodies, environmental irritants, parasites, and eyelid conformational defects should be removed or corrected. Selected antibiotics are indicated for

chlamydial and mycoplasmal infections; topical antiviral preparations (eg, 1% idoxuridine, 3% adenine arabinoside, or 1% trifluorothymidine (often instilled tid-qid and administered for 7–14 days) are indicated for herpesvirus infections when both the cornea and conjunctiva are involved. Oral supplementation in cats with 250–500 mg of L-lysine daily (often placed in the treats) may reduce the severity and frequency of recurrence of FHV-1 conjunctivitis and keratitis.

CORNEA

The size of the nearly round to oval cornea (vertical/horizontal) varies by animal species: dog (8.5 × 9.5 mm), cat (8.4 × 8.9 mm), horse (16.6 × 17.9 mm), and cow (15.2 × 16.4 mm). The animal cornea consists of the superficial epithelium and basement membrane, large and relatively acellular stroma, deeper Descemet membrane, and deep single layer endothelium. The cornea maintains a strong and durable barrier between the eye and environment, as well as a transparent medium to permit passage of light and images into the posterior segment. Corneal diseases are common in most animal species and fortunately can be treated successfully by medical, surgical, or a combination of these methods. The accessibility of the cornea permits several detailed and noninvasive diagnostic techniques.

Superficial keratitis is common in all species and is characterized by corneal vascularization and opacification, which may be due to edema, cellular infiltrates, pigmentation, or fibroplasia. If ulceration is present, pain—manifest by epiphora and blepharospasm—is an outstanding sign. Unilateral keratitis frequently is traumatic in origin. Mechanical factors, such as lid conformational defects and foreign bodies, should always be eliminated as possible causes, because improvement will not occur until they are resolved. Ulcerative keratitis may be complicated by secondary invasion by bacteria and, in horses, by saprophytic fungi. Bilateral superficial keratitis may be immune-mediated or associated with a lack of tears, eyelid conformational defects, or infectious agents.

Pannus, or Ueberreiter disease, is a specific, bilateral, progressive, proliferative, chronic, superficial keratitis that begins laterally and/or medially at the limbus and eventually extends from all quadrants to cover the cornea. Inflammatory cells (lymphocytes and plasma cells) infiltrate the cornea from the limbus, accompanied

Chronic superficial keratitis, early, German Shepherd. The cornea is progressively infiltrated with superficial blood vessels, followed by inflammation (lymphocytes and plasma cells), and lastly pigmentation.

Courtesy of K. Gelatt.

by superficial blood vessels. This immune-mediated keratitis is common in German Shepherds, Belgian Tervurens, Border Collies, Greyhounds, Siberian Huskies, and Australian Shepherds. Specific therapy consists of topical antibiotics, antiviral or antimycotic agents when appropriate, removal of any mechanical irritants, tear replacement when deficient, and corticosteroids or cyclosporine A (or both) when immune-mediated. The latter may need to be continued indefinitely and the frequency varied depending on the response. Chronic superficial keratitis when immune-mediated is a lifelong disease, requiring lifelong topical anti-inflammatory therapy. The disease appears more aggressive in young dogs and in dogs that live outside in higher altitudes. Generally, topical 1% prednisolone, 0.1% dexamethasone, or 0.2%–1% cyclosporine instilled in both eyes bid-qid is sufficient to control the disease and prolong vision. The intensity of the inflammatory response in both eyes is quite variable and may change by age, season, amount of time the dog spends outside, and other factors. To minimize costs and adverse effects, but control the disease, topical therapy is adjusted to the individual animal (topical therapy ranges from one drop in the affected eye every other day to as frequent as one drop in the affected eyes qid).

Interstitial keratitis is a deep involvement of the corneal stroma that represents one of the clinical signs associated with all chronic and many acute cases of anterior uveitis. The corneal vascularization is less branching, finer, and deeper than in superficial keratitis; if the endothelium has been disrupted, corneal edema is often marked. Systemic diseases, such as infectious canine hepatitis, bovine malignant catarrhal fever, systemic mycoses in many species, and neonatal

septicemias that localize in the eye, can cause bilateral or unilateral interstitial keratitis. Therapy is directed at the anterior uveitis, the systemic infection, or both. A specific, nonulcerative, peripheral, stromal keratitis and persistent anterior uveitis (keratouveitis) occurs in horses; prognosis and response to treatment are poor.

Ulcerative keratitis may be divided based on onset, depth, and position within the cornea. Ulcerative keratitis (based on depth) may be superficial, deep, deep with descemetocoele, or perforating. Progression of the corneal ulcer is based on the microbes involved and on the release of microbe and tissue enzymes that digest the corneal stroma. Pain, corneal irregularity, edema, and eventually vascularization are signs of ulceration. A dense, white infiltrate at the ulcer margin indicates strong leukotaxis and bacterial involvement. To detect small ulcers, topical fluorescein may be required. In dogs and horses, most ulcers are mechanical in origin; in cattle, sheep, goats, cats, and reindeer, infectious agents and mechanical causes are important; in cats and horses, herpesvirus infection is a frequent cause. All ulcers have the potential for secondary bacterial contamination as well as endogenous proteinase "melting" of the stroma. Therapy for superficial ulcers is usually medical and consists of topical broad-spectrum antibiotic(s) administered 3–6 times daily, correction of any mechanical factors, and limited 1% topical atropine to maintain iridocycloplegia and reduction of ocular pain. Adverse effects of atropine-induced reduced tear production in all species and colic in horses must be considered. Antiproteinase therapy for melting stromal ulcers includes topical serum and other drugs, and for acute ulcerations they may be instilled 4–6 times daily for the first several days. Corneal healing is monitored by frequent clinical examinations and gradual reduction in the size of the fluorescein retention by the nonepithelialized ulcer.

Syndromes of very slow-healing and recurrent superficial ulcers occur in dogs, cats, and horses; in dogs, they may be due to basement membrane disease causing faulty attachment of the corneal epithelium, whereas in cats and horses, and recently in dogs, herpesvirus should be suspected. Initial therapy is ulcer debridement followed by topical antibiotics and atropine. For refractory cases in dogs, multiple punctures or cross-hatching (punctate and grid keratotomies) of affected corneas with a 22-gauge needle stimulates most indolent

ulcers to heal within 7–10 days. Early reports suggest these keratotomies in cats may predispose to corneal sequestration and should be used with great care. Nictitating membrane flaps (or soft contact lenses or collagen shields) act as a pressure bandage and often are therapeutic for shallow ulcers. Medical treatment of deep ulcers is similar to that of superficial ulcers, but many deep ulcers also require conjunctival grafts to strengthen and maintain the integrity of the cornea.

Corneal sequestration and keratitis appear to be unique to the cat. It occurs in all breeds of cats but may be more frequent in the Siamese, Persian, and Himalayan breeds. Initially, a very small dark area develops within the anterior stroma and under intact corneal epithelium (that stains with rose Bengel and occasionally very faintly with topical fluorescein). Eventually, the stromal spot becomes larger and either dark brown or black, and is not covered by epithelium. There is variable pain and a central to paracentral, brown to black opacity composed of necrotic stroma, vascularization, and surrounding inflammation. Spontaneous extrusion may occur, especially with superficial sequestra. Treatment consists of superficial keratectomy of the entire sequestrum, that, with deeper lesions, is covered with conjunctival grafts.

Corneal stromal abscesses in horses may be sequelae of healing corneal ulcers or defects and the trapping of bacteria or fungal organisms (or both) within the stroma after reepithelialization. Recently, fungi (both *Candida* and *Aspergillus*) have been demonstrated in horses' subepithelial cornea devoid of iridocyclitis, suggesting another mode of entry. A variable, white to yellow, stromal infiltrate is surrounded by

Corneal sequestrum, domestic cat. Courtesy of K. Gelatt.

an intense stromal keratitis and vascularization and a variable but sometimes intense anterior uveitis. At least seven to nine different species of fungi have been isolated in corneal ulcers and stromal abscesses in horses, but *Aspergillus* and *Fusarium* spp are the most frequent isolates. Treatment consists of intensive topical and occasional systemic antibiotics (and if indicated, antifungals), iridocycloplegics, NSAIDs, and often surgical removal of the abscess with conjunctival and tectonic corneal grafts.

Corneal dystrophies and degenerations occur frequently in dogs, infrequently in cats, and rarely in horses. Corneal dystrophies are bilateral and often thought inherited in dogs. The appearance of these two diseases may be divided into the following categories: 1) part of cornea affected (epithelium, stroma [anterior, middle, and deep], and endothelium), 2) area of the involved cornea (central, paracentral, and limbal), and 3) possible cause (primary/inherited or secondary). Corneal dystrophies may affect the epithelium and endothelium but appear clinically to involve the stroma most frequently. The corneal degenerations are secondary to other ocular disease or systemic conditions.

Corneal dystrophies affecting the epithelium are associated with recurrent corneal erosions in dogs. The defective corneal epithelium fails to normally adhere to its defective basement membrane and results in recurrent superficial erosions (more frequent in the Boxer breed) and prolonged healing.

The stromal dystrophies appear as white, irregular deposits within the different depths of the stroma and are sometimes labeled corneal lipidosis. Corneal dystrophies are most frequent in dogs, appear inherited in ~20 breeds, affect mostly the corneal stroma, and are usually bilateral. Of the breeds affected, the Siberian Husky corneal stromal dystrophy has been investigated in the greatest detail. Most often, the corneal opacities consist of triglycerides and both intracellular and extracellular cholesterol. Treatment is not usually necessary unless vision is impaired or the deposits become irritating. For these lipid deposits to be viewed histologically, the corneas must be processed as frozen sections and alcohol dehydration processing avoided.

The corneal endothelial dystrophies occur in dogs and rarely in cats (Manx breed). In dogs, it primarily affects older Boston Terriers, Chihuahuas, and Dachshunds.

Female Boston Terriers are affected more frequently than males (with a mean age of ~7.5 yr), and this breed's disease has both clinical and histopathology similarities to those of Fuch corneal endothelial dystrophy in people. With the dystrophic and degenerating endothelium, progressive but painless bilateral corneal edema develops starting centrally. With extensive and full-thickness corneal edema, corneal epithelial bullae may develop and are quite painful. Treatment of early cases before complete corneal involvement consists of topical hyperosmotics (2%–5% sodium chloride or 40% glucose) applied frequently and, for advanced cases, thermokeratoplasty (Salaras procedure) or full-thickness (penetrating) keratoplasty.

Corneal degenerations are often unilateral and usually secondary to ocular or systemic diseases. Deposits of triglycerides, cholesterol, and also calcium are present in corneal degenerations. Corneal degeneration may be associated with other ocular diseases, such as corneal ulcerations, phthisis bulbus, lagophthalmos, and prolonged NSAID therapy. If associated with hyperlipoproteinemias or hypercholesterolemia and high-fat diets, corneal degenerations can affect both eyes, and these deposits are usually associated with corneal vascularization. They also can be altered by significant changes in diet. Baby rabbits or puppies fed whole cow milk may develop extensive lipid deposits in the corneal stroma sufficient to impair vision. Treatment for most corneal degenerations is not usually necessary, unless related to dietary or systemic diseases.

ANTERIOR UVEA

The anterior uvea consists of the iris, ciliary body, and anterior chamber (or iridocorneal) angle. The iris provides most of the eye color as well as an aperture (pupil) to regulate the amount of light that enters the eye and posterior segment. Pupil shape varies widely among animal species, including circle, vertical slit, horizontal oval, square, or even multiple pupils. The ciliary body processes provide most of the aqueous humor to nourish the anterior segment and remove its metabolic wastes, as well as the outflow channels (anterior chamber angle) for aqueous humor to reenter the venous system. The ciliary body musculature also regulates lens curvature (accommodation), which is more limited in domesticated animals than in people. The ciliary body continues posteriorly as the choroid, and diseases of the iris and ciliary body also often

involve the choroid. Diseases of the anterior uvea are common in domestic animals.

Persistent pupillary membranes are remnants of the normal prenatal vascular network that fills the pupillary region. Persistence of pigmented strands across the pupil from one area of the iris to another, or to the lens or cornea, is not uncommon in dogs and occurs occasionally in other species. In Basenjis, the condition is inherited.

Atrophy of the iris is common in older dogs and may involve the pupillary margin or the stroma. Atrophy of the pupillary margin creates a scalloped border and a weakening of the sphincter muscle, which is manifest as a moderately dilated pupil(s) or by sluggish pupillary light reflexes and increased sensitivity to bright illumination. Stromal atrophy results in dramatic holes in the iris and, often, displacement of the pupil. Neither form of atrophy appears to affect vision. Animals lacking a functional iridal sphincter may show increased sensitivity to bright light.

Iridic cysts are seen in dogs, cats, and horses. In dogs, they usually are free-floating, pigmented spheres in the aqueous humor within the pupil and anterior and posterior chambers. Although innocuous in most breeds of dogs, anterior uveal cysts (iris and ciliary body) in Golden Retrievers and Great Danes are associated with exfoliation of pigmented cells, chronic uveitis, glaucoma, and cataract formation. In cats, the cysts frequently are not usually free-floating but attached at the pupillary margin. In horses, they are present in the stroma of the iris and more frequently involve blue irides. Because vision is infrequently impaired, therapy is rarely necessary, but aspiration or noninvasive laser-induced deflation can be performed. Transillumination will usually demon-

strate their cystic nature and differentiate them from neoplasms. Enlarged and cystic dorsal corpora nigra may impair vision and mimic iridic melanomas in horses. Surgical excision or aspiration may be indicated.

Iris colobomas are rare in animals but occur occasionally in Australian Shepherds. They are usually in the upper iris, mainly in heterochromic irides, and cause an irregularity to the pupil. Viewed closely, the defect involves the iridal anterior stroma and apparently the sphincter muscle, but the pigment layer is present.

Anterior uveitis, or iridocyclitis, when acute, is manifest by miosis, increased protein and cells in the anterior chamber (aqueous flare), low intraocular pressure, bulbar conjunctival hyperemia, iridal swelling, photophobia, and blepharospasm. Secondary glaucoma, cataract, and corneal opacification may be complications.

Concurrent posterior uveitis or choroiditis is frequent. Causes of anterior uveitis can be separated into exogenous and endogenous. Penetrating and nonpenetrating trauma and, rarely, intraocular neoplasms or intraocular helminths are causes of unilateral uveitis. Common causes of bilateral uveitis include immune-mediated diseases and infectious diseases such as infectious canine hepatitis, feline infectious peritonitis, feline leukemia, feline immunodeficiency, feline toxoplasmosis, systemic mycoses in dogs and cats, canine brucellosis, leptospirosis in horses, bovine malignant catarrhal fever, infectious bovine rhinotracheitis, equine viral arteritis, classical swine fever, canine ehrlichiosis, and neonatal bacterial infections (joint, navel, and gut) of calves, lambs, kids, and foals. Recurrent uveitis that is at least in part immune-mediated affects horses (periodic ophthalmia or recurrent uveitis) and dogs (panuveitis with dermal depigmentation or uveodermal syndrome). Recurrent and chronic anterior uveitis are most often associated with complications and can produce secondary cataract formation with posterior synechiae, and glaucoma. A thorough history; examination of the cornea for injuries; physical examination; serum serology; and centesis of the aqueous for culture, serology, and cytology aid in diagnosis.

Nonspecific therapy consists of topical mydriatics to maintain pupillary dilation and movement, topical corticosteroids (if nonbacterial), a darkened environment, and prostaglandin inhibitors (such as aspirin, flunixin meglumine, or phenylbutazone). If bacterial in origin, topical, systemic,

Persistent pupillary membranes, cat. Courtesy of K. Gelatt.

and perhaps intraocular antibiotics are indicated. Treatment of immune-mediated processes may require systemic or subconjunctival as well as topical corticosteroids and oral azathioprine.

Hyphema or hemorrhage in the anterior chamber has several clinical appearances, including the following: 1) small, focal blood clots suspended within the anterior chamber or adhered to the posterior cornea, iris, or anterior lens capsule; 2) diffuse, unclotted hemorrhage throughout the entire anterior chamber, occluding deeper eye examination and vision; and 3) multiple layers of recurrent or chronic unclotted hemorrhage (the oldest is a purple or black layer in the bottom of the anterior chamber and the most recent hemorrhage is the dorsal bright red layer). Causes of hyphema include uveitis, trauma, intraocular neoplasia, retinal detachments and retinal tears, systemic hypertension, coagulation factor abnormalities, platelet disorders, hyperviscosity, congenital ocular anomalies, anterior segment neovascularization, and glaucoma. Resolution of hyphema requires exit of intact RBCs through the aqueous humor outflow channels.

Acute hyphema generally has a good prognosis provided the cause is identified and treated. Recurrent and/or chronic hyphema has a poor to guarded prognosis, because secondary glaucoma or phthisis bulbus is likely. No drugs have been proved to facilitate resolution of hyphema, but intracameral tissue-plasminogen activator (TPA) can dissolve fibrin that is <10–14 days old and release the entrapped RBCs within the anterior chamber. TPA does not prevent future fibrin formation, but topical and systemic corticosteroids may.

GLAUCOMA

The glaucomas are generally related to reduced outflow of aqueous humor through the trabecular meshwork of the anterior chamber or iridocorneal angle (conventional outflow, ~85%), and through the uveoscleral network (through the ciliary body and subsclear space, ~15%). Excessive production of aqueous humor in people appears to be rare as a cause of glaucoma and has not been reported in animals. Changes in the composition of aqueous humor have been reported recently in human and animal glaucomas and appear important in the disease genesis and progression.

The glaucomas represent a group of diseases characterized by increased intraocular pressure with resultant retinal and optic disk destruction. Low-tension

glaucoma, characterized in people by normal levels of intraocular pressure and progressive optic disk damage, has not been documented in domestic animals. In dogs, the primary (inherited) and secondary glaucomas occur in ~1.7% of the canine population in North America. The frequency of bilateral primary breed-predisposed glaucomas in purebred dogs is the highest of any animal species, except people (0.9%). Primary open-angle glaucoma in Beagles has been associated with the ADAMTS10 mutation. In cats, the glaucomas are predominately secondary to anterior uveitis and neoplasms; however, primary open-angle glaucoma occurs in the Siamese breed. In horses, the glaucomas appear underdiagnosed, because applanation tonometry is not routinely done; they appear most frequently in older animals, Appaloosas, and with concurrent anterior uveitis. In cattle, the glaucomas have been associated with congenital iridocorneal anomalies and anterior uveitis.

Diagnostic procedures essential to manage the glaucomas include tonometry, ophthalmoscopy (direct and indirect), and gonioscopy (visualization of the iridocorneal angle and anterior ciliary cleft). Newer electrophysiologic techniques, such as pattern electroretinograms and visual evoked potentials, estimate damage to the retinal ganglion cells and their axons and appear to be sensitive indicators of glaucoma-related destruction of these cells. New, clinical high-resolution imaging techniques, including ultrasound biomicroscopy for anterior segment changes and optical coherence tomography for retinal and optic nerve head changes, permit noninvasive detailed intraocular examinations. In small animals, the Schiotz indentation tonometer has been replaced by newer and more accurate applanation tonometers used to estimate intraocular pressure; in horses and cattle, only applanation-type tonometers can be used.

Intraocular pressure is reasonably consistent in most species (see TABLE 1), and diurnal variations have been documented in dogs, cats, rabbits, and nonhuman primates. Ophthalmoscopy permits detection of the intraocular pressure-related damage to the retina and optic disk. Gonioscopy is the basis for classification of all glaucomas; it detects iridocorneal and sclerociliary cleft opening outflow changes as the glaucoma progresses and helps determine the most appropriate medical and surgical treatments. Ultrasound biomicroscopy

(50–100 MHz) permits further examination of the anterior chamber angle and the entire sclerociliary cleft.

Clinical signs are traditionally divided into acute and chronic; in reality, most cases of acute high-pressure glaucoma are superimposed on chronic glaucoma rather than occurring as singular events. Most dogs with early to moderate chronic glaucoma are not taken to the veterinarian because the early clinical signs—sluggish to slightly dilated pupils, mild bulbar conjunctival venous congestion, and early enlargement of the eye (buphthalmia or megaloglobus)—are so subtle. To detect early glaucoma, repeated tonometry should be routinely performed on high-risk breeds of dogs as part of the annual, general physical examination. The clinical signs of acute and often markedly increased levels of intraocular pressure are a dilated, fixed, or sluggish pupil; bulbar conjunctival venous congestion; corneal edema; and a firm globe. With prolonged increases of intraocular pressure, secondary enlargement of the globe, lens

displacement, and breaks in Descemet membrane (corneal striae) result. Pain usually is manifest by behavioral changes and occasional periorbital pain, rather than by blepharospasm.

Classification of the glaucomas assists in the optimal plan for clinical management and preservation of vision. The choice of medical or surgical treatment, or most frequently a combination of both, is based on the progressive iridocorneal angle closure that occurs in most of the glaucomas. As the glaucoma progresses and aqueous humor outflow continues to reduce, the need for a combination of medical therapies increases. For open-angle glaucoma in dogs, short- and long-term management is by treatment with miotics, topical and systemic carbonic anhydrase inhibitors, prostaglandins, osmotics, and β -blocking adrenergics. These same treatments are used for initial control of narrow and closed-angle glaucoma, but short- and long-term management often requires supplemental surgery, eg, filtering

procedures, anterior chamber shunts, cyclocryotherapy, or laser transscleral cyclophotocoagulation. Short- and long-term management of end-stage glaucoma with buphthalmia and blindness in dogs also requires surgery, eg, intrascleral prosthesis, enucleation, cyclocryotherapy, or intravitreal gentamycin (10–25 mg) combined with 1 mg dexamethasone. Surgical procedures in dogs have traditionally provided only short-term resolution, because the filtering fistulas eventually scar over and fail. More recently, anterior chamber shunts, with and without valves, offer improved results. Antifibrotic drugs, such as mitomycin C and 5-fluorouracil, may delay or prevent scarring of the alternative aqueous outflow channels and prolong their function. In cats, medical therapy is usually the mainstay and consists of topical β -blocking adrenergics (caution in small cats), topical carbonic anhydrase inhibitors, and for those glaucomas associated with anterior uveitis, topical α_1 and/or systemic corticosteroids. In horses, single and/or repeated laser transscleral cyclophotocoagulation is most effective.

LENS

The optically clear and avascular lens consists of (from anterior to posterior) the anterior lens capsule, anterior cortex, nucleus, posterior cortex, and very thin posterior lens capsule. The lens is formed early in the development of the eye and coated with its basement membranes (anterior and posterior lens capsules), which insulate the lens proteins from the later-developing immune system. Hence in later life, if the lens capsule barrier is compromised by trauma or surgery, the immune system "attacks" the foreign lens material. The sole function of the lens is to allow unaltered passage of light and images to the retina. Diseases of the lens involve changes in its transparency.

Cataracts are an opacity of the lens or its capsule and should be differentiated from the minor lens imperfections in young dogs (seen on slit-lamp biomicroscopy) and the normal increase in nuclear density (nuclear sclerosis) that occurs in older animals. Cataract formation and cataract surgery in people and dogs have many similarities, but dogs experience more postoperative anterior uveitis. Cataract surgery is highly effective (95%) in people and is performed with advanced nuclear sclerosis and the failure of missing two lines on the Snellen eye acuity test. Cataracts usually are classified by their age of onset (congenital, juvenile, senile), anatomic location, cause,

degree of opacification (incipient, immature, mature, hypermature), and shape. Most cataracts can be detected by dilating the pupil and examining the pupillary region against the retroillumination of the tapetal fundus. Slit-lamp biomicroscopy permits optimal direct examination of the lens. Cataracts (often inherited) are more common in dogs than in other species (see TABLE 2), and vary by age of onset, rate of progression, and original site of cataract formation. Other causes include diabetes mellitus (the second most frequent group of cataract surgeries in the dog), malnutrition, radiation, inflammation, and trauma. In cats and horses, most cataracts are secondary to anterior uveal inflammation. Most reported inherited cataracts in cats are in young animals. Population studies on cataracts in cattle, rabbits (laboratory and pet), and guinea pigs suggest spontaneous cataracts occur not infrequently, but these species infrequently become blind.

In dogs, cataracts that are secondary related to diabetes mellitus are increasingly common; these cataracts represent the second largest group of cataracts operated on in dogs in the USA. The increased blood glucose causes intralenticular sorbitol to accumulate, which increases the osmotic forces of the lens, causing the lens to imbibe water and result in fiber swelling, rupture, and death. Typically, these cataracts develop rapidly and can occasionally rupture the equatorial or posterior lens capsule. Cataract surgery appears to yield the same success rate as for inherited cataracts in dogs. Other ocular sequelae of diabetes mellitus in dogs are occasional small retinal hemorrhages, presumed corneal neuropathy, and reduced corneal sensitivity. Cats seem quite resistant to diabetic cataract formation, perhaps associated with lower aldose reductase activity than in dogs.

Sight may be regained in some young dogs, cats, and horses when cataracts undergo sufficient spontaneous resorption; congenital nuclear cataracts in young animals may reduce in size with growth of the lens to permit restoration of vision as the animal matures. Animals with immature and incomplete cataracts may benefit from topical ophthalmic atropine 2–3 times/wk, which allows vision around a central or nuclear cataract. However, the only definitive therapy for cataracts is surgical removal of the lens. In dogs and horses, cataract extraction, often by phacoemulsification and with intraocular lens implantation, yields best results when performed before cataract maturation is complete and lens-induced uveitis (due to leakage of lens

material) is established. Lens-induced uveitis is intensified by cataract surgery and contributes substantially to postoperative complications. In animals in which cataract surgery is not performed, continued clinical monitoring is important. The secondary lens-induced anterior uveitis often requires longterm monitoring and repeated tonometry, with occasional corticosteroid and mydriatic therapy. Secondary glaucoma and phthisis bulbus formation are possible complications.

Lens displacement (subluxation, anterior or posterior luxation) occurs in all species but is common as a primary inherited defect associated with the ADAMTS17 mutation in several terrier breeds. Complete displacement into the anterior chamber produces acute signs and frequently is accompanied by glaucoma and corneal edema. Treatment is surgical removal by phacoemulsification or intracapsular lens extraction. Posterior displacement into the vitreous cavity is asymptomatic or associated with ocular inflammation or glaucoma. Subluxated lenses are recognized by an aphakic crescent and trembling or instability of the iris (iridodonesis) and lens (phacodonesis). The decision to remove subluxated lenses is based on the severity of ocular disease that can be attributed to the lens displacement. Lens displacements also can be produced by trauma, enlargement of the globe with glaucoma, and degenerative zonular changes with hypermature cataracts. Procedures to remove the lens for lens displacement are associated with

higher levels of postoperative complications of glaucoma and retinal detachment.

OCULAR FUNDUS

The ocular fundus consists of the upper tapetal fundus, ventral and surrounding nontapetal fundus, retinal vasculature, and optic disk (optic nerve head or optic papilla). Histologically, the posterior segment consists, from superficial to deep, of the following structures: 1) posterior sclera; 2) choroid, which contains pigmented cells, blood vessels to support the high metabolic needs of the outer retina, and the tapetum lucidum to enhance vision in dim light (tapetum cellulosum in carnivores and tapetum fibrosum in herbivores); 3) retina, which consists of the nine layers of neurosensory retina and the outer retinal pigment epithelium; and 4) the optic disk, where the retinal ganglion axons leave the eye through a weak and fenestrated scleral lamina cribrosa to synapse in the lateral geniculate body (vision) or middle brain (pupillary light reflex [Edinger-Westphal nucleus] or dazzle reflex [midbrain and rostral colliculi]). Whereas dogs, cats, horses, cattle, sheep, goats, and many other species have an upper tapetal fundus, pigs and rabbits are typically atapetal.

Diseases of the ocular fundus may be primary or may be manifestations of systemic diseases. Inherited abnormalities may be congenital or appear later and are important in the pathogenesis of retinopathies in dogs and cats. Trauma, metabolic disturbances,

systemic infections, neoplasms, blood dyscrasias, hypertension, and nutritional deficiencies are possible underlying causes for retinopathies in all species.

Inherited Retinopathies

Collie eye anomaly is a congenital, recessively inherited (CEA-CH mutation), ocular defect with variable expression in rough- and smooth-coated Collies. It also is seen in Shetland Sheepdogs, Border Collies, Australian Shepherds, Lancashire Heelers, Long-haired Whippets, Boykin Spaniels, and Nova Scotia Duck Tolling Retrievers. The basic lesion is an area of choroidal or chorioretinal hypoplasia that on ophthalmoscopy appears as a focal, variable-sized, pale area lateral to the optic disk. More severely affected dogs (10%–20%) can have additional colobomatous lesions of the optic papilla or peripapillary region and occasional retinal detachments (2%–5%). Intraocular hemorrhage may occur. Vision is not appreciably affected unless retinal detachment develops. With recent availability of the CEA-CH DNA test, additional breeds of dogs diagnosed ophthalmoscopically with Collie eye anomaly can be confirmed having the same mutation as well as potential carrier dogs within affected breeds before breeding.

Retinal dysplasia is a congenital, focal, geographic, or generalized maldevelopment of the retina that may arise from trauma, genetic defect, or intrauterine damage such as viral infections. Most forms of retinal dysplasia in dogs are inherited, and many DNA mutations have been reported. Maternal viral infections, especially during early fetal development, can result in multiple ocular anomalies with retinal dysplasia in kittens (panleukopenia virus), lambs (bluetongue disease), puppies (herpesvirus), and calves (bovine viral diarrhea). Breeds of dogs with focal, geographic, and generalized retinal dysplasia thought to be inherited as an autosomal recessive trait include American Cocker Spaniels, Beagles, Labrador Retrievers, Rottweilers, and Yorkshire Terriers. Focal areas of retinal maldevelopment may be asymptomatic or interfere with central vision. Generalized retinal dysplasia with retinal detachment, visual impairment, or blindness is inherited in English Springer Spaniels, Bedlington Terriers, Sealyham Terriers, Labrador Retrievers, Doberman Pinschers, and Australian Shepherds. Other ocular anomalies, including microphthalmia and congenital cataracts, often accompany the generalized forms. In

Labrador Retrievers and Samoyeds, retinal dysplasia may be associated with skeletal dysplasia (shortening) of the forelegs.

Progressive retinal atrophy (PRA) is a group of degenerative retinopathies consisting of inherited photoreceptor dysplasia and degenerations that have a similar clinical appearance. A large number of mutations and DNA tests have been reported for these diseases that vary by breed of dog. The photoreceptor dysplasias inherited as autosomal recessive traits in which clinical signs develop in the first year are seen in Irish Setters, Collies, Norwegian Elkhounds, Miniature Schnauzers, and Belgian Sheepdogs. The photoreceptor degenerations inherited as autosomal recessive traits in which clinical signs develop at 3–5 yr are seen in Miniature and Toy Poodles, English and American Cocker Spaniels, Labrador Retrievers, Tibetan Terriers, Tibetan Spaniels, Papillons, English Springer Spaniels, Miniature Longhaired Dachshunds, Akitas, and Samoyeds. In Siberian Huskies, PRA is inherited as an X-linked trait, whereas in Old English Mastiffs and Bull Mastiffs, PRA is inherited as an autosomal dominant. Many other breeds of dogs are also suspected of having inherited PRA. In Abyssinian cats, PRA occurs as both photoreceptor dysplasia and degeneration. Night blindness is noted early and progresses to total blindness over months to years. Ophthalmoscopic lesions are a bilateral symmetric increase in reflectivity

Choroidal hypoplasia and peripapillary coloboma (arrow), Collie. Both ocular defects support the diagnosis of Collie eye anomaly. *Courtesy of K. Gelatt.*

Progressive retinal atrophy, Miniature Poodle. Changes in tapetal reflectivity, reduced retinal vascularity, and early optic nerve atrophy are consistent with the diagnosis of progressive retinal atrophy. Courtesy of K. Gelatt.

of the tapetal fundus, decreased pigmentation of the nontapetal fundus, attenuation and a decrease in the number of retinal vessels, and eventual atrophy of the optic papilla. Electroretinography is often used to investigate and diagnose the condition. Cortical cataracts are common late in the course of PRA in many breeds and may mask the underlying retinopathy. No effective therapy is available. Blood and buccal mucosa-based DNA marker and specific gene tests have been developed to detect carrier and affected dogs before clinical signs develop in many breeds. The list of breeds affected with inherited retinal degenerations and causative genes continues to increase; for current information consult the recent literature.

Retinal pigment epithelial dystrophy (central progressive retinal atrophy) is seen in Labrador Retrievers, smooth and rough Collies, Border Collies, Shetland Sheepdogs, and Briards. The condition may be inherited in Labrador Retrievers as a dominant trait with variable penetrance. Early ophthalmoscopic findings (often before clinical signs are apparent) are small foci of irregular pigmentation in the tapetal fundus, which eventually coalesce and fade as reflectivity of the tapetal fundus increases. The pigmented nontapetal fundus becomes mottled, the retinal vasculature gradually decreases, and the optic disk atrophies. Progressive visual impairment occurs gradually over several years. Cataract formation occurs late in the disease. There is no treatment. Studies in

English Cocker Spaniels suggest vitamin E disorders may also be important in the pathogenesis of this disease complex. A similar condition in horses, equine motor neuron disease (*see* p 1248), has similar focal yellow-brown areas scattered throughout the tapetal fundus and has also been associated with vitamin E deficiency.

Chorioretinitis

Chorioretinitis frequently is a manifestation of systemic infectious disease; it is important as both a convenient diagnostic clue and a prognosticator of visual function. Unless the lesions are generalized or involve the optic nerve, they often are "silent." Scars may be differentiated from active lesions by the haze and ill-defined borders of the latter. Routine ophthalmoscopic examinations of all animals with systemic diseases often permit rapid diagnosis of many specific diseases. Chorioretinitis may be present with canine distemper, systemic mycoses in dogs and cats, protothecosis, feline toxoplasmosis, tuberculosis, bacterial septicemias in young animals, feline infectious peritonitis, thromboembolic meningoencephalitis in cattle, bovine malignant catarrhal fever, classical swine fever, and leptospirosis and onchocerciasis in horses. Therapy is directed at the systemic disease.

Retinal Detachments

Retinal detachments occur in most species. In dogs, retinal detachment or separation of the neurosensory retina from the retinal pigment epithelium is associated with congenital retinal disorders (retinal dysplasia and Collie eye anomaly), chorioretinitis, trauma, intraocular surgery, and posterior segment neoplasia. In cats, retinal detachments occur with chorioretinitis associated with feline infectious peritonitis, feline viral leukemia, and systemic hypertension. In horses, the most frequent causes are trauma, intraocular surgery, and recurrent uveitis.

Retinal detachments are divided clinically into nonrhegmatogenous (serous, exudative, hemorrhagic, secondary to vitreal syneresis) and rhegmatogenous (with retinal breaks [hole or tear]). Clinical signs include mydriasis, anisocoria, vision impairment, and intraocular hemorrhage. Diagnosis is by ophthalmoscopy and, in eyes with an opaque cornea or lens, ocular ultrasonography.

Nonrhegmatogenous serous retinal detachments are usually treated medically, with therapy directed at the primary

Early retinal detachment and hemorrhage developing lateral to the optic disc in a Collie puppy with Collie eye anomaly. Courtesy of K. Gelatt.

disease. Retinal reattachment occurs with resolution of the subretinal exudates and hemorrhage. Variable retinal degeneration may follow in the detached areas. Rhegmatogenous retinal detachments with retinal breaks generally require surgical correction.

OPTIC NERVE

Optic nerve diseases are often difficult to detect and diagnose. Of the optic nerve diseases, inflammation of the optic nerve (optic neuritis) is most frequent.

Optic nerve hypoplasia may be inherited in Miniature Poodles; in kittens and calves, it may result from in utero infections with panleukopenia and bovine viral diarrhea, respectively. In calves, the cause may be maternal avitaminosis A. The condition may be unilateral or bilateral, and it can occur with or without other ocular anomalies. Bilateral involvement is manifest as blindness in the neonate; unilateral involvement is often an incidental finding later in life or becomes manifest if the other eye acquires a blinding disease.

Bilateral optic neuritis produces acute blindness and dilated and fixed pupils. On ophthalmoscopy, the optic nerve head or optic disc is raised, edematous with blurred margins and peripapillary hemorrhages, venous congestion, and often inflammatory cells in the adjacent retina and vitreous. Causes of optic neuritis may vary by species affected and include viral, mycotic, protozoan and parasitic

infections, trauma, reticulosis, toxins, and other causes. Complete physical and medical evaluations are usually necessary to establish the possible diagnoses. Specific therapies are directed toward the cause, and systemic corticosteroids are important to reduce inflammation of and damage to the optic nerve.

Papilledema is rare in animals and often associated with orbital masses in most domestic species. Increased intracranial pressure does not usually result in papilledema in animals, except in calves with avitaminosis A. The optic disk appears raised above the surface of the adjacent retina, and venous congestion is present. Vision and the light pupillary reflexes are not usually affected unless optic atrophy develops.

Optic atrophy may develop after glaucoma, trauma, advanced retinal degeneration, prolonged ocular hypotension, or inflammation. The optic disk appears depressed and smaller than normal; it is often pigmented, with marked reduction in the optic nerve and retinal vasculature. Both direct pupillary reflex and vision are absent. There is no treatment.

ORBIT

Signs of **orbital cellulitis** are acute pain on opening the mouth, eyelid swelling, unilateral prolapse of the nictitating membrane, forward displacement of the globe, and conjunctivitis. Keratitis may develop from lagophthalmos. The condition is seen predominantly in large and hunting breeds of dogs and is rare in other species. Foreign bodies (eg, migrating grass awns) and zygomatic sialadenitis are additional causes. Orbital hemorrhage and neoplasia may mimic inflammation, except there is usually no pain on opening the mouth. In acute cases, systemic broad-spectrum antibiotics are usually curative, but if swelling behind the last molar is present, drainage of this area is indicated. Warm compresses and topical lubricants to protect the cornea are also indicated. Relapses may occur, and radiographs and ultrasonography of the adjacent teeth, sinuses, and nasal cavity are recommended.

PROLAPSE OF THE EYE

Acute prolapse or proptosis of the eye occurs as a result of trauma. It is common in dogs and infrequent in cats. Prognosis depends on the extent of the trauma, the breed of dog, depth of the orbit, duration of the proptosis, resting pupil size, condition of the exposure keratitis, and other

periocular damage. In cats, proptosis usually results from severe trauma to the head; often, other facial bones are fractured. The globe should be replaced as soon as possible if the animal's physical condition will permit induction of general anesthesia (see p 1696). Treatment consists of systemic antibiotics and occasionally corticosteroids, combined with topical antibiotics and mydriatics. Although the prognosis for retention of vision is guarded, the globe is usually saved. Return of vision occurs in ~50% of dogs but is rare in cats.

OPHTHALMIC MANIFESTATIONS OF SYSTEMIC DISEASES

Ophthalmic manifestations of systemic diseases are not uncommon with inherited, infectious, degenerative, and neoplastic disorders in animals. Often, ophthalmic examinations can assist in timely identification of the systemic disorder. Diseases affecting the vascular and nervous systems are likely to show ocular manifestations. Animals with bilateral ocular disease should be carefully evaluated for systemic diseases.

In dogs, ophthalmic diseases, such as retinal dysplasia, microphthalmia, and cataracts, have been associated with dwarfism, albinism, and merling. Infectious diseases often involve the uveal tract and present as iridocyclitis, choroiditis, and panuveitis. They may be caused by viruses (distemper, infectious hepatitis), rickettsial diseases (ehrlichiosis and Rocky Mountain spotted fever), bacteria (*Brucella canis* and *Borrelia burgdorferi*), fungi (*Blastomyces*, *Coccidioides*, *Histoplasma*, *Cryptococcus*, and *Aspergillus*), protozoa (*Toxoplasma*, *Neospora*, *Leishmania*, and *Hepatozoon*), algae (*Prototheca*), or parasites (*Dirofilaria*, *Toxocara*, and *Diptera* spp). Metabolic diseases associated with eye diseases in the dog include diabetes mellitus (cataract formation), hypocalcemia (cataracts), hyperadrenocorticism (corneal disease, cataracts, and lipemia retinalis), and hypothyroidism (keratoconjunctivitis sicca, intraocular hemorrhages from increased systemic blood pressure, and lipemia retinalis [hyperlipidemia]). Blood and vascular disorders may present as intraocular hemorrhage, retinal detachment, secondary glaucoma, and papilledema. Metastatic neoplasms, such as lymphosarcoma, most often affect the uvea, presenting as persistent uveitis, overt intraocular masses,

intraocular hemorrhage, secondary glaucoma, or retinal detachment.

In cats, systemic diseases frequently affect the eye and associated structures. Eyelid inflammations are often associated with systemic *Demodex cati* and *D. gatoi*, *Notoedres cati* (scabies), ringworm, and immune-mediated skin diseases. The pathogens that commonly cause infectious diseases of cats, eg, feline herpesvirus 1, *Chlamydia*, and *Mycoplasma*, frequently present as acute and recurrent conjunctivitis. Feline herpesvirus 1 is also associated with ulcerative and stromal keratitis, proliferative keratoconjunctivitis, corneal sequestrum, corneal symblepharon, and keratoconjunctivitis sicca. Feline infectious peritonitis, toxoplasmosis, feline immunodeficiency virus, and feline leukemia virus often present as anterior and posterior uveitis, chronic uveitis, retinal detachment, and secondary glaucoma. Acute vision loss with intraocular hemorrhage and retinal detachment in older cats may be secondary to systemic hypertension and is often associated with chronic renal failure or hyperthyroidism. Resolution of intraocular hemorrhages, repair of the retinal detachment, and possible restoration of vision depends on the successful lowering of blood pressure to normal levels, often using amlodipine, an oral calcium channel blocker.

In horses, systemic infectious diseases, such as adenovirus in immunodeficient Arabian foals, equine influenza, strangles (*Streptococcus equi*), *Rhodococcus equi* infection, leptospirosis, Lyme disease (*Borrelia burgdorferi*), and salmonellosis, may present as conjunctivitis, anterior uveitis, or posterior uveitis. Ophthalmic onchocerciasis can be markedly reduced by frequent administration of ivermectin but can present with anterior and posterior uveitis, peripapillary chorioretinitis, keratitis, keratoconjunctivitis, or lateral conjunctival vitiligo. Habronemiasis presents with inflammatory conjunctival masses of the periocular area (especially the medial canthus) associated with the aberrant migration of larvae of *Habronema muscae*, *H. microstoma*, and *Draschia megastoma*. Therapy is usually systemic ivermectin.

In cattle, microphthalmia, cataracts, retinal dysplasia, and retinal detachments are associated with hydrocephalus and in utero infection of calves with bovine viral diarrhea. The same ophthalmic defects occur in lambs affected in utero with bluetongue virus. Vitamin A deficiency in

Conjunctival habronemiasis may be concurrent with "summer sores" in horses. Courtesy of K. Gelatt.

piglets causes microphthalmia, and in calves blindness and optic nerve hypoplasia. Vitamin A deficiency in adult or growing cattle results in night blindness, mydriasis, and eventually total blindness. ●ophthalmoscopic abnormalities include papilledema, retinal degeneration, and optic nerve atrophy. Vitamin A supplementation may restore vision in animals with night blindness only. Lymphosarcoma in cattle may present as bilateral progressive exophthalmia. Many infectious diseases, such as rhinotracheitis, malignant catarrhal fever, thromboembolic meningoencephalitis, and neonatal septicemia, may present with conjunctivitis or anterior or posterior uveitis. Intoxications such as male fern poisoning (*Dryopteris filix*), bracken fern poisoning (*Pteridium aquilinum*) in sheep, coumarin poisoning (sweet clover poisoning) in cattle, and phenothiazine toxicity in cattle present with clinical signs of blindness from retinal degeneration, intraocular hemorrhage, or corneal edema. (See also TOXICOLOGY, p 2948.)

CHLAMYDIAL CONJUNCTIVITIS

Etiology and Epidemiology: Chlamydiae are obligate intracellular bacteria that form inclusions within the cytoplasm of epithelial cells. The life cycle of chlamydiae involves an alternation between the intracellular reticulate body and the extracellular elementary body, which is the infectious form of the organism. Several members of the family Chlamydiaceae have been associated with conjunctivitis in the host species they infect, including *Chlamydia caviae* (guinea pigs), *C suis* (pigs), *C psittaci* (birds), and *C pecorum* (cattle and sheep). Although chlamydial infection has been associated with keratoconjunctivitis in sheep and goats, a study that used molecular techniques to detect chlamydiae in sheep did not find a clear association between infection and disease. Chlamydial conjunctivitis in cats is caused by *C felis* (formerly *Chlamydophila felis*). *C pneumoniae* has also been detected in cats with conjunctivitis using molecular methods. *C psittaci* has been isolated from dogs with keratoconjunctivitis and respiratory signs in a dog breeding facility.

Trachoma and inclusion conjunctivitis in people are caused by *C trachomatis*. Chlamydia-like organisms (*Parachlamydia acanthamoebae*) that reside and proliferate within free-living amoeba have been detected in the eyes of cats, guinea pigs, pigs, and sheep with conjunctivitis. The pathogenic role of these organisms and their amoebic hosts is unclear.

Although the disease in cats has been referred to as feline pneumonitis, chlamydiae rarely cause pneumonia in cats. The infection always involves the eye, occasionally causing signs of rhinitis, with sneezing and nasal discharge. Although antibody titers to *C felis* are common in some cat populations, the organism is rarely isolated from clinically healthy cats. Cats with chlamydial conjunctivitis are generally <1 yr old, and cats 2–6 mo old appear to be at highest risk of infection. Cats with conjunctivitis that are >5 yr old are very unlikely to be infected, and cats <8 wk old may be less at risk because of the presence of maternal antibody. Transmission occurs as a result of direct, close contact between

cats, because the organism survives poorly in the environment. Infected cats also shed chlamydiae from their rectum and vagina, although whether venereal transmission may occur has not been confirmed. There is weak evidence that chlamydiae may be capable of causing reproductive disease and lameness in cats, although these associations have not been definitively documented.

Chlamydial infection is one of the most common causes of conjunctivitis in guinea pig populations, in which it is also known as guinea pig inclusion conjunctivitis (see p 2017). As with cats, young guinea pigs, especially those 1–2 mo old, are predisposed. Subclinical disease may also occur. Rhinitis, lower respiratory tract disease, and genital infections, causing salpingitis and cystitis in female guinea pigs and urethritis in males, may also occur.

Clinical Findings: In cats, the incubation period after exposure to an infected cat ranges from 3 to 10 days. Signs can include serous to mucopurulent conjunctivitis, nasal discharge, and sneezing. Cats with signs of rhinitis in the absence of conjunctivitis are unlikely to be infected with *C. felis*. Early signs include unilateral or bilateral conjunctival hyperemia, chemosis, and serous ocular discharge, with prominent follicles on the inside of the third eyelid in more severe cases. Keratitis is rare, and if present, may be the result of coinfection with organisms such as feline herpesvirus 1. The signs are most severe 9–13 days after onset and then become mild over a 2- to 3-wk period. In some cats, clinical signs can last for weeks despite treatment, and recurrence of signs is not uncommon. Untreated cats may harbor the organism for months after infection.

Guinea pigs may develop mild to severe conjunctivitis, with conjunctival hyperemia, chemosis, and mucopurulent ocular discharge.

Diagnosis: Chlamydial conjunctivitis in cats should be differentiated from conjunctivitis caused by feline herpesvirus 1 and feline calicivirus, and in guinea pigs from mycoplasmal and other bacterial infections (eg, “pinkeye”). Diagnosis is best confirmed using PCR for chlamydial DNA on conjunctival swabs. Cell culture for *Chlamydia* is sensitive and specific but not widely available or practical for routine diagnostic purposes. Special chlamydial transport media is required for transport of specimens for culture.

A diagnosis of ocular chlamydiosis can also be made by demonstration of intracyto-

plasmic chlamydial inclusions in exfoliative cytologic preparations. Scrapings for cytologic examination are prepared by lightly but firmly moving a spatula over the conjunctiva and smearing the scraped material onto a glass slide; the preparation is air-dried and stained. Chlamydial inclusions, which contain reticulate bodies, are round and generally stain purple with Romanowsky stains. Conjunctival cytology from guinea pigs generally reveals a neutrophilic inflammatory response. Inclusions are generally visible only early in the course of infection and sometimes not at all. Melanin granules and remnants of some ophthalmic preparations may be mistaken for inclusions, leading to false-positives, so other diagnostic tests are recommended to confirm the diagnosis.

Prevention and Treatment: Vaccines are available for chlamydiosis in cats but not for other species. Feline chlamydial vaccines do not provide complete protection from infection but may reduce disease severity and infection rates. Their use may be considered in catteries where chlamydiosis is endemic.

All *Chlamydia* isolates are susceptible to tetracyclines. The treatment of choice is doxycycline (10 mg/kg/day) for at least 4 wk. Systemic therapy is superior to topical therapy and is logical given that organisms are shed from sites other than the conjunctiva. Treatment for up to 6 wk has been required to eliminate infection in some cats. All cats in the household must be treated. Fluoroquinolones, such as enrofloxacin and pradofloxacin, and amoxicillin-clavulanic acid, also have been used to successfully treat feline chlamydiosis, although their efficacy may be less than that of doxycycline. Azithromycin does not appear to be effective.

Zoonotic Risk: On rare occasions, *C. felis* and *C. caviae* have been isolated from people living with infected cats and guinea pigs. Follicular conjunctivitis was described in a single immunocompromised person who was found to be infected with *C. felis*. There was one report of detection of *C. caviae* in a person with serous ocular discharge who worked with ~200 diseased guinea pigs. *C. caviae* was also detected in conjunctival swabs of this person's cat and rabbit, the latter of which had signs of mild conjunctivitis. Routine hygiene practices, such as hand washing before and after handling sick pets, may reduce the potential for transmission of these organisms from affected animals to people.

EQUINE RECURRENT UVEITIS

(Periodic ophthalmia, Moon blindness, Equine uveitis)

Equine recurrent uveitis (ERU) is an important ophthalmic condition with a reported prevalence of 2%-25% worldwide. The classic form of ERU is characterized by episodes of active intraocular inflammation followed by variable quiescent periods. However, some horses experience insidious ERU in which subclinical ocular inflammation persists without obvious signs of discomfort. With chronicity, the inflammatory bouts cause secondary ocular changes such as cataracts, lens luxation, glaucoma, phthisis bulbi, and retinal degeneration. As a result, ERU is the most common cause of blindness in horses in the world.

Etiology and Pathogenesis: ERU is an autoimmune syndrome that ensues after an initial episode of acute uveitis. Although not every horse with a single bout of uveitis will develop ERU, horses that have experienced acute uveitis are at risk of developing ERU for several years after the primary episode. While numerous bacterial, viral, protozoan, parasitic, and noninfectious causes, including ocular trauma, have been linked to the initiation of ERU, the pathophysiology of ERU is complex and multifactorial. Of the infectious causes investigated, *Leptospira* spp, especially *L. interrogans* serogroup Pomona, have been most studied with regard to their role in the initiation of ERU. The precise mechanisms by which *Leptospira* spp initiate ERU remain unknown, but it is likely that loss of ocular immune tolerance, cross-reaction between *Leptospira* organisms and self-antigen, and intra- and intermolecular epitope spreading all play a critical role. There is no gender or age predisposition for ERU. However, Appaloosas, warmbloods, and draft breeds are overrepresented among horses diagnosed with ERU, which suggests a heritable component. Genes of the major histocompatibility complex (MHC) have been most widely investigated and likely play a role in susceptibility to ERU and/or to leptospirosis as an inciting trigger for ERU. The prevalence of ERU varies with geographic region, with higher rates reported in tropical and temperate climates than in arid, dry climates, an observation that may be partially attributable to differences in persistence of pathogenic *Leptospira* spp within the

environment. Thus, the underlying cause of the primary uveitis, genetic composition of the horse, and environmental factors are all integral to the development of ERU.

Clinical Findings and Lesions: Clinical findings associated with ERU include acute signs of active inflammation as well as chronic secondary complications. Changes in ocular immunity allow leukocytes to invade the uvea and release proinflammatory cytokines such as prostaglandins and leukotrienes. These inflammatory mediators cause increased vascular permeability within the uvea, breakdown of the blood-ocular barrier, iris sphincter muscle spasm, decreased aqueous humor production, and ciliary body muscle spasm. These changes are responsible for the classic signs of acute uveitis: epiphora, blepharospasm, corneal edema, episcleral congestion, aqueous flare and cell, and fibrin in the anterior chamber. These anterior segment signs often reduce visualization of the posterior segment. Active posterior segment inflammation can result in vitreous haze secondary to cellular infiltrate, fibrinous traction bands, focal or diffuse retinal detachment, or chorioretinitis. Chronic sequelae of ERU include corneal scarring, iridal fibrosis, corpora nigra atrophy, posterior synechia, cataract, lens dislocation, glaucoma, phthisis bulbi, and chorioretinal scarring. ERU can be unilateral or bilateral and can affect the eyes asymmetrically.

Horses with primary ocular disease, especially corneal disease, experience many clinical signs typical of ERU, especially epiphora, blepharospasm, miosis, and corneal edema. It is critical to differentiate primary corneal disease from ERU considering the marked differences in treatment. A complete ophthalmic examination and fluorescein stain are essential. A thorough ophthalmic examination, including fundoscopy, is also critical during prepurchase or soundness examinations. Horses with chronic ERU may exhibit subtle or no anterior segment signs but have significant retinal degeneration and thus potential for vision compromise.

Diagnosis: Diagnosis is based on characteristic clinical signs combined with a history of recurrent or persistent episodes of

uveitis. A thorough ophthalmic examination of the anterior and posterior segment is critical to observing signs consistent with ERU and to excluding other primary ocular diseases. Tonometry should be performed in all cases to exclude glaucoma and document hypotony that is common with ERU. Application of fluorescein stain is important to assess corneal epithelial integrity and exclude reflex uveitis from ulcerative keratitis. In cases of acute uveitis, a physical examination is performed to exclude systemic disease. A CBC and serum biochemistry panel are often warranted as part of the minimum database. Specific tests may assist in determining the underlying cause of a primary bout of uveitis. Serologic testing for *Leptospira* spp may confirm exposure to this common risk factor but is not helpful in determining treatment. Anterior chamber or vitreous cavity paracentesis may aid in identifying a causative organism, but this procedure may cause severe intraocular damage and is not recommended.

Treatment, Prevention, and Control:

The primary goals of therapy are to reduce inflammation, relieve discomfort, and prevent vision loss. If possible, the specific underlying cause should be diagnosed and addressed as part of the initial treatment regimen. Regardless of whether the underlying cause is identified, aggressive treatment with systemic and topical anti-inflammatory medications is initiated immediately to minimize damage from intraocular inflammation. Flunixin meglumine administered systemically (especially IV) is critical to the initial management of acute uveitis in horses. The typical initial IV dosage is 1.1 mg/kg, administered at the time of diagnosis, followed by a 5- to 7-day course at a dosage of 0.5–1.1 mg/kg, PO, bid. As inflammation resolves, the dosage can be reduced to 0.25–0.5 mg/kg once daily or every other day throughout a 1- to 3-mo treatment period. Because of the potential for renal toxicity, serum creatinine is intermittently monitored if flunixin meglumine is used for >1 mo. Horses treated with flunixin meglumine should also be observed for signs of GI ulceration, and concurrent prophylactic administration of omeprazole (2 mg/kg/day, PO) may be indicated. If flunixin meglumine is not tolerated, phenylbutazone (2–4 mg/kg, PO, once to twice daily) or aspirin (10–25 mg/kg, PO, once to twice daily) can be used alternatively, but neither is as potent or effective. Historically, horses with frequent recurrences or chronic, low-grade uveitis were managed medically with daily (or every

other day) doses of oral phenylbutazone or aspirin. Although most horses tolerate this regimen well, these medications can have adverse GI, hematologic, or renal effects, and these regimens frequently do not eliminate recurrence. Systemic steroids, specifically prednisolone (100–300 mg/day) and dexamethasone (5–10 mg/day) have also been successfully used to treat acute uveitis episodes, but their longterm use has been associated with laminitis. Except in cases when bacterial infection is present, systemic antibiotics are not indicated.

Topical steroid medications, including dexamethasone (0.1% suspension or ointment) and prednisolone acetate (1% suspension), are very effective at decreasing inflammation. Topical acetate and suspension preparations of steroids are designed to penetrate the cornea and achieve adequate uveal concentrations and are thus preferred to sodium phosphate formulations. Topical hydrocortisone should be avoided, because it lacks adequate corneal penetration and is not sufficiently potent to treat anterior uveitis. A fluorescein stain is warranted before initiation of topical steroids, because these medications are contraindicated with corneal ulceration and/or infection. Topical nonsteroidal medications include flurbiprofen (0.03% solution) and diclofenac (0.1% solution); they are less potent than topical steroids but offer a wider safety margin in cases of concurrent corneal disease. Frequency of administration depends on inflammation severity; initially, administration may be 4–6 times daily. With improvement in clinical signs, frequency of administration of topical steroid or nonsteroidal medications can be gradually decreased. However, therapy should continue for 1 mo after complete resolution of active inflammation. Topical atropine (1% solution or ointment) causes mydriasis (which decreases the likelihood of posterior synechia formation) and cycloplegia (which decreases pain associated with ciliary body muscle spasm) and stabilizes the blood-ocular barrier. Atropine is applied topically 2–3 times daily until the pupil is widely dilated; the frequency can then be adjusted to maintain mydriasis. Because atropine decreases GI motility, horses treated with topical atropine should be monitored for signs of ileus. If frequent topical medication is not possible, subconjunctival injections of triamcinolone acetonide (1–2 mg) provide adequate intraocular anti-inflammatory concentrations for 7–10 days and are less likely to cause abscess or granuloma formation than other steroids, including methylprednisolone acetate (10–40 mg).

However, all subconjunctival steroids should be used with caution, because they cannot be easily removed once injected and can have devastating consequences if an infectious component is present or a corneal ulcer develops.

Two surgical procedures are commonly used in longterm management. A suprachoroidal cyclosporine implant is a sustained-release medication device that provides therapeutic concentrations of cyclosporine A, an immunosuppressive T-cell inhibitor, for ~3 yr after implantation. During this procedure, a cyclosporine A disk (~5 mm in diameter) is implanted under a scleral flap created ~8 mm posterior to the dorsolateral aspect of the limbus. Horses with implants have markedly fewer uveitic episodes than they did before surgery, and this device results in effective longterm control of ERU. Core vitrectomy removes virtually all of the vitreous through an incision posterior to the dorsolateral

aspect of the limbus. The vitreous is then replaced with either balanced salt solution or saline. The theorized benefit of this procedure is that organisms, especially *Leptospira* spp, and/or inflammatory cells in the vitreous significantly contribute to the chronic inflammation of ERU. By removing these factors, the frequency and severity of uveitic episodes are minimized.

Good husbandry practices to manage ERU ensure proper health maintenance, prevent ocular trauma, and reduce environmental triggers. Specific management recommendations include routine deworming and vaccinations, proper nutrition and dental care, a quality fly mask, minimizing contact with cattle or wildlife, draining stagnant ponds or restricting access to swampy pastures, effective fly control, and frequent bedding changes. Although such measures benefit individual horses, the extent to which they impact the clinical course of ERU has not been evaluated.

EYEWORM DISEASE

(Thelaziasis)

LARGE ANIMALS

Etiology and Epidemiology: Eyeworms (*Thelazia* spp) are common parasites of horses and cattle in many countries, including those of North America. Horses are infected primarily by *T lacrymalis*, whereas cattle are mainly infected by *T gulosa*, *T skrjabini*, and *T rhodesii*. The latter is the most common and harmful to cattle in the Old World, but it has not been recently reported in North America. The prevalence of *Thelazia* spp in livestock has declined in at least some areas where macrocyclic lactone endectocides such as ivermectin and doramectin are in common use. *Thelazia* spp are also found in pigs, sheep, goats, deer, water buffalo, dromedaries, hares, dogs and cats (see p 512), birds, and people.

The face fly, *Musca autumnalis*, is the vector of *T lacrymalis*, *T gulosa*, and *T skrjabini* in North America. Feeding habits of this fly include a preference for ocular secretions, which are ideal for transmission. The life cycle of *Thelazia* is as follows: female worms are ovoviparous and discharge larvae into the ocular

secretions; the larvae are ingested by the fly and become infective in 2–4 wk. Infective third-stage larvae emerge from the labellae of infected flies and are mechanically deposited in the host's eye by the fly during feeding. Development of sexually mature worms takes 1–4 wk in cattle, depending on worm species, and 10–11 wk for *T lacrymalis* in horses. Infections may be found year-round, but clinical disease outbreaks, particularly in cattle, usually are associated with warm season activities of the flies. *Thelazia* sp larvae may overwinter in face flies. Infection rates generally tend to increase with advancing host age, although some studies report maximal levels in hosts 2–3 yr old.

Pathogenesis: The lacrimal gland and its ducts are common sites for *T lacrymalis* and *T gulosa*, with the glands of the nictitating membrane and the nasolacrimal ducts less so. *T skrjabini* is normally found within the lacrimal ducts of the nictitating membrane. Superficial locations on the cornea, in the conjunctival sac, and under the eyelids and nictitating membrane are more typical for *T rhodesii*, but *T lacryma-*

lis, *T skrjabini*, and *T gulosa* may be found in these sites, too. Worms may also be found on the periorbital hair or skin during anesthesia or following migration after death of the host. Localized irritation and inflammation is likely due to the serrated cuticle of the worms, especially for *Trhodesii*. Invasion of the lacrimal gland and excretory ducts may cause inflammation and necrotic exudation. Inflammation of the lacrimal ducts and sac has also been reported in horses. Mild to severe conjunctivitis and blepharitis are common. Also, keratitis, including opacity, ulceration, perforation, and permanent fibrosis, may develop in severe cases, particularly with *Trhodesii* infection in cattle.

Clinical Findings and Diagnosis:

Asymptomatic infections in horses and cattle appear to be typical of thelaziasis in North America. Infection may be encountered incidentally during surgery or at necropsy. However, *Thelazia* infections in cattle in North America may not always be innocuous. They may produce mild conjunctivitis, excessive lacrimation, localized edema, corneal clouding, and occasionally, subconjunctival cysts. In Europe and Asia, thelaziasis is commonly associated with severe clinical manifestations, including conjunctivitis, photophobia, and keratitis. Characteristically, there is chronic conjunctivitis with lymphoid hyperplasia and a seromucoid exudate.

A clinically feasible technique for reliable detection of adult eyeworms is lacking. Gross inspection of the eyes may reveal the worms and is generally recommended for *Trhodesii*, commonly found in the conjunctival sac. However, *T gulosa* and *T skrjabini* in cattle, and *T lacrymalis* in horses, tend to be more invasive and are less apt to be seen. Topical anesthetics allow for tissue manipulation and are useful for detection and recovery of worms. Microscopic examination of lacrimal fluids for embryonated eggs or larvae may be attempted.

Clinical signs may be helpful in differential diagnosis. Thelaziasis tends to cause a chronic conjunctivitis. In cattle, infectious keratoconjunctivitis (see below) is an acute, rapidly spreading infection of the cornea. In horses, infective larvae of the stomach worms *Draschia* and *Habronema* sp may also produce ophthalmic lesions. These tend to occur near the medial canthus of the eyelid and are raised, ulcerative granulomas, often containing characteristic

yellow, plaque-like "sulfur granules" 1–2 mm in diameter. Likewise, microfilariae of *Onchocerca* sp invade the eye and may result in ophthalmic manifestations. Small (<1 mm), raised, white nodules in the pigmented conjunctiva adjacent to the temporal limbus are pathognomonic of *Onchocerca* infection. Depigmentation of the bulbar conjunctiva in this area is also common. Other lesions of onchocerciasis involve the cornea and include edema and punctate or streaking opacities of the stroma, superficial erosions, and a wedge-shaped sclerosing keratitis emanating from the temporal limbus. Intraocular structures also may be affected by microfilariae of *Onchocerca* sp (see p 905). Worms may be identified morphologically. In addition, PCR and sequencing assays have been developed to confirm the identity of some species, but these are not used routinely.

Treatment and Control: Mechanical removal with forceps after instillation of a local anesthetic is useful for *Trhodesii* in cattle. This also may be feasible for the more invasive *T gulosa* or *T skrjabini* in cattle or for *T lacrymalis* in horses. Irrigation of the eyes with 50–75 mL aqueous solution of 0.5% iodine and 0.75% potassium iodide has been recommended for *T gulosa* and *T skrjabini*. This also may be effective for *T lacrymalis* in horses. Topical application of 0.03% echothiophate iodide or 0.025% isoflurophate (both organophosphates) has been successful for *T lacrymalis* in horses. Concurrent use of antibiotic-steroid ointment for the inflammation and secondary invaders is recommended. These topical agents should also be useful for *T gulosa* and *T skrjabini* in cattle. Certain systemic anthelmintics have exhibited activity against eyeworms. In cattle, levamisole at 5 mg/kg, SC, and ivermectin and doramectin, both at 0.2 mg/kg, SC or IM, have shown activity against *Thelazia* spp. Pour-on formulations of ivermectin or doramectin, delivered to achieve a dosage of 0.5 mg/kg, are also effective. Doramectin has been approved in the USA for treatment of adult eyeworms in cattle. For *T lacrymalis* in horses, single doses of the commonly used anthelmintics, including ivermectin, administered via stomach tube at 0.2 mg/kg, have had limited, if any, effect on eyeworms. In contrast, the multidose regimen of fenbendazole (10 mg/kg/day for 5 days) is efficacious against *T lacrymalis*.

Fly control measures, directed especially against the face fly, aid in the control of thelaziasis in cattle and horses. Cattle on dry, open pastures have fewer face flies than those on pastures where shade and water are present.

SMALL ANIMALS

Thelazia californiensis is found in dogs, cats, and deer in western USA; *T. callipaeda* is found in dogs, cats, foxes, wolves, martens, and rabbits in Europe and Asia. *T. callipaeda* appears to be spreading in some regions of Europe. Both species are zoonotic. The worms are whitish, 7–19 mm long, and move in a rapid serpentine motion across the eye. Up to 100 eyeworms may be seen in the conjunctival sac, tear ducts, and on the conjunctiva under the nictitating membrane and eyelids. Filth flies (*Musca* spp, *Fannia* spp) serve as intermediate hosts and deposit infective larvae on the eye while feeding on ocular secretions. Zoophilic fruit flies have emerged as potential intermediate hosts of *T. callipaeda*. These include *Phortica*

variegata in Europe and *Amiota* spp in Asia.

Clinical signs include excessive lacrimation and epiphora, ocular pruritus, conjunctivitis, keratitis with corneal opacity and ulceration, hyperemia, and rarely, blindness. After local anesthetic, diagnosis and treatment are readily accomplished by observing and removing the parasites with forceps. *Thelazia* spp infections have been successfully eliminated from dogs with ivermectin SC at 0.2 mg/kg, milbemycin oxime PO at a minimum dosage of 0.5 mg/kg (two treatments 1 wk apart improved efficacy), or spot-on treatment with moxidectin 2.5%. Ocular solutions (1% moxidectin or 2% levamisole) or ointments (1% levamisole or 4% morantel) also may be effective. Infection with *T. callipaeda* has been prevented for the full season in dogs with sustained-release moxidectin at 0.17 mg/kg, SC, with milbemycin oxime PO at the dosage recommended for heartworm prevention, and with ivermectin PO at 0.2 mg/kg. Milbemycin oxime at the minimum oral dosage of 2 mg/kg showed high therapeutic efficacy in cats infected with *T. callipaeda*.

INFECTIOUS KERATOCONJUNCTIVITIS

(Pinkeye, Infectious ophthalmia)

Infectious keratoconjunctivitis of cattle, sheep, and goats is characterized by blepharospasm, conjunctivitis, lacrimation, and varying degrees of corneal opacity and ulceration.

Infectious bovine keratoconjunctivitis (IBK) is the most common ocular disease of cattle and is seen worldwide. The gram-negative rod *Moraxella bovis* is the only organism demonstrated to cause IBK in cattle. Seven different serogroups of *M. bovis* are currently recognized. Most other ocular infections of cattle are characterized by conjunctivitis with minimal or no keratitis. The primary differential diagnosis is infectious bovine rhinotracheitis (IBR), which causes severe conjunctivitis and edema of the cornea that originates near the limbus; however, corneal ulceration is uncommon. *Mycoplasma*

spp may cause conjunctivitis of cattle, either alone or in conjunction with *M. bovis*. Infection with IBR virus or other microbes may increase the severity of infection with *M. bovis*. Another *Moraxella* species that has been frequently isolated from eyes of cattle with IBK is *Moraxella bovoculi* (not to be confused with *Mycoplasma bovoculi*). Recent studies do not support a role for *Moraxella bovoculi* as a primary pathogen in causing corneal ulceration associated with IBK. It is likely that *Moraxella bovoculi* may act as a risk factor for IBK by causing conjunctivitis similar to other risk factors for infectious agents such as *Mycoplasma* spp and IBR virus. *Moraxella bovoculi* has also been reported in cases of infectious keratoconjunctivitis in reindeer. Plant awns, face flies, ultraviolet radiation from bright

Infectious bovine keratoconjunctivitis with corneal ulceration in a calf. Note severe corneal edema (opacity), corneal neovascularization, and epiphora. Courtesy of Dr. John A. Angelos.

sunlight, dry and dusty environmental conditions, and shipping stress are all risk factors associated with IBK in cattle. In cattle, additional risk factors that should be considered when making herd management decisions include trace mineral deficiencies such as selenium and copper deficiency. Flies can also serve as vectors for *M. bovis*.

In sheep and goats, naturally occurring conjunctivitis or keratoconjunctivitis can be associated with *Chlamydia pecorum*, *Mycoplasma* spp (notably *M. conjunctivae*), *Moraxella ovis*, *Coleiotes conjunctivae*, *Listeria monocytogenes*, *Acholeplasma oculi*, and *Thelazia* spp.

Clinical Findings: The disease usually is acute and tends to spread rapidly. In all species, young animals are affected most frequently, but animals of any age are susceptible. One or both eyes may be affected. The earliest clinical signs are photophobia, blepharospasm, and epiphora; later, the ocular discharge may become mucopurulent. Conjunctivitis, with or without varying degrees of keratitis, is usually present. In sheep and goats, concurrent polyarthritides may be present in association with *C. pecorum* infections. Appetite may be depressed because of ocular discomfort or visual disturbance that results in inability to locate food. The usual clinical course varies from a few days to several weeks. Most corneal ulcers in cattle with IBK heal without loss of vision; however, corneal rupture and permanent blindness can occur in the most severe cases.

Lesions: Lesions vary in severity. In cattle, one or more small ulcers typically develop near the center of the cornea.

Initially, the cornea around the ulcer is clear, but within a few hours a faint haze appears that subsequently increases in opacity. Lesions may regress in the early stages or may continue to progress. After 48–72 hr in severe cases, the entire cornea may become opaque, blinding the animal in that eye. Blood vessels may invade the cornea from the limbus and move toward the ulcer at ~1 mm/day. Corneal opacity may result from edema (hazy white to blue corneas), which is a part of the inflammatory process, or leukocyte infiltration (milky white to yellow corneas), which indicates severe infection. Continued active ulceration may cause corneal rupture. Relapse may occur at any stage of recovery.

Diagnosis: In all species, presumptive diagnosis is based on ocular signs and concurrent systemic disease. It is important to distinguish that the lesions are not due to foreign bodies or parasites (see p 510). In IBK, upper respiratory signs and conjunctivitis predominate, while keratitis accompanied by ulceration is rare. In bovine malignant catarrhal fever, respiratory signs are prominent with primary uveitis and associated keratitis. Microbial culture may be beneficial in confirming the causative organisms. *Chlamydia* and *Mycoplasma* spp require special media; the diagnostic laboratory should be consulted before sample collection. Cytologic evaluation of stained slides prepared from conjunctival scrapings of sheep and goats may reveal *Chlamydia* organisms; however, intracytoplasmic inclusion bodies can be difficult to recognize. PCR analysis can be used to detect *Chlamydia* and *Mycoplasma* spp.

Prevention and Treatment: Good management practices are of paramount importance to reduce or prevent spread of infection in cattle, sheep, and goats. Separation of infected animals is beneficial when possible. Gloves and protective clothing should be worn and then disinfected between animals when affected individuals are being handled. Temporary isolation and preventive treatment of animals newly introduced to the herd may be helpful, because some of these animals may be asymptomatic carriers. Ultraviolet radiation from sunlight may enhance disease (particularly in cattle); therefore, affected animals should be provided with shade. Dust bags or insecticide-impregnated ear tags can be

used to reduce the number of face flies (*Musca autumnalis*), an important vector for *M bovis*.

M bovis bacterins are available and can be administered before the beginning of fly season. Cattle should be started on *M bovis* vaccine series 6–8 wk before the anticipated first cases of IBK to allow time for adequate immune responses to develop. The efficacy of current commercially available *M bovis* bacterins is controversial and likely varies because of vaccinal versus outbreak strains of *M bovis* and varying degrees of cross-protection afforded by vaccination. Vaccination may reduce the severity and duration of infection in affected animals. IBR may predispose cattle to infection with *M bovis*; thus, vaccination of herds against IBR may reduce outbreaks of *M bovis*. The use of modified-live IBR vaccines has been associated with outbreaks of IBK in cattle; IBR vaccination must be appropriately timed with cattle shipments so that these events do not coincide. Vaccination of cattle with a modified-live IBR vaccine could likely exacerbate an outbreak of IBK associated with *M bovis* and/or *Moraxella bovoculi* because of increased ocular and nasal secretions spreading bacteria between herd mates as well as corneal epithelial damage. In recent studies, the efficacy of autogenous *Moraxella* spp bacterins to prevent IBK has not been demonstrated in randomized controlled field trials. Nevertheless, anecdotal evidence has suggested that, for some herds, *M bovis* and/or *Moraxella bovoculi* autogenous bacterins have provided benefit in reducing IBK problems. It is unlikely that any *Moraxella* spp vaccine will ever completely control IBK in the face of overwhelming challenge from and exposure to other risk factors such as flies, dust, other infectious agents, and trace mineral deficiencies. As such, planning and implementing a successful IBK control program should address multiple issues that may potentially reduce susceptibility of cattle to IBK beyond just vaccines against *Moraxella* spp.

M bovis is susceptible to many antibiotics. Because antibiotic susceptibility may vary in different geographic locations, bacterial culture and susceptibility testing is advised. One common treatment is bulbar conjunctival injection

with penicillin. In the USA, long-acting oxytetracycline (two injections of 20 mg/kg, IM or SC, at a 48- to 72-hr interval) and tulathromycin (2.5 mg/kg, SC, given once) are currently approved antibiotics to treat IBK in cattle. Other effective antibiotics include ceftiofur crystalline free acid (6.6 mg/kg, SC, at the base of the ear) and florfenicol (20 mg/kg, IM, two doses at a 2-day interval). A single injection of long-acting oxytetracycline (20 mg/kg, IM) along with oral oxytetracycline (2 g/calf/day for 10 days) fed in alfalfa pellets has also been shown to be effective at reducing severity of IBK during a herd outbreak. Topical applications of ophthalmic preparations should be applied at least three times a day to be effective, and thus are often not cost-effective or practical in herd settings. Effective antibiotics for topical ophthalmic use include triple antibiotic, gentamicin, and a combination oxytetracycline/polymyxin B ointment. A third-eyelid flap or partial tarsorrhaphy, which will shade the cornea from sunlight, together with subconjunctival injection, may reduce morbidity in severely affected animals. A temporary eye patch glued to the hair surrounding the eye is an inexpensive and easily applied treatment. The eye patch provides shade, prevents exposure to flies, and may help to decrease spread of organisms.

For sheep and goats in which chlamydial and mycoplasmal infections are suspected, respectively, topical tetracycline, oxytetracycline/polymyxin B, or erythromycin ointments are treatments of choice. These preparations are all effective against *Chlamydia* or *Mycoplasma* and should be applied 3–4 times daily. If topical therapy is not practical, long-acting oxytetracycline (20 mg/kg, IM) or the addition of oxytetracycline to the feed (80 mg/animal/day) may be beneficial.

Animals with substantial uveitis secondary to keratoconjunctivitis that is particularly painful may benefit from topical ophthalmic application of 1% atropine ointment 1–3 times daily. This will prevent painful ciliary body spasms and reduce the likelihood of posterior synechia formation that occurs with miosis. Because of mydriasis caused by atropine, treated animals should be provided with shade. Systemic NSAID treatment may be used to provide relief from secondary uveitis.

NEOPLASIA OF THE EYE AND ASSOCIATED STRUCTURES

The different tissues of the eye and associated structures can be the site of primary or metastatic neoplasms. Ophthalmic neoplasms vary in histologic type, frequency, and importance in different species and are a significant group of diseases in veterinary ophthalmology.

CATTLE

The most frequent ophthalmic neoplasms in cattle are the squamous cell carcinoma complex and the orbital infiltration associated with lymphosarcoma (see p 743). The latter, with extensive invasion of the orbital structures, results in progressive bilateral exophthalmia, reduced ocular mobility, exposure keratitis, and corneal ulcerations that can lead to perforation.

Ocular squamous cell carcinoma (cancer eye) is the most common neoplasm of cattle. It results in significant economic loss due to condemnation at slaughter and a shortened productive life. It occurs more frequently in the *Bos taurus* than the *Bos indicus* breeds, and it is seen most often in Herefords, less often in Simmentals and Holstein-Friesians, and rarely in other breeds. The peak age of incidence is 8 yr; actual incidence varies from 0.8% to 5.0% among herds. The cause is multifactorial, with heritability, sunlight, nutrition, eyelid pigmentation, and perhaps viral involvement playing roles. The medial and lateral limbal regions (comeoscleral junction) are affected most frequently, but the eyelids, conjunctivae, and nictitating membrane may be affected. Bilateral involvement varies but can be as high as 35%. Eyelid and conjunctival pigmentation are highly heritable and can reduce the frequency of lid squamous cell carcinomas, but they have limited effect on the development of tumors of the conjunctiva and nictitating membrane. The cancerous or precancerous lesions are bilateral or multiple in the same eye in ~28% of cases. Ultraviolet radiation and a high plane of nutrition are contributing factors. The viruses of infectious bovine rhinotracheitis and papilloma have been isolated from the neoplasms, but their significance is unknown.

The lesions usually begin as benign, smooth, white plaques on the conjunctival surfaces; they may progress to a papilloma and then to a squamous cell carcinoma or go directly to the malignant stage. Lid lesions usually begin as either an ulcerative

or a hyperkeratotic lesion (cutaneous horn). While in this benign stage, ~30% may spontaneously regress. The tumor may become quite large without invading the globe, but invasion into the eye and orbit and metastasis to parotid and submandibular lymph nodes occur in late stages of the disease. Diagnosis usually is made by the typical clinical appearance but can be confirmed rapidly by cytologic examination of impression smears. The intraocular tumor invasion must be differentiated from severely damaged and disorganized eyes after trauma or advanced infectious keratoconjunctivitis (see p 512).

Squamous cell carcinomas may respond to excision, cryotherapy, hyperthermia, radiation therapy, local chemotherapy using 5-fluorouracil, immunotherapy, or often a combination of these therapies. Surgical excision is indicated for small lesions or for debulking the larger lesions before cryotherapy or hyperthermia. Superficial keratectomy can be used to excise the limbal plaques, papillomas, and squamous cell carcinomas. After superficial keratectomy and tumor removal, cryotherapy, hyperthermia, or a permanent bulbar conjunctival graft have yielded excellent short-term results, but recurrence at the same or a different site is ~25%.

For advanced lesions confined to the globe, enucleation is recommended. When adjacent tissues are affected, removal of the globe and all orbital contents (exenteration) should be performed. Immunotherapy is

Squamous cell carcinoma, eyelid, cow.
Courtesy of K. Gelatt.

still experimental, and the resulting tumor regression may be temporary. Radiation therapy is not practical in the field but may be an option for valuable animals.

Owners of problem herds should be advised of the heritability factor, with affected animals and their offspring culled to decrease the incidence of tumors. Active breeding bulls with ocular squamous cell carcinoma should be culled.

HORSES

In horses, tumors of the skin, eye, and genital system are the most frequent, and ~80% of eye neoplasms are malignant. Neoplasms of the eyelids and conjunctivae are the most frequent ophthalmic tumors in horses; most are either squamous cell carcinoma or sarcoid. Orbital neoplasms are rare and are usually local extensions of eyelid, conjunctiva, or sinus tumors or systemic neoplasms, including lymphosarcoma. Intraocular neoplasms, usually malignant melanomas, are rare.

Squamous cell carcinoma occurs most frequently in horses 8–10 yr old and may occur more frequently in those with non- or lightly pigmented eyelids. The Appaloosa and draft breeds are affected most frequently. Ultraviolet radiation may be important, because the incidence in North America is higher in southern and western mountainous areas and in areas of increased altitude or mean solar radiation. The eyelids (~15%), conjunctivae and limbus (~25%), and nictitating membrane (~30%) can be affected with ulcerative or proliferative masses. Bilateral involvement is infrequent (~15%). Squamous cell carcinoma of the nictitans is more likely to invade the orbit than are those from other sites. Treatment of ocular squamous cell carcinoma in horses

is similar to that in cattle, although presentation for treatment is usually earlier, and greater emphasis is placed on cosmetic appearance after therapy. Surgical excision for equine squamous cell carcinoma yields ~50% success when used alone. When surgery is combined with cryotherapy, hyperthermia, or local chemotherapy, the success rate is markedly increased. As expected, small squamous cell carcinomas can be excised more widely, and the need for later reconstructive blepharoplasties or corneoconjunctival surgeries is more limited. Often, referral to specialty services that routinely treat these types of neoplasms can yield the best possible outcomes. The preventive role of face shields or masks with the goal of reduced ultraviolet exposure to the external eye is unknown, but their use should start at a very young age.

The equine sarcoid (*see p 954*) generally affects young horses (average 3.8 yr old) and represents ~40% of all neoplasms in horses. Because sarcoids are locally destructive and have a high recurrence rate after surgery, effective treatment when the periocular tissues are involved presents cosmetic and functional problems. Sarcoids are grouped into occult, verrucous, nodular, fibroblastic, mixed, and malignant types, and they are divided histologically into neurofibroma, neurofibrosarcoma, myxosarcoma, and fibromyxosarcoma. They appear initially as subcutaneous masses in the eyelids or canthi; they usually enlarge rapidly and may invade the skin, appearing as red, fleshy masses. Treatment is surgery, hyperthermia, cryotherapy, chemotherapy, radiation, or a combination of these therapies. After attempts to surgically remove the sarcoid, recurrence may be rapid and precede wound healing. Immunotherapy using BCG (*bacille Calmette-Guérin*) as a potentiator of the cellular immune system is often successful (~70%). Injections should be repeated at 2- to 4-wk intervals until the mass disappears. Systemic corticosteroids and antiprostaglandins before and after treatment may decrease the likelihood of systemic anaphylactic reactions. Gamma radiation therapy using platinum-sheathed iridium¹⁹² is highly successful (~95%) but less convenient and available and usually requires a total dose of 7,000–9,000 rads.

Fleshy mass representing squamous cell carcinoma of the limbus in a white horse. The area should be closely examined, because this mass often can be removed by keratectomy and covered by a permanent advancing bulbar conjunctival graft. *Courtesy of K. Gelatt.*

DOGS

Eyelid neoplasms are the most frequent group of ophthalmic neoplasms in dogs. Adenoma and adenocarcinoma of the meibomian gland are the most common lid neoplasms (~60%) in older dogs; local disfigurement and irritation necessitate excision,

which is usually successful. Meibomian (sebaceous) adenocarcinomas are locally invasive and histologically malignant but are not known to metastasize. Lid melanomas, exhibited as spreading pigmented masses on the eyelid margin or a mass within the lid, should be widely excised. Other frequent eyelid neoplasms include histiocytoma, mastocytoma, and papilloma and may require biopsy to determine the best mode of therapy and prognosis. The vast majority of canine eyelid neoplasms are treated successfully by only surgical excision.

Canine conjunctival neoplasms have a greater propensity for malignancy and local infiltration than eyelid neoplasms and require more extensive surgical excision. Because recurrence may occur, periodic reexaminations are recommended.

Orbital neoplasms in dogs produce exophthalmia, conjunctival and eyelid swelling, strabismus, and exposure keratitis. The globe cannot be retropulsed. Usually, there is no pain. Because ~90% of the neoplasms are malignant and ~75% arise within the orbit, the prognosis for long-term survival is often poor. The most frequently diagnosed tumors include osteosarcomas, fibrosarcomas, and nasal adenocarcinomas. The neoplasm type should be determined histologically, and the extent of the mass determined by physical examination, skull radiographs (including special contrast procedures, CT, and MRI), and ultrasonography before treatment by surgical excision or radiation. Excision of the orbital mass with the globe and all orbital tissues (including adjacent bone) may decrease the possibility of recurrence but is more disfiguring, especially in shorthaired dogs. Prognosis

is guarded or poor; 25%–40% of affected dogs are euthanized on diagnosis. Surgery, sometimes combined with chemotherapy, can often prolong life for ≥6 mo.

Corneal and limbal neoplasms are uncommon in dogs and can be confused with nodular fasciitis and proliferative keratoconjunctivitis in Collies. Biopsy is often necessary to establish the diagnosis and the specific plan for the best therapy. Limbal or epibulbar malignant melanomas are focal, usually superficial, pigmented masses that extend both onto the cornea and caudally toward the globe's equator. After close intraocular examination (including gonioscopy and B-scan ultrasonography) to detect possible penetration of the sclera, partial to full-thickness surgical excision with scleral grafts, cryotherapy, or laser photocoagulation is usually successful. If intraocular extension occurs, enucleation is performed.

Melanomas are the most common uveal neoplasm, are usually pigmented, and most frequently involve the iris and ciliary body, with the latter being the site of origin. Choroidal melanomas, common in people, are rare in dogs. Clinical signs of anterior uveal melanomas may include an obvious mass, persistent iridocyclitis, hyphema, glaucoma, and pain. These melanomas are divided into melanocytic melanomas (80%–90%) and malignant melanomas (10%–15%). Metastasis is infrequent (<5%). Ciliary body adenoma and adenocarcinoma are the most frequent epithelial neoplasms of the anterior uvea. Signs may include hyphema, glaucoma, and usually a nonpigmented mass behind the iris and in the pupil. Neoplasms of neuroectodermal origin are rare. Treatment is usually enucleation. Recent studies in iridal melanomas, especially in young Labrador Retrievers, suggest that noninvasive diode laser photocoagulation may be effective and can be repeated if necessary, thereby avoiding enucleation.

Secondary uveal adenocarcinomas are relatively infrequent and originate from a number of distant sites. Other neoplasms, such as transmissible venereal tumor and hemangiosarcoma, may metastasize to the anterior uvea. Lymphosarcoma frequently involves the anterior uvea and other ocular structures and may present as bilateral disease. Systemic therapy with topical and/or systemic anti-inflammatory treatment for intraocular lymphoma may be attempted using one of several available lymphoma protocols (eg, combination of cyclophosphamide, prednisolone, vincristine, and/or doxorubicin), but dogs with both intraocular and systemic lymphoma have shorter survival times.

Lid masses in dogs are mostly adenomas or adenocarcinomas that arise from the meibomian glands. Surgical excision is usually effective, with infrequent recurrence. Courtesy of K. Gelatt.

CATS

Ocular neoplasms are less frequent in cats than in dogs and tend to be more malignant. Approximately 2% of feline patients present with neoplasia, and of these, 2% are affected with ophthalmic tumors. Eyelid and conjunctival tumors are the most frequent primary ophthalmic neoplasms. These neoplasms are usually malignant and more difficult to treat in cats than in dogs. Squamous cell carcinomas, which are more common in white cats with nonpigmented eyelid margins, can involve the eyelids, conjunctivae, and the nictitating membrane; they are pink, roughened, irregular masses or thickened ulcerations. Other less frequent neoplasms include adenocarcinomas, fibrosarcomas, neurofibrosarcomas, and basal cell carcinomas. Treatment varies with the tumor type, location, and size and includes surgical excision, radiation therapy, and cryotherapy. Prognosis for these malignant tumors is poor, with survival of only 1–2 mo.

The most common primary intraocular neoplasm in cats is diffuse iridal melanoma, which presents as progressive hyperpigmentation of the iris with an expanding irregular surface. Pupillary abnormalities, secondary glaucoma due to iridocorneal angle obstruction, and buphthalmia occur late in the disease. Enucleation is recommended for masses that are fast-growing or produce pupillary abnormalities, iridocorneal angle involvement, and/or glaucoma, because metastasis is frequent in advanced cases.

Post-traumatic intraocular sarcoma occurs in older cats with a history of chronic uveitis, previous intraocular damage, or intraocular injections of gentamicin. Clinical signs are either glaucoma, phthisis bulbi, or chronic uveitis. Intraocular cartilage and osteoid production is common. Early enucleation is recommended.

Diffuse iridal melanoma in a cat, with progressive pigmentation of the anterior surface of the iris. Courtesy of K. Gelatt.

Feline lymphosarcoma-leukemia complex (FeLLC) is the most common secondary ocular neoplasm. Cats with ocular FeLLC have clinical signs ranging from isolated ocular lesions (affecting one or both eyes) to severe systemic illness. Corneal abnormalities may include keratitis, edema, neovascularization, corneal infiltrates, and hemorrhages within the stroma. Ulcerative keratitis may result. Masses can be found in the orbit, globe, conjunctivae, and eyelids. Pupillary abnormalities, including mydriasis, anisocoria, spastic pupil syndrome, “D” or reverse “D” pupil shape, and lack of light-induced pupillary reflexes, may develop months before other clinical signs. Anterior uveitis is the most common clinical finding in FeLLC. Other findings include ocular hypotension, changes in iridal pigmentation and color, keratic precipitates, hyphema, anterior and posterior synechiae, miosis, and aqueous flare. Posterior segment changes include retinal hemorrhages, tortuous dilated vessels, perivascular cuffing, and detachment and degeneration of the retina. Few therapy studies of cats with ophthalmic lymphoma exist, but cats with lymphoma and feline leukemia virus infection have lower overall survival times.

DEAFNESS

Deafness—the absence of perception of sound—and reduced hearing are common in dogs and cats, and to a lesser extent in other species. Deafness can be hereditary or acquired, and sensorineural or conductive.

Hereditary deafness can be cochleosaccular or neuroepithelial in origin. Cochleosaccular deafness is usually seen in dogs with the piebald or merle genes and in cats with white coat color. It produces deafness

in one or both ears and is often associated with blue eyes and white pigmentation. Pigment-associated deafness also occurs in equine, bovine, porcine, and other species. This is the most common cause of deafness in dogs and cats and should be the first differential diagnosis considered in an animal with any white pigmentation. The condition develops within 1–3 wk after birth secondary to stria vascularis degeneration that results from the suppression of melanocytes by the pigment gene, leading to cochleosaccular neuronal degeneration. Unilaterally deaf animals may go undetected without brain stem auditory evoked response (BAER) testing but will pass on an increased deafness risk to offspring if bred; inheritance does not appear to be simple autosomal. Neuroepithelial deafness is not associated with pigment patterns, is usually bilateral, and results from primary hair cell loss over the same time course as cochleosaccular deafness; vestibular signs may also be present (eg, in Doberman Pinschers).

Congenital deafness (usually hereditary) has been reported in ~100 dog breeds and is especially prevalent in the piebald-carrying breeds of Dalmatian, Bull Terrier, Australian Cattle Dog, English Setter, English Cocker Spaniel, Boston Terrier, and Parson Russell Terrier, and in the different merle-carrying breeds. The prevalence of deafness in white cats (dominant white gene), especially those with blue eyes, is high, but blue-eyed cats from Siamese breeds do not appear to be affected. No DNA testing is currently available to identify carriers of genetic deafness in dogs or cats, so BAER testing and selective breeding are the only available options to reduce prevalence within breeds. A late-onset form of genetic neuroepithelial deafness may exist in Rhodesian Ridgebacks.

Conduction deafness results from obstruction or reduction of sound reaching the cochlea, usually from otitis media (see p 531), chronic otitis externa (see p 527), or excess cerumen, and less commonly from tympanum rupture or ossicle damage. Resolution of the obstruction or tissue damage usually restores hearing. Recovery after otitis media may require weeks while the body phagocytizes the infection residue, accompanied by progressive recovery of hearing. Primary secretory otitis media (glue ear), especially in Cavalier King Charles Spaniels, produces a persistent conductive deafness that may be treated by myringotomy, bulla osteotomy, or tympanostomy tubes.

Sensorineural deafness results from loss of cochlear nerve cells and is not

reversible in mammalian species. Acquired sensorineural deafness may result from intrauterine infection or toxins, otitis interna or meningitis, mechanical or noise trauma, ototoxicity, anesthesia, neoplasms, or aging (presbycusis). Loss can be bilateral or unilateral, and partial or complete. Otitis interna (see p 531) will frequently be accompanied by vestibular signs such as head tilt and circling. Hunting or military dogs exposed to loud percussive sounds such as gunfire experience cumulative losses that may initially go unnoticed. This is often observed in hunting dogs, in which the distance at which a trained dog responds to commands shrinks by half or more.

A variety of drugs and chemicals are ototoxic and vestibulotoxic, especially the aminoglycoside antibiotics (gentamicin, amikacin), antineoplastic drugs (cisplatin), salicylates, diuretics (ethacrynic acid, furosemide), and antiseptics (chlorhexidine). The toxicity is permanent. Aminoglycoside toxicity, the most common, functions through reactive oxygen species, and human studies have shown that coadministration with aspirin or N-acetylcysteine ameliorates the toxicity; it is unknown if postexposure treatment is of value. High frequencies are affected first, slowing recognition of the toxicity, which may appear at a delay of weeks after treatment has been discontinued. Dogs or cats undergoing general anesthesia for teeth or ear cleaning occasionally awaken bilaterally deaf, but the mechanisms, which can be conductive or sensorineural, are unknown. Few reports have been seen for procedures on body regions other than mouth and ear, and no unilateral deafness from anesthetic procedures has been reported.

Many geriatric animals develop **presbycusis**. Mid to high frequencies are affected first, followed by progressive loss at all frequencies. The loss may appear to be acute in onset but reflects the animal's eventual inability to compensate for the progressive loss that had been developing for some time. There does not appear to be a gender difference in prevalence. Onset is typically in the last third of a breed's typical lifespan and will progress to complete deafness if the animal lives long enough.

Unilaterally deaf animals show negligible signs, primarily an inability to localize sound origins and orienting toward the good ear, but many compensate and show no signs. Bilateral orienting pinnae movements persist in unilaterally deaf animals. Bilaterally deaf animals do not respond to sound stimuli but become adept at

increased attention to other sensations such as vision and vibration. Affected animals “key” off the behavior of littermates or other household pets. Breeders of breeds with high prevalence often choose to euthanize bilaterally deaf (and spay/neuter unilaterally deaf) animals because of a frequent outcome of poor quality of life and liabilities from owning a deaf dog, such as startle biting. Bilaterally deaf dogs can be successfully raised, but more dedication than normal is required. Owners of deaf dogs should be counseled to protect their pets against undetected dangers such as motor vehicles.

Dogs that lose hearing later in life appear to cope well but on occasion exhibit transient behavior suggestive of auditory sensations similar to subjective tinnitus in people. There is no evidence that deaf animals otherwise experience pain or discomfort from the condition.

Identification of deafness is most accurate with BAER testing at referral centers, but behavioral testing is typically

used in the clinic. Observations are made for a response to a sound stimulus outside the animal's visual field. Limitations include the inability to identify unilateral deafness, stimulus detection through other senses, blunted responses in stressed animals, and failed responses from expired novelty of a repeated stimulus. Failure of a sleeping animal to waken to an auditory stimulus that does not activate other senses is a reliable indicator of bilateral deafness in the home environment.

Otoscopic examination of the external ear and tympanum, radiography of the tympanic bullae, and neurologic examination may reveal the cause, especially in conduction deafness, which usually responds to appropriate medical or surgical treatment. Early intervention in ototoxicity may reduce or reverse loss but usually is not successful. Once developed, sensorineural deafness cannot be reversed, and its cause cannot be determined. Congenital deafness in breeds with white pigmentation is nearly always of genetic origin.

DISEASES OF THE PINNA

A variety of dermatologic conditions affect the pinna. Rarely, a disease affects the pinna alone or the pinna is the initial site affected. As with all dermatologic conditions, a diagnosis is best made with the results of a thorough history, a complete physical and dermatologic examination, and with careful selection and evaluation of specific diagnostic tests. This overview is not all inclusive but discusses diseases that solely or commonly affect the pinna of domestic animals.

ARTHROPOD BITE PINNAL DERMATITIS

Arthropods commonly cause dermatitis of the pinnae either through direct damage from the bite of the parasite or as a result of hypersensitivity. Ticks can cause irritation at the site of attachment and may be found on the pinna or in the ear canal. The spinous ear tick (*Otobius megnini*), found in the southwestern USA, south and central Americas, southern Africa, and India, is a soft-shelled tick, the larval and nymphal forms of which parasitize the external ear

canal of horses, cattle, sheep, goats, deer, rabbits, cats, and dogs. Clinical signs include head shaking, head rubbing, or drooped pinnae. Both the animal and the environment should be treated. Treatment involves mechanical removal of as many ticks as possible with a forceps and spraying or dipping the coat with pyrethrin/pyrethroid products or malathion. Treatment of secondary bacterial or yeast otitis externa is also important. Precautions to prevent reinfections should be instituted.

Gotch ear is a condition described in cattle, and also in a goat, that results from infestation of the pinna with the Gulf Coast tick, *Amblyomma maculatum*. Adult ticks prefer feeding on animal ears, and when ticks are present in sufficient numbers the pinna becomes edematous, erythematous, and crusting at the tick-attachment sites. Curling of the tip of the ear and excoriations may also be seen. Spotted fever group rickettsiae, such as *Rickettsia parkeri*, have been suggested to cause the skin lesions, because ticks removed from the pinna of animals with gotch have been, in some cases, positive for *Rickettsia* spp by PCR. However, efforts to find the organ-

isms in skin samples from affected areas have failed. Removal of ticks and treatment of any secondary infection are curative.

INSECT BITE DERMATITIS

This worldwide problem is caused by inflammatory mediators or toxic substances present in the saliva of various hematophagous insects. It typically affects dogs, cats, and horses. Clinical signs are characterized by small papules and wheals with central hemorrhagic crusts that can progress to multiple small ulcers. Lesions are found on the apexes of the pinnae of cats and dogs with erect ears or on the folded surfaces of the pinnae of dogs with flopped ears. The causative insect can vary with the season and environment and include, among others, mosquitoes (*Aedes* spp, *Culex* spp), the stable fly (*Stomoxys calcitrans*), and black flies (*Simulium* spp). Mosquitoes can also cause a hypersensitivity reaction in cats characterized by inflammatory lesions on the pinnae, face, and feet (see below). The rabbit flea (*Spilopsyllus cuniculi*) is found mainly in Europe and Australia and can be transmitted to dogs and cats. It adheres tightly to the skin of the host and typically affects the tip of the pinna, where it may cause dermatitis. In horses, bites of the stable fly, black flies, and *Culicoides* spp can cause a hypersensitivity reaction or severe dermatitis that results in lesions on the dorsal and/or ventral trunk and face in addition to the pinna. Treatment includes fly repellents, controlling the fly population with environmental clean up (manure, compost, etc), and insecticides. Topical or oral short-acting glucocorticoids may be necessary to reduce the inflammation and pruritus in severe cases.

MITE INFESTATIONS

Sarcoptes scabiei is a common mange mite in pigs and dogs, and *Notoedres cati* is common in cats throughout the world (see also MANGE, p 914). In the USA, sarcoptic mange is rare in horses and sheep and is considered a reportable disease. Papular eruptions progress to scaling, crusting, and excoriations of the ear margins and other parts of the body. Pruritus is severe. Transmission is by direct contact with infected animals or contaminated fomites. Diagnosis is based on clinical signs, history, and discovery of mites from multiple skin scrapings. Negative scrapings do not exclude the diagnosis, however, because mites are often difficult to find. If the diagnosis is suspected, treatment should be

instituted. Mites are much easier to find on skin scrapings of cats with notoedric acariasis. Treatment options include 2%–4% lime sulfur dips (safe in all species) every 5 days for 4–6 treatments, amitraz dips at a strength of 250 ppm (in dogs only) applied weekly for 4 to 6 treatments, and ivermectin at 200–300 mcg/kg, PO or SC, every 1–2 wk for 3–4 treatments. Treatment response is not consistent when using lime sulfur dips or amitraz in small animals; therefore, these topicals are not good options for a treatment trial (ie, mites are not found on skin scrapings). Oral milbemycin oxime has been reported to be safe and effective in the treatment of sarcoptic mange in dogs but is not FDA approved for this purpose. The recommended treatment protocol is 2 mg/kg once weekly for 4 to 6 treatments or twice weekly for 3 wk. Selamectin, also extra-label, has also shown efficacy; the recommended protocol is four applications at 2-wk intervals. Moreover, imidacloprid 10% moxidectin 2.5% spot-on applied twice at a 30-day interval or every 3 wk for three treatments has been shown to be efficacious. There are also anecdotal reports of efficacy of these treatment modalities for treatment of notoedric mange in cats. Because mites can survive off the host for a variable amount of time, all bedding, brushes, tack, and fomites should be treated as well. All in-contact animals also should be treated because of the contagious nature of these acarioses.

Ivermectin is widely used to treat sarcoptic mange in dogs and has been used to treat notoedric mange in cats, but it is not approved by the FDA for these indications. Therefore, every caution should be taken, and clients specifically informed of inherent risks with this drug. Dog breeds susceptible to ivermectin toxicity include Collies, Shetland Sheepdogs, Australian Shepherds, English Shepherds, Longhaired Whippets, McNabs, Silken Windhounds, and Old English Sheepdogs. Before using ivermectin in any of these breeds, a genetic test for the mutation of the ABCB1 (formerly MDR1) gene, which encodes for the multidrug transporter P-glycoprotein, should be performed. (This test is available at the University of Washington.)

Nonburrowing psoroptic mites cause otitis externa in horses and goats. Animals may be asymptomatic or present with pruritus, head shaking, and a drooping ear. Crusted papules, alopecia, and/or scaling are typically present on the pinnae. Diagnosis is confirmed by finding the mites on skin scraping or in otic exudate, but mites may

be difficult to find in the ear canal. Ivermectin at 200 mcg/kg, PO, every 2 wk for two treatments has been shown to be effective.

ALLERGY

Environmental-induced (eg, house dust, house dust mites, pollens of trees, grasses and weeds, molds) or food-induced **atopic dermatitis** are common allergic disorders of dogs and cats and frequently cause erythema and pruritus of the pinnae and external ear canals. The allergic condition predisposes to develop secondary bacterial or yeast otitis externa, which can extend to the pinna. In these cases, papules, crusts, and lichenification may develop in addition to the erythema. Other body sites such as the face (ie, periocular region, muzzle, chin), axilla, groin, and feet are also often affected. Diagnosis is based on a characteristic history, clinical signs, and the elimination of other pruritic skin diseases. A strict food elimination trial is important for animals with year-round clinical signs to determine whether food allergens are triggering the atopic signs. If food allergy is excluded or is only part of the allergic condition, intradermal or serologic allergy tests can be performed to support a presumptive diagnosis of environmental-induced atopic dermatitis and, more importantly, to institute allergen-specific immunotherapy. It is very important to identify and treat any secondary ear and skin bacterial or yeast infections, because they aggravate the allergic dermatitis. Treatment of food-induced atopic dermatitis consists of solely feeding the diet used during the food trial or avoiding food ingredients known to trigger the allergic reaction. Treatment of atopic dermatitis consists of using anti-inflammatory/immunomodulatory drugs, including oral short-acting glucocorticoids such as prednisone or prednisolone at 1 mg/kg/day and tapering to the lowest possible dosage administered every other day. Cyclosporine at 5 mg/kg/day can also be used in animals that cannot tolerate or do not respond well to glucocorticoid therapy. Omega-3 and/or omega-6 fatty acids can be used as adjunctive therapy. H₁-receptor antihistamines typically are not very efficacious to control the pruritus or inflammation associated with atopic dermatitis, but their safety profile and relatively low cost make them worthwhile to try. Allergen-specific immunotherapy based on intradermal or serologic test results is currently the only specific therapy for atopic dermatitis and should be considered as a treatment option.

Feline mosquito hypersensitivity is an allergic reaction to mosquito bites that can cause an ulcerative and crusted dermatitis of the pinnae, nose, and less commonly the footpads, eyelids, chin, and lips of cats. Lesions progress from wheals to papules to plaques to crusted ulcers that coalesce to affect extensive areas. Pruritus is a consistent sign, and regional lymphadenopathy may occur. In severe cases, fever or other systemic signs may develop. Histologically, the lesions are characterized by severe superficial and deep perivascular to interstitial eosinophilic dermatitis, often associated with flame figures, folliculitis, and furunculosis. Differential diagnoses include pemphigus foliaceus, herpesvirus ulcerative dermatitis, other causes of eosinophilic dermatitis (food allergy, atopy, idiopathic), notoedric mange, and dermatophytosis. Treatment includes keeping the cat inside and using a pyrethrin repellent (avoid permethrin-containing products in cats) when exposure to mosquitoes is anticipated. Systemic glucocorticoids may be necessary in severe cases. (See also MOSQUITOES, p 888.)

AURAL CONTACT DERMATITIS

Aural contact dermatitis commonly affects the concave aspect of the pinna, likely because it lacks hair. Topical ear medications, particularly those containing aminoglycosides and/or propylene glycol, are common causes in animals being treated for otitis externa. Lesions may develop 1–7 days after starting therapy. Contact dermatitis can also result from ointments applied transdermally to the concave aspect of the pinnae. Clinical signs include erythema, edema, papules that may coalesce and form plaques, erosions, and/or ulcerations. Pruritus and pain are variable. A definitive diagnosis can rarely be made, because drug challenge is not recommended. Discontinuation of all topical medications is the indicated treatment. Changing to a different topical drug is not recommended because most products have identical vehicles, which are the offending cause in most cases.

PINNAL ALOPECIA

Symmetrical noninflammatory alopecic disorders affecting the pinna, such as periodic pinna alopecia, pattern baldness, and alopecia associated with melanoderma, may affect dogs and cats and are typically idiopathic.

Periodic pinna alopecia in Miniature Poodles is characterized by progressive

bilateral alopecia of the convex surfaces of the ear. The hair loss is acute in onset and progresses throughout several months, but hair may spontaneously regrow. There are no other clinical signs. A similar condition was reported in Siamese cats in which complete or patchy alopecia of the convex aspect of both pinna develops. Treatment is unnecessary.

Pattern baldness affecting only the pinna has been reported in Dachshunds, Chihuahuas, Italian Greyhounds, and Whippets and is thought to have a hereditary predisposition. The age of onset is ≤ 1 yr of age. Lesions start as thinning of the hair coat, and complete pinnal alopecia may occur by 8–9 yr of age. Other commonly affected areas are the ventral neck and thorax and the caudal medial thighs. The hair loss is asymptomatic. Histologically, the skin is normal, and hair follicles are diminished in size but normal in appearance. No effective treatment has been reported, but pentoxifylline (15–20 mg/kg, bid-tid), melatonin (3 mg for small breeds and 6 mg for large breeds, bid-tid), and topical minoxidil have anecdotally been described as helpful. Pattern baldness restricted to the pinna has also been reported in cats; however, use of minoxidil in cats should be avoided, because it has been associated with death in two cases.

Alopecia associated with melanoderma has been described mostly in Yorkshire Terriers and occasionally in Doberman Pinchers. Alopecia and marked hyperpigmentation (melanoderma) are first noticed between 6 mo and 3 yr of age and affect both pinna and the bridge of the nose. Other areas such as the tail and feet may also be affected. The alopecic and hyperpigmented skin has a smooth, shiny, and leathery appearance. The condition tends to worsen as the dog ages, and it typically does not spontaneously resolve. There is no treatment.

EAR MARGIN SEBORRHEA

This condition is common in Dachshunds, although other breeds with pendulous pinnae may be affected. Lesions usually affect the apex of the pinnae on both sides but can progress to involve the whole ear margin. The cause is unknown. Lesions appear as waxy, gray to yellow scales adherent to the base of hair shafts. Plugs of hair can be easily epilated, leaving behind a shiny surface to the skin. In severe cases, the ear margins are edematous and fissured. Histologic findings include severe hyperkeratosis and follicular keratosis with

dilated follicles filled with keratin debris. Differential diagnoses include sarcoptic mange, pinnal alopecia, proliferative thrombovascular necrosis, dermatophytosis, and frostbite. Dermatophytosis, in particular, can cause a scaling pinnal dermatitis in dogs, cats, and horses, but the ear margin is not typically involved and other areas of the body are generally affected as well. Treatment includes antiseborrheic shampoos (eg, sulfur, salicylic acid, benzoyl peroxide), keratolytic products, dioctyl sodium sulfosuccinate (DSS), and systemic medications that may help normalize the abnormal keratinization process (eg, vitamin A and synthetic retinoids, essential fatty acids). Topical or oral glucocorticoids and pentoxifylline (10–15 mg/kg, bid-tid) may be beneficial when severe inflammation and fissures develop.

SEBACEOUS ADENITIS

Sebaceous adenitis is uncommon in dogs and rare in cats. The cause is unknown, but the strong predisposition of certain canine breeds suggests that genetics plays a role. The proposed pathogenesis includes cell-mediated immunologic destruction of the sebaceous gland; a primary cornification disorder of the glandular duct, resulting in obstruction and secondary inflammation of the gland; an anatomic defect of the sebaceous gland, leading to lipid leakage and a foreign body reaction; or an abnormal lipid metabolism, leading to glandular destruction. Predisposed breeds include Standard Poodles, Akitas, Samoyeds, Vizslas, Havanese, Springer Spaniels, and Lhasa Apsos; however, various other breeds can be affected. Lesions typically affect the pinnae, forehead, face, tail, and dorsal trunk and are characterized by alopecia and adherent scales that cast hair shafts. The severity and characteristics of clinical signs vary among breeds. Pruritus is variable and mostly associated with secondary bacterial infection. Histopathologic findings include diffuse absence of sebaceous glands, granulomatous to pyogranulomatous inflammation at the site of previous glands, and follicular keratosis. Currently, the most efficacious therapy for sebaceous adenitis is oral cyclosporine (5 mg/kg/day) in association with topical therapy. Oral vitamin A (1,000 IU/kg/day) or synthetic retinoids (eg, isotretinoin or acitretin) may be efficacious in some cases. The combination of tetracycline (250 mg, tid, for dogs < 10 kg; 500 mg, tid, for dogs > 10 kg) or doxycycline (5 mg/kg, bid) and niacinamide

(250 mg, tid, for dogs <10 kg; 500 mg, tid, for dogs >10 kg) is an option for milder cases or when owners are concerned about costs and/or adverse effects associated with cyclosporine or retinoids. Topical therapy in the form of medicated shampoos and emollient rinses or sprays should be used in conjunction with systemic therapy. Omega-3 and omega-6 fatty acids can also be used as adjunctive therapy. To help soften the adherent scales, a mixture of 70%–75% propylene glycol in water can be sprayed or used as a rinse on the animal's coat and allowed to act for 2–3 hr before bathing with a medicated shampoo. Another option is to apply baby oil soaks (undiluted or diluted with water 1:1) for 1–6 hr before bathing with a medicated shampoo.

AURICULAR HEMATOMAS

Auricular hematomas are small-to-large, fluid-filled swellings that develop on the concave surface of the pinnae in dogs, cats, and pigs. The pathogenesis for the development of the lesions is unknown, but head shaking or ear scratching due to pruritus is almost always involved. In dogs, the condition is seen with atopic dermatitis and food allergy in which the ear canals are the primary sites of allergic inflammation, pruritus, and secondary infection. In pigs, sarcoptic mange, pediculosis, and meal in the ears (from overhead feeders) have been implicated as a cause of head-shaking that has led to auricular hematomas. Bites from other pigs also may be at fault (see below). Treatment is surgical to allow drainage. After draining and flushing, several mattress sutures can be placed to eliminate the "pocket." The addition of a drain made out of a tea tube, piece of soft urinary catheter, or IV catheter increases the success rate of surgery. Drainage and glucocorticoid instillation are successful in ~50% of cases. Drainage is best obtained with a butterfly connection or an IV catheter. Glucocorticoids are instilled to fill the cavity without causing skin distention. A short course of a low anti-inflammatory dosage of oral glucocorticoids is commonly added to this treatment.

EQUINE AURAL PLAQUES

Equine aural plaques, also known as papillary acanthoma or ear papillomas, are caused by papillomavirus. Currently, four papillomaviruses have been isolated from aural plaques. Black flies (*Simulium* spp) are likely the mechanical vector. The flies are active at dawn and dusk, when they attack the head, ears, and ventral abdomen

of horses. Clinically, the lesions are characterized by depigmented, hyperkeratotic, coalescing papules and plaques localized to the concave aspect of the pinna. Often, both pinnae are affected. Lesions are usually asymptomatic, but in some cases the fly bite itself causes dermatitis and discomfort. Histologically, the lesions are characterized by mild papillated epidermal hyperplasia and marked hyperkeratosis. Increased size of keratohyalin granules, koilocytosis, and hypomelanosis may also be present in the epidermis. Intranuclear viral particles have been seen in electron microscope studies. Various treatments have been anecdotally tried, with minimal to no response. A recent, open-label pilot study showed that iniquimod cream is effective in the treatment of aural plaques; however, the severe inflammation induced by the drug makes this treatment difficult to use, with most horses requiring sedation. The recommended protocol consists of applying iniquimod 2–3 times weekly (nonconsecutive days) every other week. Frequent applications of fly repellent and stabling the horse during the fly's feeding times are important measures to reduce discomfort and prevent recurrence. Lesions typically do not regress spontaneously.

NECROTIC EAR SYNDROME IN SWINE

(Ear necrosis, Necrotic auricular dermatitis)

Pigs with necrotic ear syndrome have unilateral or bilateral necrosis of the pinnae, are unthrifty, and commonly develop septic arthritis or die from secondary bacterial septicemia. The condition occurs sporadically in weaned and growing pigs under all management systems, particularly when challenged with endemic diseases that may influence feed intake.

Etiology, Transmission, and Pathogenesis:

The causes have not been determined conclusively. Circumstantial evidence strongly suggests that necrotic ear syndrome is due to trauma (fighting) and subsequent bacterial invasion of the damaged tissue. Another potential factor that may contribute to the problem is inadequate dietary lysine levels in the feed, although no scientific data exist to prove this assumption.

Histologic and microbiologic findings suggest that the aggressive, erosive to ulcerative lesion is due to secondary bacterial infection. In the early phases of

the disease, large numbers of *Staphylococcus hyicus* and low to moderate numbers of β -hemolytic streptococci are found in the surface exudate; later, during the ulcerative and necrotic stage, large numbers of the streptococci are found deep in the lesion. It is hypothesized that *S. hyicus* colonizes the traumatized tissue, which prepares the way for the highly invasive streptococci that induce the changes that lead to ulceration and necrosis. Efforts to reproduce the disease by experimental inoculation of the two organisms have been unsuccessful. Spirochetes have also been found in skin samples from ear lesions using silver stain, and *Treponema* spp were amplified and sequenced from DNA prepared from ear lesion scrapings and broth cultures. However, the primary role of spirochetes in causing ear necrosis in pigs is unknown at this time. Moreover, porcine circovirus type 2 infection may contribute to ear necrosis, because controlling the infection through systematic vaccination has been reported to reduce the frequency of ear necrosis on farms.

Clinical Findings, Lesions, and Diagnosis:

The nature and extent of clinical signs depend on the severity of the local lesion and development of secondary bacterial septicemia. Thus, a spectrum of signs, including unthriftiness, anorexia, fever, septic arthritis, collapse, and death, may be seen.

Mild lesions consist of superficial scratches covered with thin, dry, brown crusts. Mild edema or erythema may be present near the scratches. In more severe cases, thick, brown, moist crusts cover deep ulcers. In the most severe cases, there is extensive necrosis. The lesions evolve from mild, superficial dermatitis to severe, deep inflammation with exudation, ulceration, thrombosis, and necrosis. In mild cases, resolution occurs with no loss of ear tissue; in severe cases, the margins, tips, or even the entire pinna may be lost.

Diagnosis is made based on the appearance of the affected ears.

Management and Control: Tincture of iodine, applied topically bid for 1 wk, has reduced the incidence and severity of the disease. Antibacterial drugs administered in the feed are effective in some herds but not in others. Lack of effectiveness could be due to drug resistance. In cases of antibacterial ineffectiveness, specimens should be collected aseptically from the deep aspect of the ulcerative lesions for culture and

sensitivity testing. Traumatizing events should be minimized. Management practices (ventilation, location and functioning of waterers, pen design, group size, mixing) and proper levels of dietary lysine should be checked and corrected if deficiencies are detected. Proper immunization against porcine circovirus type 2 is important to reduce the frequency of ear necrosis on farms.

MISCELLANEOUS DISEASES OF THE PINNA

Several immune-mediated diseases such as **pemphigus foliaceus**, **pemphigus erythematosus**, **drug eruption**, **toxic epidermal necrolysis**, and **immune-mediated vasculitis** may affect the pinna and the ear canal. (See also AUTOIMMUNE SKIN DISORDERS, p 827.) Other areas of the body are typically affected and may include footpads, mucous membranes, mucocutaneous junctions, nails and nail beds, and the tip of the tail. Immune-mediated diseases are confirmed with biopsy of primary lesions (papules, vesicles, pustules, erythematous margins of secondary lesions) and histologic evaluation by a dermatohistopathologist.

Folded ear tips in cats are most often associated with longterm glucocorticoid therapy (eg, daily eye or otic preparations). They may also be caused by solar radiation damage. Ear folding may not be reversible.

Feline solar dermatitis or actinic dermatitis is seen most commonly in white cats or cats with white pinnae that have been chronically exposed to sun. Lesions first appear as erythema and scaling on the sparsely haired tips of the ears. Crusting, exudation, and ulceration may develop as the actinic keratosis undergoes transformation into a squamous cell carcinoma. During early stages of the disease, treatment consists of limiting exposure to ultraviolet light through confinement indoors between the hours of 10 AM and 4 PM and the use of topical sunscreens. Squamous cell carcinoma of the pinnae is treated with surgical excision followed by radiation therapy. If surgery and radiation therapy are not an option, topical treatment with iniquimod cream 2–3 times weekly has shown promising results.

Feline proliferative and necrotizing otitis externa is a rare disease of unknown cause. It can affect cats from 2 mo to 12 yr of age, with most cases occurring at 4 yr of age. No breed predilection has been reported, but males appear to be overrepresented. It most

commonly affects the concave aspect of the pinna and external aural orifice, but it can extend into the ear canal. The preauricular, pericircular, and perioral regions may also be affected. Lesions are characterized by thick hyperkeratotic crusts covering erythematous plaques that may erode or ulcerate. Secondary bacterial and yeast infections may aggravate the condition. Most cats appear indifferent to the lesions, but mild pruritus and discomfort may be present when ulceration develops. Diagnosis is confirmed by the histopathologic findings, which are characterized by epidermal hyperplasia associated with scattered apoptotic-appearing keratinocytes that extend to the superficial follicular epithelium. Parakeratotic hyperkeratosis is also a feature. Spontaneous resolution has been reported to occur in some cases but only after 12–24 mo. Therapy with topical tacrolimus or oral cyclosporine at 5 mg/kg/day is reported to be efficacious.

Proliferative thrombovascular necrosis of the pinnae is rare in dogs. There are no known breed, sex, or age predilections, and the cause is unknown. Lesions, which consist of scaly, thickened, hyperpigmented skin surrounding a necrotic ulcer, begin at the apex of the ear and spread along the concave surface. Eventually, necrosis may deform the margin of the pinna. Pentoxifylline (15–20 mg/kg, bid-tid) and/or the combination of tetracycline (250 mg tid for dogs <10 kg; 500 mg tid for dogs >10 kg) or doxycycline (5 mg/kg bid) and niacinamine (250 mg tid for dogs <10 kg; 500 mg tid for dogs >10 kg) have been anecdotally reported to be efficacious in some cases. Topical glucocorticoids are also an option but must be used carefully because of their atrophogenic effects. If medical therapy has failed, surgical removal of diseased tissue should be considered.

Auricular chondritis has been reported rarely in cats and dogs. Clinical signs include pain, swelling, erythema, and deformation of the pinnae. Both ears are typically affected. Systemic signs may accompany some cases, and involvement of other organs such as the joints, eyes, and heart has been reported. Histologically, lesions consist of lymphoplasmacytic infiltrates, basophilia, and loss or necrosis of cartilage. Treatment may not be required if the condition is nonpainful and no systemic signs are present. Oral glucocorticoids have been reported to be ineffective, but dapsone (1 mg/kg/day) has induced remission in some cases. Permanent

deformity of the pinnae is to be expected whether or not treatment has been instituted.

Vasculitis is an uncommon disorder of dogs and cats. Lesions consist of purpura, erythema, well-demarcated ulcers, crusts, and sloughing of necrotic tissue. The pinnae, tail, and footpads are typically affected. It is usually difficult to determine the triggering cause, which may be immune-mediated, drug-induced, a concurrent infection, neoplasia, or idiopathic. Differential diagnoses include fight wounds, cold agglutinin diseases, frostbite, and coagulopathies. Treatment involves identifying and eliminating the inciting cause and administering oral, short-acting glucocorticoids (such as prednisone/prednisolone at 1–2 mg/kg/day, then tapering to the lowest possible dose administered every other day), tetracycline (250 mg tid for dogs <10 kg; 500 mg tid for dogs >10 kg) or doxycycline (5 mg/kg bid) and niacinamine (250 mg tid for dogs <10 kg; 500 mg tid for dogs >10 kg), pentoxifylline (15–20 mg/kg, bid-tid), and cyclosporine (5 mg/kg/day) or other immunomodulating drugs.

Frostbite may occur in animals poorly adapted to cold climates and is more likely in wet or windy conditions. It typically affects poorly insulated body regions, including the tips of the ears, feet, and tail. The skin may be pale or erythematous, edematous, and painful. In severe cases, necrosis and sloughing of the ear tips may follow. Treatment consists of rapid, gentle warming and supportive care. Amputation of affected regions may be required but should be delayed until the extent of viable tissue is determined, which may take some time.

Canine juvenile cellulitis is an uncommon disorder of puppies and is characterized by sterile papules, nodules, and pustules on the face and pinnae, in addition to submandibular lymphadenopathy. It is seen in puppies 3 wk to 4 mo old and rarely in older animals. Golden Retrievers, Gordon Setters, and Dachshunds appear to be at greater risk than other breeds. A purulent otitis externa is common, along with edematous, thickened pinnae. Systemic signs such as anorexia, lethargy, and fever may be present in some cases. The diagnosis can be confirmed by biopsy, which shows a pyogranulomatous inflammatory infiltrate with no microorganisms, and by negative bacteriologic culture. Early treatment is recommended to avoid scarring. Prednisone or prednisolone (2 mg/kg, PO, divided bid) should be tapered slowly throughout 4–6 wk or until

the disease is inactive. Antibiotics may be needed to treat secondary bacterial infection. Cyclosporine at 10 mg/kg/day has been reported to be effective in a case refractory to glucocorticoid therapy.

Canine sterile nodular granulomatous dermatitis of the pinna is a rare condition reported only anecdotally to date. Currently, existence of an age predilection is unknown, and Great Danes and Rottweilers appear to be overrepresented. Clinical signs are characterized by multiple nodules that tend to coalesce and are primarily localized to the ear margin. Loose to adhered scales typically cover the nodules. Histopathology shows multiple dermal nodules composed primarily of histiocytes. Leishmaniasis (see p 800) is an important differential diagnosis in endemic areas. Other sterile nodular diseases that

need to be excluded are sterile granuloma and pyogranuloma disease and cutaneous reactive histiocytosis; however, other body sites are commonly affected in these diseases. Cases typically respond to oral glucocorticoids (eg, prednisone/prednisolone 1–2 mg/kg/day until remission then tapered) or cyclosporine (5 mg/kg/day); however, more conservative treatments, such as topical glucocorticoid (0.01% flucinolone acetonide plus 60% DMSO) and tetracycline (250 mg tid for dogs <10 kg; 500 mg tid for dogs >10 kg) or doxycycline (5 mg/kg bid) combined with niacinamine (250 mg tid for dogs <10 kg; 500 mg tid for dogs >10 kg), have been efficacious in some cases. Once the disease is in remission, a maintenance treatment regimen must be instituted.

OTITIS EXTERNA

Otitis externa is inflammation of the external ear canal distal to the tympanic membrane; the ear pinna may or may not be involved. It may be acute or chronic and unilateral or bilateral. It is one of the most common reasons for small animals to be presented to the veterinarian. Clinical signs can include any combination of headshaking, odor, pain on manipulation of the ear, exudate, and erythema. It can be seen in rabbits (in which it is usually due to the mite *Psoroptes cuniculi*) and is uncommon in large animals.

Etiology and Classification System:

Causes of otitis externa are now defined as primary or secondary, with factors that contribute to or promote disease. It is also standard of care to determine whether the cause is curable or lifelong management is required. **Primary causes** of otitis externa are those that create disease in a normal ear. They can cause otitis without any other cause or factor and can be subtle; they often go unrecognized by owners and veterinarians until secondary causes develop. Primary factors alter the ear environment, which allows secondary infections to develop. The major primary causes of otitis externa are allergy, autoimmune (eg, pemphigus), endocrine, epithelialization disorders, foreign bodies, glandular disorders, immune-mediated (eg, drug

reactions), fungal (eg, aspergillosis), parasites, viral (eg, canine distemper), and miscellaneous (auricular chondritis, eosinophilic diseases, juvenile cellulitis, proliferating necrotizing otitis of cats). **Secondary causes** are those that cause disease in an abnormal ear. These causes are relatively easy to eliminate and include bacteria, fungi, medication reactions, overcleaning, and yeast overgrowth.

Factors are elements related to the disease or pet that contribute to or promote the otitis externa by altering the structure, function, or physiology of the ear canal. Factors are subdivided into predisposing factors, which are present before the development of the ear disease, and perpetuating factors, which occur as a result of the inflammation. **Predisposing factors** include conformation of the ear, excessive moisture, obstruction of the ear canal (eg, polyp, feline apocrine cystadenomatosis), primary otitis media (eg, primary secretory otitis media, otitis media due to neoplasia or respiratory disease), systemic diseases (eg, catabolic states), and treatment effects (eg, alterations of normal microflora, trauma from cleaning).

Perpetuating factors include changes in the ear epithelium (eg, failure of migration), ear canal (eg, edema, stenosis, proliferation), tympanic membrane (eg, dilated, ruptured), glandular (eg, sebaceous

hyperplasia), pericartilaginous fibrosis (eg, calcification), and middle ear (eg, filled with debris, otitis media). This system is currently referred to as the PSPP classification system. A prognosis should be given for otitis externa. Curable means that the component of the problem is readily resolved with treatment (for weeks) or via surgery. Longterm management indicates that the component of the ear problem may be resolvable, but it can take months of treatment. Lifelong treatment indicates that the owner will need to play an active role in management for the life of the pet.

Clinical Findings and Diagnosis: There is no recognized sex distribution for otitis externa. Young animals may be more commonly affected. There are clear breed predispositions for otitis, which directly reflect the breed predispositions for skin disease (eg, allergies in retrievers and terriers). The most common historical findings are headshaking and aural pruritus.

The first step in physical examination is determination of the severity of pain. This can be done by gentle palpation or petting of the animal. If the ear is painful or the degree of discomfort is high, the animal should be sedated before performing any further diagnostic testing. The second step is gentle palpation and manipulation of the ear canal and pinna to determine the presence of swelling, pruritus, fibrosis, or calcification. The presence or absence of these findings will help determine whether advanced diagnostics are needed, specifically imaging of the ear canal. Next, the outside of the ear should be examined, noting erythema, edema, crusts, scale, ulcers, lichenification, hyperpigmentation, or exudate. The pinnae and periauricular regions should be examined for evidence of self-trauma, erythema, and primary and secondary skin lesions. Pinnal deformities, hyperplastic tissue in the canal, and headshaking suggest chronic otic discomfort. If the otitis is unilateral, the unaffected ear should be examined first to prevent iatrogenic contamination of the unaffected ear with organisms (eg, *Pseudomonas aeruginosa* or *Proteus mirabilis*) that may be present in the diseased ear. The unaffected ear may, in fact, be diseased, meaning that the differential diagnosis list should also include causes of bilateral otitis.

Otoscopy examination is often not possible because the ear is painful, swollen, or filled with exudate; sedation is usually required. Swelling of the ear canal often makes it impossible to see the tympanic membrane. A handheld otoscope

must have enough light and magnification to clearly visualize the external canal to the level of the tympanic membrane. Disposable otoscopic ear cones are recommended, because studies have demonstrated contamination of cones. Handheld otoscopes are available with a variety of heads, including magnification options and surgical operating heads, that allow for visualization of the ear canal while inserting another instrument. The surgical head is used when biopsies, foreign body removal, or deep flush of the canal is anticipated.

A video otoscope provides magnification of the ear canal and tympanic membrane. Most have a working channel through which biopsy instruments, catheters for flushing debris from the canal, and laser tips can be passed. Video otoscopes allow visualization through water and saline to determine the integrity of the tympanic membrane and to facilitate sampling and culture of the middle ear.

During an otoscopic examination, the ear canal should be inspected for changes in diameter, pathologic changes in the skin, quantity and type of exudate, parasites, foreign bodies, neoplasms, and changes in the tympanic membrane. The tympanic membrane should be examined for evidence of disease or rupture. However, in many cases of otitis, the character of the ear canal and tympanic membrane cannot be visualized at all until the exudate is gently flushed from the canal. Samples for cytologic evaluation and culture should be obtained before the ear is flushed. Examination is attempted again after the ear is dried. In chronic cases, the canal may be too stenotic, either from hyperplasia or edema, to be examined. Systemic glucocorticoids given daily for 1 wk may reduce swelling enough to allow examination.

If sedation is not needed, samples for ear diagnostic tests should be collected: skin cytology from the external and inner pinnae, cytology of any exudates present, hair trichograms and skin scrapings for *Demodex*, and ear swab cytology with mineral oil in young and adult animals (especially cats, because feline demodicosis can present as pruritic otitis). Wood's lamp examinations need to be done with care, keeping in mind that the key color is apple-green fluorescence and that sebum can glow yellow. Dermatophytosis affects the hair of the pinnae and hairs in the concave surface of the ear canal.

Cytologic evaluation of exudate or cerumen taken from the horizontal ear canal may provide immediate diagnostic

information. The external ear canals of most dogs and cats harbor small numbers of commensal gram-positive cocci. These organisms may become pathogenic if the microenvironment is changed and encourages their overgrowth. Exudate obtained with a cotton-tipped applicator can be rolled onto a glass slide, stained with a 3-step quick stain or modified Wright's stain, and examined under a microscope. (A study has shown that heat fixing is not necessary for ear swab cytology.) Smears should be examined microscopically under 4×, 10×, and oil immersion to look for numbers and morphology of keratinocytes, bacteria, yeasts, and WBCs; evidence of phagocytosis of microorganisms; fungal hyphae; and acantholytic or neoplastic cells.

A stained smear can quickly determine whether microbial overgrowth is present. Coccal organisms are usually staphylococci or streptococci. Rod-shaped organisms are usually *Pseudomonas aeruginosa*, *Escherichia coli*, or *Proteus mirabilis*; their appearance in large numbers indicates that a bacterial culture with antibiotic sensitivity should be performed because of their known resistance to many antimicrobial agents. The presence of many neutrophils phagocytizing bacteria confirms the pathogenic nature of the organisms.

The yeast *Malassezia pachydermatis* is found in low numbers in the ear canals of many healthy dogs and cats. Because yeasts colonize the surface of the ear canal, they are most easily found adhered to clumps of exfoliated squamous epithelial cells. *M. pachydermatis* is identified readily on microscopic examination and its numbers easily assessed. There is no specific number that indicates yeast overgrowth. The key determining factor is whether the ears are pruritic. In addition, if previous treatment did not include antifungal therapy and if otitis externa is recurrent, antifungal therapy is warranted.

A dark exudate in the canal usually signals the presence of either *Malassezia* spp or a parasite but may also be seen with a bacterial or mixed infection. In addition to stained cytology, otic exudate should be examined for eggs, larvae, or adults of the ear mite *Otodectes cynotis* and for *Demodex* mites in dogs and cats, and *Psoroptes cuniculi* in rabbits and goats. Smears are made by combining cerumen and otic discharge with a small quantity of mineral oil on a glass slide. A coverglass should be used, with the smear examined under low-power magnification. Rarely,

refractory ceruminous otitis externa may be associated with localized proliferation of *Demodex* sp in the external ear canals of dogs and cats and may be the only area on the body affected.

Microbial cultures are taken before otoscopy is completed and before any cleaning is done. Samples for culture should be taken with a sterile culturette from the horizontal canal (the region where most infections arise) or from the middle ear in cases of tympanic rupture. A bacterial culture and antibiotic sensitivity and an antibiotic mean inhibitory concentration should be done.

Histopathologic changes associated with chronic otitis externa are often nonspecific. Histopathologic evidence of a hypersensitivity response may support a recommendation for intradermal allergy testing or for a hypoallergenic diet trial. In addition, biopsies from animals with chronic, obstructive, unilateral otitis externa may reveal whether neoplastic changes are present.

Radiography of the osseous bullae is indicated when proliferative tissues prevent adequate visualization of the tympanic membrane, when otitis media is suspected as a cause of relapsing bacterial otitis externa, and when neurologic signs accompany otitis externa. Fluid densities and proliferative or lytic osseous changes provide evidence of middle ear involvement. Unfortunately, radiographs are normal in many otitis media cases. CT or MRI, if available, should be performed for cases of severe, chronic otitis.

Treatment: Key to treatment is a discussion with the owner regarding the suspected or known cause of the otitis externa, whether the otitis is curable, and whether treatment must be longterm for resolution or lifelong management will be required. All primary and secondary causes and predisposing factors need to be identified, managed, and treated. Management of pain or pruritus must be included in the initial treatment protocol. Tramadol for the first 5–7 days at 5 mg/kg, PO, tid, may be especially beneficial. In addition, otitis externa is one of the few dermatologic conditions in which glucocorticoids are beneficial in the face of concurrent antimicrobial use or sepsis. Glucocorticoids decrease swelling of the ear canal and may be key to successful treatment. Prednisone or triamcinolone is used most commonly. Duration depends on the severity. Ear hygiene is important; in particular, the hair from the pre- and periauricular area should

be clipped, as well as hair from the surface of the inner pinnae and ends of the ears. This facilitates cleaning and treatment of the ears. Plucking of hair from the ear canal is controversial but may be needed to adequately resolve the ear infection. Hair plucking is painful and should be done under anesthesia.

The first ear cleaning should be done in the veterinary clinic, and owners should be instructed not to clean the ears until recheck in 5–7 days. Owners are often unable to clean the ears and/or are too aggressive, causing further damage. Owners should initially focus on administration of topical and/or systemic drugs and can begin to clean the ears after the first recheck and if the otitis is resolving. It is important to remember that topical medications are inactivated by exudates, and excessive cerumen may prevent medications from reaching the epithelium. The ears should be gently cleaned with an ear cleaner that will remove the debris in the canal. Thick, dry, or waxy material requires a ceruminolytic solution such as carbamide peroxide or dioctyl sodium sulfosuccinate (DSS). If rods are seen, the ear cleaner should contain squalene, because one possible cause is *Pseudomonas*, which can produce a biofilm that protects bacteria from antibiotics. The ears should be thoroughly rinsed with warm water to remove residual ear cleaner. If the tympanic membrane is ruptured, detergents and DSS are contraindicated; milder cleansers (eg, saline, saline plus povidone iodine, Tris EDTA) should be used to flush the ear.

Effective treatment may require both topical and systemic antimicrobial therapy, along with pain medications and glucocorticoids. The duration of treatment may vary from 7–10 days to >30 days, depending on the diagnosis. In treatment of acute bacterial otitis externa, antibacterial agents in combination with corticosteroids reduce exudation, pain, swelling, and glandular secretions. The least potent corticosteroid that will reduce the inflammation should be used (see p 2710).

Most commercial topical products contain a combination of antibiotic/antifungal and glucocorticoids. The volume of the ear canal in most dogs is 1 mL, and adequate treatment requires instillation of at least this volume twice daily. Products with an aqueous base or those that have a thin film should be used; ointments are to be avoided.

Irritating medications (eg, home remedies and vinegar dilutions) should

be avoided. They cause swelling of the lining of the ear canal and an increase in glandular secretions, which predispose to opportunistic infections. Substances that are usually not irritating in normal ear canals may cause irritation in an ear that is already inflamed. This is particularly true of propylene glycol. Powders, such as those used after plucking hair from the canal, can form irritating concretions within the ear canal and should not be used.

Systemic therapy should be incorporated into the treatment regimen in most cases of chronic otitis and in any case in which otitis media is suspected. The most common cause of recurrent otitis externa is undiagnosed otitis media. Failure to use systemic antimicrobial therapy is an important cause of chronic ear disease in dogs. Systemic antibiotics should be used when neutrophils or rod-type bacteria are found on cytology, in cases of therapeutic failure with topical antimicrobial agents, in chronic recurring ear infections, and in all cases of otitis media. (See also SYSTEMIC PHARMACOTHERAPEUTICS OF THE INTEGUMENTARY SYSTEM, p 2571.) Yeast infections in dogs can be treated with oral ketoconazole 5 mg/kg/day, PO, for 15–30 days. Ketoconazole should not be used in cats; itraconazole 2–3 mg/kg/day for 15–30 days or one week on/one week off is recommended.

Duration of treatment will vary depending on the individual case but should continue until the infection is resolved based on reexamination and repeat cytology and culture. Animals with bacterial and yeast infections should be physically examined, with cytologies evaluated weekly to every other week until there is no evidence of infection. For most acute cases, this takes 2–4 wk. Chronic cases may take months to resolve, and in some instances, a therapeutic regimen must be continued indefinitely.

Methicillin-resistant *Staphylococcus intermedius* and *Pseudomonas* otitis (caused by *Pseudomonas aeruginosa*) have emerged as frustrating and difficult perpetuating causes of otitis because of the development of resistance to most common antibiotics. These infections are often chronic in course (>2 mo) and associated with marked suppurative exudation, severe epithelial ulceration, pain, and edema of the canal. Successful treatment is multifaceted and should include the following steps: 1) identify the primary cause of the otitis and manage it, 2) remove the exudate via irrigation of the ear canal, 3) identify and treat concurrent otitis media, 4) select an appropriate

antibiotic from the results of culture and mean inhibitory concentration on the organism and use it at an effective dosage for an appropriate duration, and 5) treat topically and systemically until the infection resolves (weeks to months).

The best treatment of chronic otitis is prevention. In addition to identifying the cause of acute otitis, topical and/or systemic medications should be chosen based on cytology or culture; they should have a narrow spectrum and be specific for the current condition. Aminoglycosides and fluoroquinolone antibiotics should not be used unless absolutely required for successful treatment but are the most common ingredients in topical otic medications. Because many topical products contain a combination of glucocorticoid, antibiotic, and antifungal medications, it is imperative to educate the owner on proper use (frequency and duration). Many owners discontinue treatment when the ear "looks better" before the infection is resolved. Polymyxin B and fluoroquinolone antibiotics have shown the best success in controlling *Pseudomonas* infections in cases in which

resistance has been identified through culture. However, resistance is developing to fluoroquinolones.

Maintenance Care: Owners should be shown how to properly clean the ears. The frequency of cleaning usually decreases over time from daily to once or twice weekly as a preventive maintenance procedure. The ear canals should be kept dry and well ventilated. Using topical astringents in dogs that swim frequently and preventing water from entering the ear canals during bathing should minimize maceration of the ear canal. Chronic maceration impairs the barrier function of the skin, which predisposes to opportunistic infection. Preventive otic astringents may decrease the frequency of bacterial or fungal infections in moist ear canals. Clipping hair from the inside of the pinna and around the external auditory meatus, and plucking it from hirsute ear canals, improves ventilation and decreases humidity in the ears. However, hair should not routinely be removed from the ear canal if it is not causing a problem, because doing so can induce an acute inflammatory reaction.

OTITIS MEDIA AND INTERNA

Otitis media, inflammation of the middle ear structures, is seen in small and large domestic animals, including dogs, cats, rabbits, ruminants, horses, pigs, and camelids. It can be unilateral or bilateral and can affect animals of all ages. Although typically sporadic, outbreaks are possible in herds. Otitis media usually results from extension of infection from the external ear canal through the tympanic membrane or from migration of pharyngeal microorganisms through the auditory tube. Occasionally, infection extends from the inner ear to the middle ear, or reaches the middle ear by the hematogenous route. Primary otitis media has been reported in certain breeds of dogs, particularly Cavalier King Charles Spaniels. Untreated otitis media can lead to **otitis interna** (inflammation of the inner ear structures) or to rupture of an intact tympanic membrane with subsequent otorrhea or otitis externa.

Clinical Findings and Diagnosis: Signs of otitis media include head shaking, rubbing or scratching the affected ear, and

tilting or rotating the head toward the affected side; self-trauma can lead to aural hematoma. The most common cause of recurrent otitis externa is undiagnosed otitis media. When otitis externa (see p 527) accompanies otitis media, the external ear canal may look inflamed and contain an abnormal discharge. The pinna or ear canal may be painful and malodorous, and the hair surrounding the base of the ear may be wet or matted. Because the facial (cranial nerve VII) and sympathetic nerves course through the middle ear, animals with otitis media may exhibit signs of facial nerve paralysis (eg, ear droop, lip droop, ptosis, collapse of the nostril) and/or Horner syndrome (eg, miosis, ptosis, enophthalmos, protrusion of the nictitating membrane) on the same side as the affected ear. Exposure keratitis and corneal ulceration may develop. With facial paralysis, the nasal philtrum or lip may deviate away from the affected side. These signs help to distinguish otitis media from simple otitis externa.

With otitis interna, inflammation impairs function of the vestibulocochlear nerve (cranial nerve VIII), resulting in hearing loss and signs of peripheral vestibular disease such as head tilt, circling, leaning or falling toward the affected side, general incoordination, or spontaneous horizontal nystagmus with the fast phase away from the affected side. Extension of infection from the inner ear to the brain leads to meningitis,

meningencephalitis, or abscesses, with signs referable to those conditions. In horses, severe otitis media/interna can result in fusion and fracture of the tympanohyoid joint; extension of the fracture line to the calvarium can lead to intracranial spread of infection or cause hematoma and death.

Whereas animals with otitis media/interna are usually alert, nonfebrile, and have a good appetite, those with meningitis

Deep structures of tympanic bulla and tympanic membrane, cat. Illustration by Dr. Gheorghe Constantinescu.

or meningoencephalitis are usually depressed, febrile, and inappetent. A major differential diagnosis for otitis media/interna in ruminants is listeriosis. However, in listeriosis, cranial nerves other than VII and VIII may be affected, causing signs such as dysphagia or loss of facial sensation, and affected animals are usually depressed.

In large animals, otitis media and interna are presumptively diagnosed based on history and clinical signs. A history of bottle feeding or feeding of contaminated milk to neonates, concurrent or previous respiratory disease, chronic ear infection, or aural foreign body, in conjunction with typical signs of otitis media/interna, should prompt examination of the ear canal. Otitis media is confirmed by visualizing a bulging, discolored, or ruptured tympanic membrane. Although the tympanic membrane may be visualized using a simple otoscope in many cases, the anatomy of the ear canal hinders visualization in some species, such as horses and llamas; endoscopy, or video otoscopy, is an alternative approach. Imaging methods assist in diagnosis and assessment of lesion severity. Radiography can detect osseous changes in the tympanic bulla and fluid in the tympanic cavity if appropriate positioning and techniques are used. However, CT and MRI are more sensitive and are the preferred methods when feasible. In some cases, diagnosis is made only at necropsy, using special techniques to expose the tympanic region. Diagnosis of clinical otitis media/interna in one ear should always prompt examination of the other ear to determine whether subclinical otitis is present.

Otitis media has been reported to be present in 16% of dogs with otitis externa and in >50% of dogs with chronic otitis externa. The tympanic membrane has also been reported to be intact in >70% of cases, and the disease is usually bilateral in dogs. Primary and secondary causes and factors of otitis externa can lead to otitis media. Diagnosis can be challenging, because the tympanic membrane can be intact. Palpation of the tympanic membrane with a blunt instrument is not an accurate method of determining the patency of the tympanic membrane. Advanced imaging techniques (CT or MRI) are more sensitive than routine radiographs but are not 100% sensitive and specific. In some cases, exploratory (and therapeutic) bulla osteotomy may be necessary.

Treatment and Prognosis: Treatment of otitis media/interna is most successful

when started early in the course of the disease. Chronic cases are often refractory to treatment or recur after apparent remission. When otitis externa accompanies otitis media/interna, the ear should be examined closely for mites and foreign bodies, such as plant awns, and the discharge cultured for bacteria. Many aerobic and anaerobic bacteria have been cultured from the ears of animals with otitis media/interna, and mixed infections are common. Pathogens that warrant mentioning because of their frequency of isolation include *Malassezia* spp and *Pseudomonas* spp in small animals; *Streptococcus suis* in pigs; *Streptococcus* spp in horses; *Mycoplasma* spp in goats; and *Mannheimia haemolytica*, *Pasteurella multocida*, *Histophilus somni*, and *Mycoplasma bovis* in cattle. *M. bovis* is particularly problematic in dairy calves fed unpasteurized waste milk from cows with intramammary infection. However, other pathogens, such as coliform bacteria, *Staphylococcus* spp, *Neisseria* spp, corynebacteria, and *Trueperella pyogenes* are frequently isolated from the ears of affected animals. Isolation of a bacterial pathogen(s) or mites from the ear helps direct initial treatment but does not necessarily imply causation of otitis media/interna, because the same organisms can be isolated from the external ear canals of apparently healthy animals.

Ear mites, when present, should be treated with an appropriate systemic antiparasitic agent (see p 2576). Topical acaricides can be instilled into the external ear canal once it is cleaned. Bacterial infection should be treated with appropriate systemic antimicrobial agents (see p 2571), based on culture and susceptibility test results. If the tympanic membrane is intact, a culture can be obtained via a myringotomy incision with a tom cat catheter. It may be possible to aspirate fluid. If not, 0.5 mL of sterile water can be instilled into the bulla and the fluid aspirated for culture. No antimicrobial agents are labeled for treatment of otitis media/interna in food-producing animals in the USA, so extra-label drug use guidelines must be followed and prohibited drugs avoided.

In addition to antimicrobial and/or anthelmintic therapy, the external ear canal should be cleaned and flushed if otorrhea or otitis externa is present; physiologic saline or dilute antiseptic solutions, such as iodine, chlorhexidine, or hydrogen peroxide, are commonly used for flushing. Steroids or NSAIDs can help reduce inflammation and pain associated with

otitis media/interna. Corneal ulceration, aural hematomas, and concurrent infections should be treated appropriately, if present, and the animal protected from further self-injury.

If the tympanic membrane is intact and otitis media/interna does not respond sufficiently to systemic antimicrobial and anti-inflammatory therapy, myringotomy (perforation of the tympanic membrane) can be performed to relieve pressure and enable culture and drainage of fluid from the tympanic cavity. In chronic, nonresponsive or recurrent cases of otitis media/interna, it may be necessary to perform bulla osteotomy or total ear canal ablation to establish sufficient drainage and enable

effective lavage. Tympanostomy tubes can be implanted into the tympanic membrane after myringotomy to allow continuous drainage in Cavalier King Charles Spaniels with primary secretory otitis, but such tubes are not useful to drain more purulent exudate.

Early diagnosis and treatment of otitis media/interna can result in complete resolution of infection and clinical signs. However, with severe, chronic, or nonresponsive cases, owners should be advised that neurologic deficits and hearing loss may persist even if infection is resolved. In small animals, otitis media may be resolved only by surgery (total ear canal ablation), particularly if multidrug-resistant bacteria are present.

TUMORS OF THE EAR CANAL

Ear canal tumors may arise from any of the tissues lining or supporting the ear canal, including the squamous epithelium, the ceruminous or sebaceous glands, or the mesenchymal tissues. Malignant tumors arising from the external ear canal and pinna are more common in cats than in dogs.

True neoplasia in the ear is often misdiagnosed during physical examination, because hyperplastic epithelial tissue and glands can appear as growths along the canal. Treatment of the infection and inflammation over time can change the appearance of these growths and, in some cases, they will actually disappear. In contrast, neoplastic growths will not resolve with topical otic therapy.

Although the precise cause of ear canal tumors is unknown, several theories have been postulated. Chronic inflammation of the ear canal may lead to hyperplasia, followed by dysplasia and finally neoplasia. Bacterial degradation of the fatty acids and other products produced in inspissated apocrine secretions from hyperplastic ceruminous glands during otitis externa episodes may also stimulate carcinogenesis in the ear canal. Middle-aged dogs and cats are more likely to have benign otic tumors, whereas dogs and cats >11 yr old seem to have more malignant tumors. This seems to be attributed to chronicity of ear disease rather than simply age. Tumors in the ear canal decrease the lumen volume, which leads to decreased drying of the canal and impaired drainage of inflammatory exudates and volatile fatty acids.

Chronic infection and inflammation do not subside, allowing neoplastic changes to continue to develop.

Incidence of benign and malignant ear tumors is higher in American Cocker Spaniels than in other breeds. The density of glandular tissue in the ear canal of this breed may be the reason. Middle-aged to older cats are predisposed to benign and malignant ear canal tumors, whereas young cats (3 mo to 5 yr) are more likely to develop nasopharyngeal polyps. Clinical signs of an ear canal tumor include unilateral chronic otic discharge (ceruminous, purulent, mucoid, or hemorrhagic) and necrotic odor, head shaking, and ear scratching. Often, aural hematomas result from the head shaking associated with ear canal tumors. Draining abscesses in the parotid region below the affected ear may result. If there is middle or inner ear involvement, neurologic signs may be present, including deafness, vestibular signs (eg, head tilt, ataxia, nystagmus), facial nerve palsy or paralysis (facial drooping, salivation, and dropping food from the lips), Horner syndrome (eyelid droop, pinpoint pupil, and inward rolling of the globe), and occasional protrusion of the third eyelid. In any case of medically refractory unilateral otitis, a neoplasm of the ear canal or middle ear should be suspected.

Ear canal tumors in dogs are more likely to be benign than malignant. Malignant otic neoplasms are locally invasive, with <10% showing any lymph

node involvement. Invasion of tumor into the bulla or surrounding tissue indicates a poorer prognosis. Cats have a higher incidence of malignant otic tumors. The most common pinna neoplasms in dogs are sebaceous gland tumors, histiocytoma, and mast cell tumors. In cats, common pinna neoplasms include squamous cell carcinoma, basal cell tumors, hemangiosarcoma, and melanocytic tumors. The most common external ear canal tumors reported in dogs are ceruminous gland adenomas and adenocarcinomas. Other tumors reported in the external ear canal of dogs include inflammatory polyps, papillomas, sebaceous gland adenomas, histiocytomas, plasmacytomas, melanomas, fibromas, squamous cell carcinomas, and hemangiosarcomas. The most common external ear canal masses reported in cats are nasopharyngeal polyps, squamous cell carcinomas, and ceruminous gland adenocarcinomas. Lymphoma, fibrosarcoma, and squamous cell carcinomas are occasionally seen in the middle or inner ear of dogs and cats. (See also TUMORS OF THE SKIN AND SOFT TISSUES, p 942.)

CERUMINOUS GLAND TUMORS

(Ceruminous gland adenoma or adenocarcinoma)

Ceruminous gland tumors are best visualized in a degreased, clean ear using a video otoscope. These tumors may be pedunculated or broad based but rise above the level of the epithelium. They may be smooth or multilobulated in appearance. In breeds other than the American Cocker Spaniel, these tumors are often primarily in the vertical ear canal. In the American Cocker, these tumors can be found in the horizontal ear canal as well. Properly taken, ear canal biopsies can give useful information. However, superficial ear canal biopsies are often reported as polyps with granulation tissue covered by epithelium. Deep en-bloc biopsies of the same tissue are often reported correctly as tumors. CT or MRI may be very useful in assessing the tympanic bulla more completely and in determining the extent of tumor invasion, especially in malignant tumors.

Surgical removal of benign ear canal tumors may be accomplished via lateral ear canal resection for access to the tumor mass. Laser surgery, especially when used in conjunction with a video otoscope, has made intraotic removal of these tumors relatively easy without having to open the

canal surgically. More aggressive surgeries, such as total ear canal ablation and bulla osteotomy, are recommended for malignant tumors of the middle ear. Lateral ear canal resection for malignancies results in a >75% recurrence rate. Median survival time for animals with malignant ear canal tumors has been reported to be >58 mo in dogs and >11.7 mo in cats. Dogs with extensive tumor involvement had a less favorable prognosis. Radiation therapy can be used to treat excised ceruminous gland adenocarcinomas in dogs and cats, with a 56% 1 yr survival rate reported. No data are available on the efficacy of chemotherapy for otic tumors of dogs and cats.

Prognosis of animals with otic neoplasms can best be determined by histopathologic examination of removed tissues.

NASOPHARYNGEAL POLYPS

Nasopharyngeal polyps are uncommon, benign, smooth, pink, fleshy, pedunculated, inflammatory growths of connective tissue found in the external ear canals of young cats. They arise from the mucosal lining of the tympanic bulla, the pharyngeal mucosa, or the auditory tube. These polyps may be congenital, or they may result from chronic bacterial otitis media, commonly found in cats with upper respiratory diseases. They are rarely found in dogs. They are not neoplastic, and viruses have not been identified in polyp tissue.

Diagnosis involves sedation and deep otoscopic examination of the horizontal canal. Purulent discharge from the bulla may need to be flushed and suctioned from the ear canal to visualize the polyp. Use of a video otoscope greatly facilitates visualization and treatment of polyps. Polyps originating from the eustachian tube may be seen by retracting the soft palate rostrally. Radiography of the bullae may reveal an opacity in the affected bulla. CT or MRI may be helpful if a mass is suspected in the tympanic bulla that cannot be seen otoscopically. Definitive diagnosis is made via histopathology.

Surgical removal is curative as long as the entire polyp and stalk are removed. This often involves performing a bulla osteotomy, because the base of the polyp is often in the tympanic bulla. Incomplete removal of the base of the polyp by traction avulsion alone leads to rapid regrowth and return of clinical signs in 15%–50% of cats. Topical steroids in the bulla for 30–45 days seems to retard this regrowth. Systemic antibiotic therapy for the bacterial otitis media is also indicated.

ENDOCRINE SYSTEM INTRODUCTION

The endocrine system encompasses a group of tissues that release hormones into circulation for travel to distant targets. An endocrine tissue is typically a ductless gland (eg, pituitary, thyroid) that releases its hormones into capillaries permeating the tissue. These glands are richly supplied with blood. However, nontypical endocrine tissues also contribute important hormones to circulation, eg, secretion of atrial natriuretic peptide from the heart, erythropoietin from the kidney, insulin-like growth factor from the liver, and leptin from fat. New hormones continue to be discovered. Some act only on a single tissue, whereas others have effects on virtually all cells of the body. The effects of hormones on their targets are varied—from enhancement of nutrient uptake to altering cell division and differentiation, among many others.

GENERAL CHEMICAL STRUCTURE AND FUNCTION

There are three main chemical categories of hormones: protein/polypeptides, steroids, and those made from modified amino acids.

Protein/Polypeptide Hormones:

Examples of protein/polypeptide hormones include adrenocorticotropin (ACTH) from the pituitary, insulin from the pancreas, and parathyroid hormone (PTH). These hormones range in size from three amino acids (thyrotropin-releasing hormone) to considerably larger proteins with subunit structure (eg, luteinizing hormone). They are produced in their endocrine tissue of origin by transcription/translation of the gene coding for the hormone and synthe-

sized initially as larger products (prepro- or pre-forms) that undergo processing to authentic hormone inside the cell before secretion. Embedded in the gene coding for protein structure are amino acid sequences (signal peptides) that communicate to the cell that these molecules are destined for the regulated secretory pathway. Other post-translational modifications may occur during processing, including folding, glycosylation, disulfide bond formation, and subunit assembly. The folded and processed hormone is then stored in secretory granules or vesicles in preparation for release by the exocytotic process. Release of hormone is triggered by unique signals; eg, secretion of PTH is stimulated by a decline in the concentration of ionic or free calcium present in the extracellular fluid bathing the parathyroid chief cells. In most cases, cells producing protein/polypeptide hormones store significant amounts of these substances intracellularly; therefore, they can respond quickly when increased amounts are needed in circulation. Generally, protein/polypeptide hormones have relatively short half-lives in blood (minutes) and do not travel in blood-bound carrier proteins (exceptions exist, eg, insulin-like growth factor 1 is highly protein bound).

Protein/polypeptide hormones act on their target cells by binding to receptors located on the cell surface. These receptors are proteins and glycoproteins embedded in the cell membrane that traverse the membrane at least once so that the receptor is exposed to both the extracellular and intracellular environments. There are several classes or types of cell surface hormone receptors that translate the hormonal message to the cell

interior by different means. Some are the G-protein (guanosine) coupled type, with seven transmembrane spanning domains. After hormone binding, these receptors activate a G-protein that is also located in the membrane. One or more of the G-protein subunits affects other downstream molecules (known as effectors) such as enzymes (eg, adenylate cyclase or phospholipase C) or ion channels. Activation may result in production of a second messenger, such as cyclic AMP, that can then bind to protein kinase A, causing its activation and subsequent phosphorylation of other proteins. Thus, signal transduction is a cascading and often amplifying series of events triggered when a hormone binds to its receptor. The ultimate effects in target cells are multiple and include such things as triggering secretion, increasing uptake of a molecule, or activating mitosis. Other receptors, such as the one for insulin, not only bind hormone but also act as enzymes, with the ability to phosphorylate tyrosine residues. The phosphorylated tyrosines in turn serve as docking sites for downstream signaling proteins.

Cell surface receptors are dynamic; their numbers and/or activity change with physiologic conditions. In some cases, such as exposure to excessive amounts of hormone, receptor down-regulation can occur. Down-regulation and a decline in target tissue responsiveness may be due to internalization of receptors after ligand binding or to desensitization whereby the receptor is chemically modified and becomes less active. Conversely, a lack of hormonal exposure can lead to an increase in receptor numbers on target cells (up-regulation). Diseases have been linked to mutations in hormone receptors, which can result in inactivation or constitutive or nonhormonal activation of the pathway. In some instances, a single amino acid substitution is responsible.

Steroid Hormones: Steroid hormones are derivatives of cholesterol and include products of the adrenal cortex, ovaries, and testes as well as the related molecule, vitamin D. Unlike protein/polypeptide hormones, steroid hormones are not stored in large amounts. When needed, they are rapidly synthesized from cholesterol by a series of enzymatic reactions. Most of the cholesterol needed for rapid steroid hormone synthesis is stored intracellularly in the tissue of origin. In response to appropriate signals, the precursor is moved to organelles (mitochondria and smooth endoplasmic reticulum), where a series of

enzymes (eg, isomerases, dehydrogenases) rapidly convert the molecule to the appropriate steroid hormone. The identity of the final steroidal product is thus dictated by the set of enzymes expressed in that tissue.

Steroid hormones are hydrophobic and pass through cell membranes easily. In the blood, they are bound to a great extent to carrier proteins. Albumin binds many steroids fairly loosely; in addition, specific binding globulins exist for many steroid hormones. Most of the steroid hormone in circulation is bound to carrier proteins, and a small fraction circulates free or unbound. This latter fraction is thought to be available for target cell entry, ie, the biologically active portion. A rapid equilibrium exists between protein-bound and unbound steroid in extracellular fluid. Possible roles for steroid hormone-binding proteins include aiding in tissue delivery of steroids by providing an even distribution to all cells within a target tissue, buffering against large fluctuations in free hormone, and prolonging the half-life of steroids in blood. Relative to protein/polypeptide hormones, steroids usually have longer half-lives, often in the range of many minutes to hours.

Steroid hormones act on target cells via receptors located in the cell interior. These receptors are generally found in the nucleus, although some appear to reside, when unoccupied, in the cytoplasm. There are several classes of steroid receptors—those for glucocorticoids, mineralocorticoids, progestins, etc. Steroid receptors comprise a family of related proteins that also show homology to receptors for the thyroid hormones and vitamin D. The receptor has regions or domains that carry out specific tasks: one for recognition and binding of the steroid, another for binding to a specific region on chromosomal DNA, and a third for helping regulate the transcriptional complex. Steroid hormones enter targets by diffusing through the cell membrane and then binding to the receptor, causing a conformational change in the new complex. This, in turn, leads to release of associated proteins (eg, heat-shock proteins) and movement to the nucleus (if necessary), followed by binding of the complex to regions of DNA located near specific steroid-regulated genes. The result is a change in the rate of transcription of specific genes, either increasing or decreasing their expression. Thus, steroid hormones primarily function by affecting the production rates of specific messenger RNA and proteins in targets. Steroid action is relatively slow in onset (hours) but may be long lasting because of the duration of production and half-lives of the messenger

RNA and proteins induced in target cells. It is increasingly clear that some steroids also act via nongenomic mechanisms. For example, many of the anti-inflammatory effects of glucocorticoids are thought to be due to the glucocorticoid-receptor complex binding to, and inhibiting the action of, pro-inflammatory transcription factors inside cells.

Steroids in the blood are eliminated by metabolism in the liver. Reduced forms are produced and subsequently conjugated to glucuronic acid and sulfate. These metabolites are freely soluble in blood and are eliminated from the body by renal excretion and through the GI tract. Small amounts of free steroid hormone are also directly excreted by the kidneys.

Modified Amino Acid Hormones:

This class of hormones is made by chemical modification of amino acids, mainly tyrosine. They include thyroid hormones and the catecholamines epinephrine and norepinephrine. Thyroxine (T_4) and triiodothyronine (T_3) are stored in the thyroid as a part of thyroglobulin; secretion of these hormones involves thyroidal cell uptake and breakdown of this large molecule liberating T_4 and T_3 . Thyroid hormones act on targets much like steroids; they are relatively water insoluble, transported by carrier proteins in blood, and act on targets via intracellular receptors. Catecholamines are manufactured by hydroxylation, decarboxylation, and methylation of tyrosine and are secreted into the blood from the adrenal medulla. They have exceedingly short half-lives (<5 min), are not protein bound, and act on targets via cell surface receptors (α - and β -adrenergic receptors).

MEASUREMENT OF HORMONES

Because hormones circulate in low quantities in blood, accurate measurement of these substances requires sensitive assays, usually in the form of a competitive immunoassay. The original method (still widely used) is radioimmunoassay employing an antibody directed against the hormone and a radio-labeled form of the hormone. The labeled hormone competes with unlabeled hormone for antibody-binding sites. A standard curve containing known amounts of hormone is used for comparison to calculate the concentration of hormone in patient samples. The use of radioactive tags permits detection of low concentrations of hormone, which typically circulate in the pico- (10^{-12}) or

nanomolar (10^{-9}) range. In recent years, nonradioactive tags, "sandwich-type" assays, and ELISA methods have been developed for hormone measurement.

Accurate measurement in veterinary species presents some challenges, because normal concentrations of a given hormone can vary significantly between species. For example, normal total T_4 concentrations in dogs and cats are ~ 4 times lower than those in people. Concern about cross-reactivity is important; protein/polypeptide hormones vary in amino acid composition and in other structural ways (eg, patterns of glycosylation) across species. As a consequence, antibodies made against a particular hormone may not recognize that material from another species. Finally, while steroid hormones are structurally identical across species (cortisol in dogs is identical to that in people), substances present in the serum of a given species can sometimes interfere in an assay, leading to inaccurate results. Overall, it is important that a laboratory providing measurement of a particular hormone in a species demonstrate that the assay is valid in that species and that the laboratory has established normal ranges.

REGULATION OF ENDOCRINE SYSTEMS

Secretion of hormones is regulated by a system of sensing elements possessing the means to detect need for both increased and decreased secretion. The particular sensing network, feedback elements, and network of control responses are unique for each hormone. Hormonal pathways maintain homeostasis, and adjustments in secretion usually result in changes that will help maintain the status quo. In addition, secretion and activity of a particular hormone may be adjusted upward or downward in response to challenges such as chronic stress, disease, or change in nutritional status. The concept of negative feedback and its relationship to control of hormonal pathways is important in understanding pathway regulation and evaluation of endocrine function tests. For example, insulin is released in response to an increase in glucose concentration bathing the β -cells in the pancreatic islets of Langerhans. One of insulin's actions is to lower glucose concentrations in extracellular fluid by enhancing its uptake in target tissues. This decline in glucose leads to reductions in insulin secretion. In patients suspected of having an insulin-secreting tumor, the finding of a low blood glucose concentration (hypoglycemia) together with an increased

insulin concentration demonstrates inappropriate feedback, characteristic of such a tumor. In another example, patients showing increased blood calcium concentrations should have low levels of PTH in circulation. Measurement of high PTH levels in such patients indicates a malfunction at the level of the parathyroid, most often associated with parathyroid adenoma.

Secretory patterns of hormones vary tremendously. The thyroid hormones tend to have less variability than the steroid hormones and show only moderate daily or weekly variation. In contrast, blood levels of the adrenal steroid cortisol show much more fluctuation, with occasional bursts of secretion followed by periods of low activity (low blood levels) occurring throughout the day.

PATHOGENESIS OF ENDOCRINE DISEASE

Endocrine diseases can arise from many causes. Hormones can be over- or underproduced, receptors can malfunction, and normal pathways for hormone removal may be disrupted. Clinical signs consistent with malfunction in an endocrine tissue may develop because of a problem originating in the source of the hormone itself or may be due to disruption in another location that is secondarily affecting hormone secretion or action.

In veterinary medicine, the most common types of endocrine disease are hormonal overproduction associated with either a tumor or hyperplastic tissue manufacturing excessive amounts of hormone, and hormonal deficiency due to destruction of the endocrine tissue source. Common diseases associated with hormonal overproduction are hyperthyroidism in cats and hyperadrenocorticism (Cushing disease) in dogs. Often, the abnormal endocrine tissue not only overproduces hormone but also fails to respond normally to feedback signals, contributing to inappropriate release of hormone. Hormonal overproduction from an endocrine tissue can also result from stimulation arising from a secondary source; eg, renal disease can result in parathyroid hyperplasia and oversecretion of PTH. Hyperphosphatemia occurs as a consequence of some types of renal disease. This leads to decreased formation of the active form of vitamin D, 1,25-dihydroxycholecalciferol (calcitriol). In turn, low calcitriol concentrations contribute to low calcium levels in extracellular fluid, which act as a stimulus for PTH secretion. Nonendocrine tissues can produce and secrete hormones in

sufficient amounts to cause clinical signs; eg, certain tumors (apocrine gland tumors of the anal sac in dogs, lymphoma) can manufacture PTH-related protein that can mimic PTH action, resulting in hypercalcemia.

Syndromes associated with deficient or absent hormone secretion also have multiple causes. Endocrine tissue destruction secondary to cell-mediated autoimmune attack is often believed to be the cause. Examples of endocrine hypofunction resulting from primary tissue loss include canine hypothyroidism, type 1 diabetes mellitus, primary hypoparathyroidism, and primary hypoadrenocorticism. In early stages of tissue loss, compensatory mechanisms involving feedback pathways stimulate activity (hormone production) from the remaining tissue. For example, in primary hypoadrenocorticism (Addison disease), secretion of pituitary ACTH increases as the adrenal cortex disappears. The increased trophic support results in full activation of the remaining tissue and often provides sufficient hormone secretion to delay signs of deficiency until tissue loss simply eliminates the hormonal source. Disorders resulting in clinical signs of endocrine hypoactivity may also occur due to disruption in tissues distant from the hormone source. Secondary hypothyroidism results from pituitary thyroid-stimulating hormone insufficiency that reduces the stimulus needed at the thyroid for T_4 and T_3 production and secretion. Patients receiving glucocorticoid therapy may experience atrophy of the cortisol-producing zones in the adrenal cortex. The exogenous steroid initiates negative feedback on the pituitary gland, suppressing ACTH secretion and leading to adrenal cortical atrophy. Another potential cause of endocrine hypofunction relates to tissue loss secondary to compressive and/or destructive growth of nonfunctional tumors.

Endocrine disease and related maladies also result from alterations in tissue responsiveness to hormones. An important example is type 2 or non-insulin-dependent diabetes mellitus, in which relative insensitivity to insulin is observed, often associated with obesity. Nephrogenic diabetes insipidus is due to renal insensitivity to the actions of vasopressin (antidiuretic hormone). The renal insensitivity to vasopressin in this syndrome may relate to congenital abnormalities in the vasopressin receptor but more often is secondary to other diseases (eg, pyometra, hyperadrenocorticism) or abnormalities in ion concentrations (eg, hypokalemia, hypercalcemia).

PRINCIPLES OF THERAPY

Endocrine diseases involving hyperactivity may be treated surgically (tumor removal), by radiotherapy (eg, ^{131}I for hyperthyroidism), or medically (eg, methimazole as an antithyroid drug). Syndromes of hormone deficiency are often successfully managed by simply replacing the missing hormone(s), such as insulin treatment in diabetes mellitus or thyroid hormone replacement therapy in hypothyroidism. Replacement therapy for deficiencies related to protein/polypeptide hormones can present a challenge. Often, the species-specific version of the hormone is not available, the drug may need to be injected several times per day, or the possibility of antibody formation and anaphylaxis must be considered. Steroid and thyroid hormones can usually be administered orally. Some protein/polypeptide hormones or analogues are effective when given by routes other than injection (eg, the antidiuretic hormone analogue desmopressin acetate is effective when administered by a variety of routes).

Hormonal replacement therapy should be monitored by assessment of clinical

response and other suitable measures such as therapeutic blood monitoring (eg, post-pill measurement of T_4 concentrations, measurement of sodium and potassium in serum in patients with primary hypoadrenocorticism). Replacement therapy is often required for a time after surgical removal of an endocrine tumor. However, remaining normal tissue that was atrophied as a consequence of the disease often recovers activity in a fairly short period of time, obviating need for lifelong replacement therapy. Animals show significant variation in drug bioavailability; thus, a proper dosing schedule should be tailored to each patient.

Glucocorticoids are commonly used therapeutic drugs, particularly because of their anti-inflammatory and anti-allergic activity. Proper use requires an understanding of their adverse effects, including the potential appearance of signs of hyperadrenocorticism resulting from longterm therapy or from use of potent derivatives. Such adverse effects can be minimized by use of orally administered glucocorticoids given on alternate days.

THE PITUITARY GLAND

The pituitary gland (hypophysis) is composed of the adenohypophysis (anterior lobe) and the neurohypophysis (posterior lobe).

Adenohypophysis: The adenohypophysis, which surrounds the pars nervosa of the neurohypophyseal system to varying degrees in different species, consists of the pars distalis, the pars tuberalis, and the pars intermedia. The pars distalis is the largest part and contains multiple populations of endocrine cells. The pars tuberalis functions primarily as a scaffold for the capillary network of the hypophyseal portal system. The pars intermedia forms the junction between the pars distalis and pars nervosa. It contains two populations of cells in dogs, one of which synthesizes adrenocorticotrophic hormone (ACTH).

A specific population of endocrine cells in the pars distalis (and in the pars intermedia for ACTH in dogs) synthesizes and secretes each of the pituitary trophic hormones. Pituitary cells have a secretory cycle and

enter an actively synthesizing phase in response to increased demand for a particular hormone. Secretory cells in the adenohypophysis are often subdivided into chromophils (acidophils, basophils) and chromophobes based on interaction of the secretory granules with pH-dependent histochemical stains.

Acidophils are further subdivided into somatotrophs that secrete growth hormone (GH, somatotropin) and lactotrophs that secrete prolactin. Basophils include gonadotrophs that secrete both luteinizing hormone (LH) and follicle-stimulating hormone (FSH), and thyrotrophs that secrete thyrotrophic hormone (thyroid-stimulating hormone [TSH]). Chromophobes include the endocrine cells involved in the synthesis of ACTH and melanocyte-stimulating hormone (MSH), nonsecretory follicular cells, and undifferentiated stem cells.

Endocrine cells in the adenohypophysis are under the control of corresponding hypothalamic-releasing hormones. These

releasing hormones are conveyed by the hypophyseal portal system to specific cells in the adenohypophysis, where they stimulate the rapid release of preformed trophic hormones.

Separate hypothalamic-releasing hormones regulate the rate of secretion of each trophic hormone from the adenohypophysis. For most pituitary trophic hormones, negative feedback control is accomplished by a feedback loop involving the blood concentration of the hormone produced by the target endocrine gland (eg, thyroid gland, adrenal cortex, ovary, and testis). Hormones such as prolactin, GH, and MSH have more complex feedback mechanisms. For example, prolactin affects primarily the mammary gland, and GH has its principal effect on the liver—both nonendocrine tissues. The negative feedback in such cases includes metabolites and other messengers (eg, insulin-like growth factor I produced by the liver). In the case of GH, there is an inhibitory (somatostatin) as well as stimulatory (GH-releasing hormone) hypothalamic regulator.

Neurohypophysis: The neurohypophysis (pars nervosa, posterior lobe) has three anatomic subdivisions. Secretion granules that contain the neurohypophyseal hormones, ie, antidiuretic hormone (ADH, vasopressin) and oxytocin, are synthesized in the hypothalamus but are released into the bloodstream in the pars nervosa. The infundibular stalk joins the pars nervosa to the overlying hypothalamus.

ADH, an octapeptide synthesized in the hypothalamus, is packaged into membrane-limited granules with a corresponding binding protein (neurophysin) and transported to the pars nervosa, where it is released into the circulation. ADH binds to specific receptors in the distal part of the nephron and collecting duct of the kidney; it increases the renal tubular reabsorption of water from the glomerular filtrate.

The output of ADH is directly related to the degree of hydration of the body. Hydration of the body inhibits release of ADH, whereas dehydration or injection of hypertonic electrolyte solutions favors release of ADH, which in turn causes increased water resorption from the glomerular filtrate, resulting in dilution and decreased osmolality of body fluids. Barbiturates, ether, chloroform, morphine, acetylcholine, nicotine, and pain increase ADH release, which leads to less urine formation. Ethanol inhibits ADH release, which leads to diuresis.

The pressor effect of ADH is less prominent than the antidiuretic effect. At a dosage

several hundred times larger than the antidiuretic dosage, ADH has a pronounced pressor effect, which may also lead to coronary constriction. The contractile mechanism of the capillaries, as well as GI and uterine muscle, is stimulated, and a prolonged increase in blood pressure follows.

Oxytocin has specific effects on the smooth muscle of the uterus and the myoepithelial cells of the mammary gland. It has no established physiologic function in the male, although an effect on sperm transport has been suggested.

HYPERADRENOCORTICISM

(Cushing disease)

Hyperadrenocorticism may be divided into two broad categories. One category, pituitary-dependent hyperadrenocorticism, arises from adenomatous enlargement of the pituitary gland, resulting in excessive ACTH production. The other category, adrenal-dependent disease, is associated with functional adenomas or adenocarcinomas of the adrenal gland. Ectopic ACTH secretion has not been reported in dogs; however, in people, ectopic ACTH secretion is associated with certain lung tumors. Iatrogenic hyperadrenocorticism results from chronic excessive exogenous steroid administration.

Clinical Findings: Hyperadrenocorticism is seen in middle-aged to older dogs (7–12 yr old); ~85% have pituitary-dependent hyperadrenocorticism (PDH), and ~15% have adrenal tumors. Breeds in which PDH is commonly seen include Miniature Poodles, Dachshunds, Boxers, Boston Terriers, and Beagles. Large-breed dogs often have adrenal tumors, and there is a distinct predilection in females (3:1). In cats, hyperadrenocorticism is found in middle-aged to older cats, with a slight predilection in females (60%).

Hyperadrenocorticism in a 7-yr-old intact, female Miniature Poodle. Courtesy of Dr. Stephen White.

The most common clinical signs in dogs and cats are polydipsia, polyuria, polyphagia, heat intolerance, lethargy, abdominal enlargement or "potbelly," panting, obesity, muscle weakness, and recurrent urinary tract infections. The panting and increased respiratory rate may be a result of the enlarged liver pushing against the diaphragm and limiting the depth of respiration. Dermatologic manifestations of hyperadrenocorticism in dogs can include alopecia (especially truncal), thin skin, phlebotomias, comedones, bruising, cutaneous hyperpigmentation, calcinosis cutis, pyoderma, dermal atrophy (especially around scars), secondary demodicosis, and seborrhea. In cats, the most striking dermatologic sign is increased skin fragility; many cats present with self-inflicted cutaneous wounds. Secondary infections (especially respiratory) are also common in cats.

Uncommon clinical manifestations include hypertension, pulmonary thromboembolism, bronchial calcification, congestive heart failure, and neurologic signs, such as polyneuropathy or myopathy, behavior changes, blindness, or pseudomyotonia. Hypercortisolemia may be evident as weakening of collagen manifesting as cranial cruciate rupture (small dog) or a nonhealing corneal ulceration. Reproductive signs of hyperadrenocorticism can include perianal adenoma in a female or castrated male, clitoral hypertrophy in females, testicular atrophy in intact males, or prostatomegaly in castrated male dogs.

In dogs, serum chemistry abnormalities associated with hypercortisolemia include increased serum alkaline phosphatase (SAP), increased ALT, hypercholesterolemia, hyperglycemia, and decreased BUN. Hypercholesterolemia is due to steroid stimulation of lipolysis. SAP is increased primarily from induction of a specific hepatic isoenzyme; some also comes from hepatic glycogen deposition and vacuolization impinging on the biliary system. SAP is seldom increased in cats (<20%), because they lack the specific hepatic isoenzyme for it. Increased serum ALT and AST are caused by hepatocellular necrosis, glycogen accumulation, and swollen hepatocytes. Decreased serum phosphorus may be a result of increased urinary excretion due to polyuria. Abnormalities noted on the biochemical profile may also include hyperglycemia due to increased gluconeogenesis and decreased peripheral tissue utilization through insulin antagonists. Approximately 10% of Cushingoid dogs are diabetic; however, in cats with hyperadrenocorticism, almost 80% present with overt

diabetes mellitus and insulin resistance. The hemogram is characterized by evidence of regeneration (erythrocytosis, nucleated RBCs) and a classic stress leukogram (eosinopenia, lymphopenia, and mature leukocytosis). Basophilia is occasionally seen. Many dogs with hyperadrenocorticism show evidence of urinary tract infection without pyuria (positive culture), bacteriuria, and proteinuria resulting from glomerulosclerosis. In cats, polydipsia and polyuria are a result of concurrent diabetes mellitus, and urine specific gravity is usually high. In dogs, cortisol-induced interference with ADH binding results in hyposthenuria, and central diabetes insipidus may occur as a result of pituitary tumor enlargement.

Diagnosis: There is no single test or combination of tests that is 100% accurate for diagnosing hyperadrenocorticism. The sensitivity and specificity of individual tests or combinations of tests are increased when they are applied to a patient population likely to have hyperadrenocorticism. The diagnosis should be based on appropriate clinical signs followed by supporting minimum database abnormalities (eg, high cholesterol, SAP), and confirmed via an appropriate screening test for hyperadrenocorticism. If screening test results are inconclusive, or if laboratory abnormalities associated with hyperadrenocorticism (eg, increased SAP) are noted in a dog without clinical signs, the dog should be retested 3–6 mo later rather than treated without a definitive diagnosis. In particular, the diagnosis of sex steroid-induced Cushing disease may be especially difficult.

The urine cortisol to creatinine ratio (UCCR) is a highly sensitive test to differentiate healthy dogs from those with hyperadrenocorticism, but it is not highly specific because dogs with moderate to severe nonadrenal illness also exhibit increased ratios. UCCR should be determined based on free-catch urine collected at home by the owner. The stress of transporting the dog to the veterinary hospital, the stress of cystocentesis, or both, can be enough to cause a falsely increased UCCR. An increased UCCR should be confirmed with an ACTH stimulation test, an IV low-dose dexamethasone suppression (LDDS) test, or an oral LDDS test.

The LDDS test is the screening test of choice for canine hyperadrenocorticism when properly used. Only 5%–8% of dogs with PDH exhibit suppressed cortisol concentrations at 8 hr (ie, are false-negatives). In addition, 30% of dogs with PDH exhibit suppression at 3 or 4 hr followed by "escape" of suppression at 8 hr;

this pattern is diagnostic for PDH, making further testing unnecessary. The major disadvantage of the LDDS test is the lack of specificity in dogs with nonadrenal illness: >50% of dogs with nonadrenal illness have a positive LDDS test. In such cases, the dog should be allowed to recover from the nonadrenal illness before testing for hyperadrenocorticism with an LDDS test. Another option, particularly in cats, is to perform an oral LDDS test using the UCCR as the discriminator. In this test, morning urine is collected for a baseline on days 1 and 2. On the second day after urine collection, three doses of dexamethasone at 0.1 mg/kg (cats) or 0.01 mg/kg (dogs) is administered every 6 hr and a urine sample is collected for UCCR measurement the next morning. The first two samples can be combined into a single "pre" or baseline sample. If the UCCR does not decrease into the normal range after oral dexamethasone, the diagnosis of hyperadrenocorticism can be confirmed.

The ACTH stimulation test is used to diagnose various adrenopathic disorders, including endogenous or iatrogenic hyperadrenocorticism and spontaneous hyperadrenocorticism. As a screening test for the diagnosis of naturally occurring hyperadrenocorticism, it has a diagnostic sensitivity of ~80%–85% and a higher specificity than the LDDS test. In one study, only 15% of dogs with nonadrenal disease had an exaggerated response to ACTH stimulation. Adrenal tumors may be particularly difficult to diagnose using an ACTH stimulation test; however, an ACTH stimulation test is the test of choice for iatrogenic hyperadrenocorticism.

Dogs with adrenal sex steroid excess may have negative ACTH stimulation and LDDS tests, because serum cortisol concentrations are normal. This may be due to excess cortisol precursors. Increases in progesterone, 17-OH-progesterone, androstenedione, testosterone, and estrogens may require dynamic adrenal testing using the ACTH stimulation test and measurement of sex steroids in addition to cortisol.

After the diagnosis of hyperadrenocorticism has been confirmed, differentiation of pituitary- versus adrenal-dependent disease may be necessary. Although most dogs with hyperadrenocorticism have PDH, in atypical cases (eg, anorectic dogs with hyperadrenocorticism), a differentiation test is appropriate. In particular, differentiation of PDH (often macroadenomas) from adrenal tumors is often necessary in large breeds.

The high-dose dexamethasone suppression (HDDS) test works on the principle that autonomous ACTH hypersecretion by

the pituitary can be suppressed by supraphysiologic concentrations of steroid. Dogs with autonomous cortisol-producing adrenal tumors have maximally suppressed ACTH production via the normal feedback mechanism; therefore, administration of dexamethasone, no matter how high the dose, cannot suppress serum cortisol concentrations. In dogs with PDH, however, the high dose of dexamethasone is able to suppress ACTH and, hence, cortisol secretion. One important caveat is that dogs with pituitary macroadenomas (15%–50% of dogs with PDH) do not suppress on the HDDS test.

Measurement of endogenous plasma ACTH concentrations is the most reliable way to discriminate between PDH and adrenal tumors. Dogs with adrenal tumors have low to undetectable ACTH concentrations; in contrast, dogs with PDH have normal to increased ACTH concentrations. Recently, researchers have found that the addition of the protease inhibitor, aprotinin, to whole blood in EDTA tubes inhibits the degradation of ACTH. Samples may be collected, spun in a nonrefrigerated centrifuge, and kept for as long as 4 days at <4°C.

Diagnostic imaging of the pituitary and the adrenal glands can be accomplished via abdominal radiography, ultrasonography, CT, or MRI. Abdominal radiographs should be performed in all dogs that do not suppress on an HDDS; ~30%–50% of dogs with adrenal tumors have a mineralized mass in the area of the adrenal glands. Abdominal ultrasonography is a more sensitive way to identify adrenal tumors. In addition, liver metastasis or invasion into the vena cava may be demonstrated in dogs with adrenal carcinomas. CT or MRI of the brain or abdominal cavity in dogs that do not suppress on the HDDS may demonstrate unilateral adrenal enlargement (50%), pituitary macroadenoma (25%), or pituitary microadenoma (25%).

Treatment and Prognosis: Three treatment options are available for hyperadrenocorticism in dogs. Medical, surgical, and radiation therapy have all been used with varying degrees of success.

Dogs with PDH may be treated using the adrenolytic agent mitotane (o,p'-DDD), beginning with an induction dosage of 25–50 mg/kg/day for 7–10 days. Dogs should be monitored for signs of hypoadrenocorticism, such as anorexia, vomiting, and diarrhea; if such signs occur, mitotane therapy should be discontinued and glucocorticoids administered. Water consumption or

appetite may be measured to provide an endpoint for therapy; water consumption should decrease to <60 mL/kg/day (dogs). After 7–10 days of therapy with mitotane or a reduction in water or food consumption, an ACTH response test should be performed to determine whether cortisol suppression is adequate. Cortisol levels measured both before and after the ACTH response test should be in the normal range. To maintain suppression of cortisol secretion, mitotane is administered at a dosage of 50 mg/kg/wk. Dogs on longterm treatment with mitotane should have an examination and ACTH response test every 3–4 mo. Gradually increasing dosages of the drug are often required to maintain adequate clinical remission.

Adverse effects of mitotane at the recommended dosage include GI irritation (vomiting and anorexia), CNS disturbances (ataxia, weakness, seizures), mild hypoglycemia, and a moderate increase in SAP. Signs such as depression or ataxia can be alleviated by dividing the daily dose into two equal parts administered at 8- to 12-hr intervals. Persistence of CNS signs after mitotane is discontinued suggests an expanding pituitary macroadenoma.

Reports have demonstrated the efficacy of the adrenal enzyme inhibitor trilostane in the treatment of PDH in dogs. Studies in dogs with hyperadrenocorticism have shown that trilostane is an effective steroid inhibitor with minimal adverse effects. Trilostane must be administered daily and often twice daily to achieve a decrease in glucocorticoid secretion from the adrenal glands. Mineralocorticoid insufficiency, which is reversible, can also be seen in animals receiving trilostane; a few cases of adrenal necrosis with permanent adrenal insufficiency have been seen after trilostane administration. Trilostane may prove to be a reasonable alternative to mitotane therapy for PDH in dogs. Dogs with sex steroid imbalance also may benefit from trilostane therapy, because the enzyme inhibitor affects precursors of cortisol synthesis in addition to inhibiting cortisol synthesis itself.

Radiation therapy of pituitary tumors is associated with a high rate of response; however, most dogs and cats require ancillary trilostane or mitotane therapy for several months after radiation treatment because of residual ACTH secretion. In dogs with PDH undergoing hypophysectomy, 80% achieved remission, with an 11% recurrence; thyroid and glucocorticoid support may be needed after surgery, and animals may lose the ability to secrete vasopressin, leading to diabetes insipidus

as well. Selegiline is an irreversible monoamine oxidase (type B) inhibitor that increases dopamine levels. Dopamine inhibits ACTH release from the pituitary gland. However, only ~20% of cases with PDH can be expected to respond; no significant changes in serum cortisol or creatinine, ACTH stimulation, or LDDS have been noted with selegiline therapy.

Treatment of iatrogenic hyperadrenocorticism should include a change to an oral, short-acting steroid such as prednisone or prednisolone. Gradually, the steroid dose is decreased from ~1 mg/kg to 0.5 mg/kg throughout several weeks and then tapered to an alternate-day schedule until the adrenal glands can respond to ACTH stimulation. Monthly ACTH stimulation tests may be performed to determine when steroid treatment can be discontinued.

Surgical removal of unilateral adrenal adenomas or adenocarcinomas may be indicated in some cases; however, surgical and anesthetic complications (eg, hypotension) may develop secondary to hypoadrenocorticism, which occurs immediately after surgical removal of the tumor. Median survival for dogs with carcinomas treated with surgical excision was 778 days. The metastatic rate was 5% at time of surgery and 14% longterm. With unilateral adrenalectomies, mortality within 1 mo after surgery was 14%–60%; overall rate for cure for adrenal tumors was ~50%. Medical treatment of adrenal tumors is difficult, because they tend to be resistant to the effects of mitotane. Adrenal tumors are relatively resistant to mitotane; dogs require as much as four times the dose of mitotane to respond, and clinical response tends to be less favorable. Finally, if the dog is showing neurologic signs (eg, anorexia, stupor, or seizures) and a large pituitary tumor (macroadenoma) is identified, radiation therapy of the pituitary gland is indicated. Newer types of radiation therapy (cyberknife, gamma knife) may prove to be superior to previously available modalities and can treat pituitary tumors in <3 days with minimal adverse effects. Results of radiation therapy in dogs show that this is an effective method of treatment with low morbidity; however, it may take several months for the signs of PDH to subside. These dogs do well longterm, however, because the primary disease process (pituitary tumor) has been addressed.

Prognosis of dogs with PDH has been estimated to be ~2 yr with or without medical therapy. Radiation treatment of pituitary tumors causing PDH or

hypophysectomies is associated with a relatively good long-term prognosis (2–5 yr). Prognosis of dogs with unilateral adrenalectomy was 18 mo.

NONFUNCTIONAL PITUITARY TUMORS

Nonfunctional pituitary tumors are uncommon in most species. Chromophobe adenomas appear to be endocrinologically inactive, but they may cause compression atrophy of adjacent portions of the pituitary gland and extend into the overlying brain. Clinical disturbances occur because of either a lack of secretion of pituitary trophic hormones and diminished target organ function (eg, adrenal cortex) or dysfunction of the CNS. Affected animals often are depressed, incoordinated, and weak and may collapse with exercise. (*See also* ADULT-ONSET PANHYPOPITUITARISM, below.)

Endocrinologically inactive pituitary adenomas often attain considerable size before they cause obvious signs (or death). The proliferating tumor cells incorporate the remaining structures of the adenohypophysis and infundibular stalk. The entire hypothalamus may become compressed and replaced by the tumor.

HIRSUTISM ASSOCIATED WITH ADENOMAS OF THE PARS INTERMEDIA

(Hypertrichosis)

Hirsutism is the long, nonshedding hair coat that develops in older horses (typically ≥ 18 yr old) and is associated with pituitary pars intermedia dysfunction (PPID) caused by an adenoma of the cells of the pars intermedia of the pituitary gland. Such adenomas often

severely compress the overlying hypothalamus, which is the primary center for homeostatic regulation of body temperature, appetite, and cyclic shedding of hair. In addition, pars intermedia adenomas secrete increased amounts of alpha melanocyte-stimulating hormone (MSH), a factor in the growth of a long hair coat in winter.

Clinical Findings and Lesions: Signs of PPID include polyuria and polydipsia (PU/PD), poor muscle tone, weakness, somnolence, abnormal distribution of adipose tissue, swelling of the periorbital fossa, laminitis, increased susceptibility to infections, intermittent hyperpyrexia, and generalized hyperhidrosis. Hirsutism often becomes evident because of failure of the cyclic seasonal shedding of hair. Before generalized hirsutism is observed, horses may have longer hair on the legs, ventral abdomen, and throat latch. Eventually, the hair over most of the trunk and extremities becomes long (up to 4–5 in. [10–12 cm]), abnormally thick, wavy, and often matted.

Pars intermedia adenomas are the most common pituitary tumors in horses. They are yellow to white, multinodular, and compress the pars nervosa. Horses with PPID may have hyperglycemia (insulin-resistant) and glycosuria. It is not known why some horses with PPID become insulin resistant and others do not. However, cortisol and other hormones that may be present in increased concentrations in horses with PPID are insulin antagonists.

Plasma immunoreactive adrenocorticotropin and alpha-MSH levels may range from modestly to extremely increased. Blood cortisol concentrations generally remain in the normal range but lack normal diurnal rhythm and escape suppression by administration of dexamethasone much more quickly than in healthy animals.

Diagnosis: Hyperglycemia and insulin insensitivity are suggestive of pituitary adenoma in horses, but because they occur in horses with equine metabolic syndrome (*see* p 1006) or other insulin dysregulation syndromes, they are not diagnostic of PPID. Other nonspecific findings include an absolute or relative neutrophilia, eosinopenia, and lymphopenia; lipemia; hypercholesterolemia; and a mild, normochromic, normocytic anemia. Liver enzymes may be increased. Electrolytes are usually normal. Urinalysis is normal except for occasional glycosuria and a low to normal specific gravity.

Definitive diagnosis is based on evocative testing or measurement of

Hirsutism in a pony, associated with advanced pituitary pars intermedia dysfunction. Courtesy of Dr. Janice Kritchevsky.

resting endogenous ACTH concentrations. Dexamethasone (40 mcg/kg, IM) often will not suppress cortisol levels to at least 30% of baseline or to <1 mcg/dL, as it does in healthy horses 6–15 hr after administration. In addition, cortisol concentrations return to within 80% or greater of baseline values 24 hr after dexamethasone administration in horses with PPID. Healthy horses have suppressed cortisol levels 24 hr after dexamethasone administration. Horses with PPID react with an exaggerated response to domperidone administration. Increase in plasma endogenous ACTH to $\geq 100\%$ of baseline levels 2–4 hr after administration of domperidone at 5 mg/kg, PO, is consistent with PPID. Horses with PPID have an increase in plasma endogenous ACTH concentration 10 min after administration of 1 mg thyroid-releasing hormone (TRH), and the TRH stimulation test is believed to be the most sensitive means to detect a pituitary tumor. Horses experience a seasonal rise in endogenous ACTH in the autumn (August through November in the northern hemisphere). Healthy horses are less likely to have a decreased cortisol concentration in response to dexamethasone administration and may demonstrate an exaggerated response to domperidone or TRH in the autumn as well. For this reason, unless there are season-specific normal values available for the testing being performed, it is recommended to perform diagnostic testing for PPID from January through July.

Differential diagnoses include syndromes resulting in chronic debilitation, eg, poor management and nutrition, parasitism, and chronic systemic diseases. The PU/PD must be differentiated from that due to chronic renal disease or diabetes insipidus. The hyperglycemia, glycosuria, and PU/PD must be differentiated from that caused by primary diabetes mellitus. High insulin concentrations or an increased glucose to insulin ratio must be differentiated from primary hyperinsulinemia (equine metabolic syndrome). Pheochromocytomas (*see* p 576) may cause hyperhidrosis, hyperglycemia, and tachypnea, although they usually are nonfunctional and found only incidentally at necropsy. Differential diagnosis for hirsutism includes being of the Bashkir Curly breed or having a congenital curly coat abnormality. There is no other recognized condition in which adult horses acquire a long, curly hair coat. For this reason, hirsutism can be considered a positive diagnostic test for PPID.

Treatment: Horses with PPID are relatively fragile, with poor immune

function. Thus, most require diligent attention to good husbandry. Pergolide, a dopaminergic agonist, is currently the only agent demonstrated to decrease endogenous ACTH concentrations in horses with PPID. Starting dosages are 0.006–0.01 mg/kg/day, PO. This typically results in a dose of 0.5–1 mg/day. If this amount does not result in improvement in clinical signs and endocrinologic testing, it may be increased gradually. Reported adverse effects of pergolide therapy include depression and anorexia. Often, these signs are transitory and resolve over time. If they do not, the dose may be decreased temporarily or split and given twice daily. Although its use has not been documented to result in improvement in clinical signs when given alone, cyproheptadine at a dosage of 0.6–1.2 mg/kg/day, PO, may exert synergistic effects when combined with pergolide, and the combination may result in outcomes better than those achieved with pergolide alone. Trilostane, a competitive β -3 hydroxysteroid dehydrogenase inhibitor, has not been investigated adequately in the horse, although its use has improved clinical results.

ADULT-ONSET PANHYPOPITUITARISM

Endocrinologically inactive, nonfunctional pituitary tumors develop most commonly in adult to aged animals; there is no apparent breed predisposition. The most common cause is a chromophobe adenoma arising in the pars distalis. Other infrequent causes include extensive inflammatory destruction of pituitary tissue, ischemic necrosis of the pituitary due to infarction from invasion of tumor cells, parasitic or septic emboli, diffuse necrosis associated with toxemia, invasion by neoplasms arising in adjacent structures (eg, meninges, sphenoid bone, nasal cavity, etc), and widespread hemorrhage and subsequent scarring after traumatic injury. Dogs and cats with nonfunctional adenomas develop clinical disturbances related to a lack of secretion of pituitary trophic hormones and diminished target organ function or to dysfunction of the CNS.

Clinical Findings: Affected animals often are depressed and incoordinated and collapse with exercise. Occasionally, they exhibit a change in attitude, become unresponsive to people, and develop a tendency to hide at the slightest provocation. In chronic cases, there may be evidence of blindness, with dilated and fixed pupils due to compression and

disruption of optic nerves by dorsal extension of the pituitary tumor. Affected dogs often show a progressive weight loss with muscle atrophy due to loss of the protein anabolic effect of growth hormone. Compression of the cells that secrete gonadotropic hormones or the corresponding releasing hormone from the hypothalamus results in atrophy of the gonads. Disturbances of water balance result from interference with the synthesis of antidiuretic hormone (ADH) or its release into capillaries of the pars nervosa. The posterior lobe, infundibular stalk, and hypothalamus are compressed or disrupted by neoplastic cells.

Animals with panhypopituitarism appear dehydrated despite increased water consumption. Dogs and cats with large nonfunctional pituitary tumors usually excrete large volumes of dilute urine with a low specific gravity (≤ 1.007) and may break housetraining. Clinical signs are not highly specific and can be confused with those of other CNS disorders (eg, brain tumors or encephalitis) or chronic renal disease.

Hypopituitarism caused by pituitary tumors should be included in the differential diagnosis of diseases characterized by incoordination, depression, polyuria, blindness, and sudden behavioral changes in adult or aged animals. Because the blindness is central in origin, ophthalmoscopic examination usually does not reveal significant lesions. There is no effect on body stature associated with compression of the pars distalis and probable interference of growth hormone secretion, because these tumors usually arise in dogs that have already completed their growth. Parakeets with chromophobe adenomas often develop exophthalmos due to extension of neoplastic cells along the optic nerve.

Lesions: Endocrinologically inactive pituitary adenomas usually reach considerable size before they cause obvious signs or death. The proliferating tumor cells incorporate the remaining structures of the adeno-hypophysis and infundibular stalk. The entire hypothalamus may be compressed and replaced by tumor.

Thyroid glands in dogs and cats with large pituitary adenomas often are smaller than normal, although to a much lesser degree than the adrenal cortex. The adrenal glands are small and consist primarily of medullary tissue surrounded by a narrow zone of cortex. Seminiferous tubules are small and show little evidence of active spermatogenesis.

Skin atrophy and loss of muscle mass may be related to a lack of protein anabolic effects of growth hormone in an adult dog or cat. Interference with the secretion of pituitary trophic hormones often results in gonadal atrophy resulting in either decreased libido or anestrus.

JUVENILE-ONSET PANHYPOPITUITARISM

(Pituitary dwarfism)

Pituitary dwarfism occurs most frequently in German Shepherds but has been reported in other breeds such as the Spitz, Miniature Pinscher, and Karelian Bear Dog. It is inherited as a simple autosomal recessive trait.

Pituitary dwarfism is usually associated with a failure of the oropharyngeal ectoderm of the cranial pharyngeal duct (Rathke's pouch) to differentiate into trophic-hormone-secreting cells of the pars distalis. Consequently, the adeno-hypophysis is not completely developed. The second most common cause is craniopharyngioma, a benign tumor derived from the oropharyngeal ectoderm of Rathke's pouch. Compared with other types of pituitary neoplasms, these tumors tend to develop in younger dogs. Craniopharyngiomas cause subnormal secretion of growth hormone, which results in dwarfism.

Clinical Findings: Dwarf pups are indistinguishable from normal littermates up to 2 mo old. Subsequently, the slower growth rate compared with littermates, retention of puppy coat, and lack of primary guard hairs gradually become evident. German Shepherds with pituitary dwarfism appear coyote- or fox-like, owing to their small size and soft, woolly coat. Bilaterally symmetric alopecia develops gradually and often becomes complete except for the head and tufts of hair on the legs. Permanent dentition is delayed or completely absent. Closure of the epiphyses is delayed as long as 4 yr depending on the severity of the hormonal insufficiency and is caused by deficiencies of both thyroid-stimulating hormone and growth hormone. The testes and penis are small, calcification of the os penis is delayed or incomplete, and the penile sheath is flaccid. The ovarian cortex is hypoplastic, and estrus is irregular or absent. Lifespan is shortened because of the resulting secondary endocrine dysfunction, such as hypothyroidism and hypoadrenocorticism. Puppies with panhypopituitarism often have a shrill bark.

Lesions: Pituitary cysts fill with mucus and eventually occupy the entire pituitary area, resulting in severe compression of the pars nervosa and infundibular stalk. Craniopharyngiomas are large, solid, cystic areas that extend into the overlying hypothalamus. They may also grow along the ventral aspect of the brain, where incorporation of several cranial nerves results in specific nerve function deficits.

Diagnosis: Levels of thyroxine, triiodo-thyronine, and cortisol are reduced or in the low-normal range. In those animals with an equivocal change in basal hormone level, the responses to challenge by exogenous thyrotropin or adrenocorticotropin are subnormal, owing to the hypoplasia or atrophy of the thyroid gland and adrenal cortex. Other useful diagnostic aids include comparison of height with that of litter-mates, evidence of delayed epiphyseal closure or dysgenesis on skeletal radiographs, and skin biopsy. Cutaneous lesions include hyperkeratosis, follicular keratosis, hyperpigmentation, adnexal atrophy, loss of elastin fibers, and a loose network of collagen fibers in the dermis. Hair shafts are absent, and hair follicles are primarily in the telogen stage of the growth cycle.

The activity of somatomedin C (insulin-like growth factor 1) is low in dwarf dogs. Intermediate somatomedin C activity is present in phenotypically normal ancestors suspected to be heterozygous carriers. Assays for somatomedin C provide an indirect measurement of circulating growth hormone activity in dogs with suspected pituitary dwarfism. Basal levels of circulating canine growth hormone are reported to be detectable but low (normal range: 1.75 ± 0.17 mg/mL) in pituitary dwarfs and do not increase after a provocative test for secretion via clonidine injection (30 mcg/kg, IV) as they do in healthy dogs. Insulin hypersensitivity has been demonstrated in pituitary dwarf dogs, probably due to a change in insulin receptor numbers or affinity of binding in response to the low level of growth hormone.

DIABETES INSIPIDUS

Central diabetes insipidus is caused by reduced secretion of antidiuretic hormone (ADH). When target cells in the kidney lack the biochemical machinery necessary to respond to the secretion of normal or increased circulating levels of ADH, nephrogenic diabetes insipidus results. It occurs infrequently in dogs, cats, and laboratory rats, and rarely in other animals.

Etiology: The hypophyseal form develops as a result of compression and destruction of the pars nervosa, infundibular stalk, or supra-optic nucleus in the hypothalamus. The lesions responsible for the disruption of ADH synthesis or secretion in hypophyseal diabetes insipidus include large pituitary neoplasms (endocrinologically active or inactive), a dorsally expanding cyst or inflammatory granuloma, and traumatic injury to the skull with hemorrhage and glial proliferation in the neurohypophyseal system.

Clinical Findings: Affected animals excrete large volumes of hypotonic urine and drink equally large amounts of water. Urine osmolality is decreased below normal plasma osmolality (~ 300 mOsm/kg) in both hypophyseal and nephrogenic forms, even if the animal is deprived of water. The increase of urine osmolality above that of plasma in response to exogenous ADH in the hypophyseal form, but not in the nephrogenic form, is useful in the clinical differentiation of the two forms of the disease.

Lesions: The posterior lobe, infundibular stalk, and hypothalamus are compressed or disrupted by neoplastic cells. This interrupts the nonmyelinated axons that transport ADH from its site of production (hypothalamus) to its site of release (pars nervosa).

Diagnosis: This is based on chronic polyuria that does not respond to dehydration and is not due to primary renal disease. To evaluate the ability to concentrate urine, a water deprivation test should be done if the animal is not dehydrated and does not have renal disease. The bladder is emptied, and water and food are withheld (usually 3–8 hr) to provide a maximum stimulus for ADH secretion. The animal should be monitored carefully to prevent a loss of $>5\%$ body wt and severe dehydration. Urine and plasma osmolality should be determined; however, because these tests are not readily available to most practitioners, urine specific gravity is frequently used instead. At the end of the test, urine specific gravity is >1.025 in those animals with only a partial ADH deficiency or with antagonism to ADH action caused by hypercortisolism. There is little change in specific gravity in those animals with a complete lack of ADH activity, whether due to a primary loss of ADH or to unresponsiveness of the kidneys.

An ADH response test should follow to differentiate among conditions that may result in large volumes of urine that is chronically low in specific gravity but

otherwise normal. These include nephrogenic diabetes insipidus (an inability of the kidneys to respond to ADH), psychogenic diabetes insipidus (a polydipsia in response to some psychological disturbance but a normal response to ADH), and hypercortisolism (which results in a partial deficiency of ADH activity due to the antagonistic effect of cortisol on ADH activity in the kidneys). This test also can be used to evaluate animals in which a water deprivation test could not be performed. Urine specific gravity is determined at the start of the test, desmopressin acetate is administered (2–4 drops in the conjunctival sac), the bladder is emptied at 2 hr, and urine specific gravity is measured at set intervals (4, 8, 12, 18, and 24 hr) after ADH administration. Specific gravity peaks at >1.026 in animals with a primary ADH deficiency, is significantly increased above the level induced with water deprivation in those with a partial deficiency in ADH activity, and shows little change in those with nephrogenic diabetes insipidus.

If osmolality is measured, the ratio of urine to plasma osmolality after water deprivation is >3 in healthy animals, 1.8 – 3 in those with moderate ADH deficiency, and <1.8 in those with severe deficiency. The ratio of urine osmolality after ADH administration as compared with water deprivation is >2 in animals with primary ADH deficiency, between 1.1 and 2 in those with inhibitors to ADH action, and <1.1 in those unresponsive to ADH.

As an alternative to the water deprivation test, or in cases in which this test does not establish a definitive diagnosis, a closely monitored therapeutic trial with desmopressin (*see below*) can be performed. Again, all other causes of polyuria and polydipsia should initially be excluded, limiting the differential diagnosis to central diabetes insipidus, nephrogenic diabetes insipidus, and psychogenic polydipsia. For cats, the owner should measure the animal's 24-hr water intake 2–3 days before the therapeutic trial with desmopressin, allowing free-choice water intake. The intranasal preparation of desmopressin is administered in the conjunctival sac (1–4 drops, bid) for 3–5 days. A dramatic reduction in water intake ($>50\%$) during the first treatment day strongly suggests an ADH deficiency and a diagnosis of central diabetes insipidus or partial nephrogenic diabetes insipidus.

Diabetes insipidus also needs to be distinguished from other diseases with polyuria. The most common are diabetes mellitus with glycosuria and high urine specific gravity, and

chronic nephritis with a urine specific gravity that is usually low and shows evidence of renal failure (protein, casts, etc).

Treatment: Polyuria may be controlled using desmopressin acetate, a synthetic analogue of ADH. The initial dose is 2 drops applied to the nasal mucosae or conjunctivae; this is gradually increased until the minimal effective dose is determined. Maximal effect usually occurs in 2–6 hr and lasts for 10–12 hr. Water should not be restricted. Treatment should be continued once or twice daily for the life of the animal.

FELINE ACROMEGALY

Acromegaly, or hypersomatotropism, results from chronic, excessive secretion of growth hormone in the adult animal. Acromegaly in cats is caused by a growth hormone-secreting tumor of the anterior pituitary. In cats, these tumors grow slowly and may be present for a long time before clinical signs appear.

Clinical Findings: Feline acromegaly occurs in older (8–14 yr) cats and appears to be more common in males. Clinical signs of uncontrolled diabetes mellitus are often the first sign of acromegaly in cats; therefore, polydipsia, polyuria, and polyphagia are the most common presenting signs. Net weight gain of lean body mass in cats with uncontrolled diabetes mellitus is a key sign of acromegaly. Organomegaly, including renomegaly, hepatomegaly, and enlargement of endocrine organs, is also seen. Some, but not all, cats show the classic enlargement of extremities, body size, jaw, tongue, and forehead that is characteristic of acromegaly in people. Some of the most striking manifestations are seen in the musculoskeletal system and include an increase in muscle mass and growth of the acral segments of the body, including the paws, chin, and skull. Stridor may be detected as a result of increased soft-tissue enlargement of the epiglottis and surrounding tissues. Cardiovascular abnormalities such as cardiomegaly (radiographic and echocardiographic), systolic murmurs, and congestive heart failure develop late in the disease course. Azotemia also develops late in the course of the disease in $\sim 50\%$ of acromegalic cats. Neurologic signs of acromegaly in people, such as peripheral neuropathies (paresthesias, carpal tunnel syndrome, sensory and motor defects) and parasellar manifestations (headache and visual field defects), are not generally detected in acromegalic cats.

Impaired glucose tolerance and insulin resistance resulting in diabetes mellitus are seen in all cats with acromegaly. Measurement of endogenous insulin reveals dramatically increased serum insulin concentrations. Despite severe insulin resistance and hyperglycemia, ketosis is rare. Hypercholesterolemia and mild increases in liver enzymes are attributed to the diabetic state. Hyperphosphatemia without azotemia is also a common clinicopathologic finding. Urinalysis is unremarkable except for persistent proteinuria. In a recent study, acromegaly was the most common (25%) underlying cause of non-insulin-dependent diabetes mellitus in cats, and it should be suspected in any cat that does not respond to standard therapy for type 2 diabetes mellitus (high-protein, low-carbohydrate diet and glargine insulin) within 4 mo of initiating therapy.

Lesions: Gross necropsy findings in acromegalic cats may include a large expansile pituitary mass, hypertrophic cardiomyopathy with marked left ventricular and septal hypertrophy (early) or dilated cardiomyopathy (late), hepatomegaly, renomegaly, degenerative joint disease, lumbar vertebral spondylosis, moderate enlargement of the parathyroid glands, adrenocortical hyperplasia, and diffuse enlargement of the pancreas with multifocal nodular hyperplasia. Histopathologic examination of the endocrine glands reveals acidophil adenoma of the pituitary; adenomatous hyperplasia of the thyroid gland; and nodular hyperplasia of the adrenal cortices, parathyroid glands, and pancreas.

Diagnosis: A definitive diagnosis requires measurement of increased plasma growth

hormone or insulin-like growth factor 1 (IGF-1) concentrations in suspected cases. Unfortunately, feline growth hormone assays are no longer available. Serum IGF-1 concentrations are often dramatically increased in acromegalic cats (as in affected people). Currently, the most definitive diagnostic test is CT of the pituitary region. Results of CT, coupled with the exclusion of other disorders that cause insulin resistance (hyperthyroidism, hyperadrenocorticism) and clinical signs and laboratory abnormalities, support a diagnosis of acromegaly.

Treatment and Prognosis: Medical therapy in people includes the use of dopamine agonists, such as bromocriptine, and somatostatin analogues (octreotide). Treatment with octreotide has been unsuccessful in acromegalic cats. The lack of efficacy of the long-acting somatostatin analogues may result from species-specific tissue binding. Radiation therapy probably offers the greatest chance for success with low rates of morbidity and mortality. The disadvantages include the slow rate of tumor shrinkage (>3 yr) and the occurrence of hypopituitarism, cranial and optic nerve damage, and radiation injury to the hypothalamus.

The short-term prognosis in cats with untreated acromegaly is fair to good. Insulin resistance is generally controlled satisfactorily by using large doses of insulin divided into several daily doses. Mild cardiac disease can be managed with diuretics and vasodilators. The longterm prognosis is relatively poor, however, and most cats die of congestive heart failure, chronic renal failure, or signs of an expanding pituitary mass. The longterm prognosis may improve with early diagnosis and treatment.

THE THYROID GLAND

All vertebrates have a thyroid gland. In mammals, it is usually bilobed and located just caudal to the larynx, adjacent to the lateral surface of the trachea. The two lobes may be connected by a fibrous isthmus (eg, ruminants, horses), or a connecting isthmus may be indistinct (eg, dogs, cats). The gland is extremely vascular. In birds, it is found within the thoracic cavity; both lobes are located near the syrinx, adjacent to the

carotid artery near the origin of the vertebral artery.

Ectopic or accessory thyroid tissue is relatively common in most species, especially dogs and cats. It may be located anywhere from the larynx to the diaphragm and may be responsible for maintaining normal thyroid function after surgical thyroidectomy. In addition, ectopic thyroid tissue occasionally is the site of hyperplasia or neoplasia.

Physiology: Thyroid hormones are the only iodinated organic compounds in the body. Thyroxine (T_4) is the main secretory product of the normal thyroid gland. However, the gland also secretes 3,5,3'-triiodothyronine (T_3), reverse T_3 , and other deiodinated metabolites. T_3 is ~3–5 times more potent than T_4 , whereas reverse T_3 is thyromimetically inactive.

Although all T_4 is secreted by the thyroid, a considerable amount of T_3 is derived from T_4 ; therefore, T_4 has been called a prohormone. Its activation to the more potent T_3 is a step regulated individually by peripheral tissues.

Thyroid hormone secretion is regulated primarily via negative-feedback control through the coordinated response of the hypothalamic-pituitary-thyroid axis: thyrotropin-releasing hormone (TRH) binds to the thyrotroph cell in the pituitary and stimulates secretion of thyrotropin (thyroid-stimulating hormone, TSH), which binds to the follicular cell membrane and stimulates thyroid hormone synthesis and secretion.

Thyroid hormones are water-insoluble lipophilic compounds that are bound to plasma proteins (thyroxine-binding protein, thyroxine-binding prealbumin [transthyretin], and albumin). The major function of the thyroid hormone-binding proteins is probably to provide a hormone reservoir in the plasma and to "buffer" hormone delivery into tissue. In healthy euthyroid animals, 0.1% of total serum T_4 is free (not bound to thyroid hormone-binding proteins), whereas ~1% of circulating T_3 is free. Evidence suggests that the fractions of circulating free T_4 and free T_3 determine the amount of hormone available for uptake by tissues.

Action of Thyroid Hormones: Thyroid hormones act on many different cellular processes; however, no single reaction or metabolic event can be equated with their action. Although both T_4 and T_3 have intrinsic metabolic activity, T_3 is 3–5 times more potent in binding to the nuclear receptors and similarly more potent in stimulating oxygen consumption.

Effects of thyroid hormones generally are divided into two categories: those that manifest within minutes to hours after hormone receptor binding and do not require protein synthesis, and those that manifest later (usually >6 hr) and require synthesis of new proteins. About half the increase in oxygen consumption produced by thyroid hormones is related to activation of the plasma membrane-bound Na^+/K^+ ATPase;

thyroid hormones also stimulate mitochondrial oxygen consumption. These changes are linked directly to the calorigenic effect of thyroid hormones. More chronic effects invariably are related to the cellular actions that require interaction with nuclear T_3 receptors, followed by an increase in protein synthesis crucial to physiologic processes such as growth, differentiation, proliferation, and maturation.

Thyroid hormones, in physiologic quantities, are anabolic. In conjunction with growth hormone and insulin, protein synthesis is stimulated and nitrogen excretion is reduced. However, in excess (hyperthyroidism), they can be catabolic, with increased gluconeogenesis, protein breakdown, and nitrogen wasting.

HYPOTHYROIDISM

In hypothyroidism, impaired production and secretion of the thyroid hormones result in a decreased metabolic rate. This disorder is most common in dogs but also develops rarely in other species, including cats, horses, and other large, domestic animals.

Etiology: Although dysfunction anywhere in the hypothalamic-pituitary-thyroid axis may result in thyroid hormone deficiency, >95% of clinical cases of hypothyroidism in dogs appear to result from destruction of the thyroid gland itself (primary hypothyroidism). The two most common causes of adult-onset primary hypothyroidism in dogs include lymphocytic thyroiditis and idiopathic atrophy of the thyroid gland. Lymphocytic thyroiditis, probably immune-mediated, is characterized histologically by a diffuse infiltration of the gland by lymphocytes, plasma cells, and macrophages and results in progressive destruction of follicles and secondary fibrosis. Idiopathic atrophy of the thyroid gland is characterized histologically by loss of thyroid parenchyma and replacement by adipose tissue. (See also AUTOIMMUNE THYROIDITIS, p 831.)

In dogs, the most common cause of secondary hypothyroidism is destruction of pituitary thyrotrophs by an expanding, space-occupying tumor. Because of the nonselective nature of the resulting compressive atrophy and replacement of pituitary tissue by such large tumors, deficiencies of other (one or more) pituitary hormones also usually occur.

Other rare forms of hypothyroidism in dogs include neoplastic destruction of thyroid tissue and congenital (or juvenile-onset) hypothyroidism. Congenital

primary hypothyroidism may result from one of various forms of thyroid dysgenesis (eg, athyreosis, thyroid hypoplasia) or from dysmorphogenesis (usually an inherited inability to organify iodide). Congenital secondary hypothyroidism (associated with clinical signs of disproportionate dwarfism, lethargy, gait abnormalities, and constipation) has been reported in Giant Schnauzers, Toy Fox Terriers, and Scottish Deerhounds. Congenital secondary hypothyroidism also has been reported in German Shepherds with pituitary dwarfism associated with a cystic Rathke's pouch. However, the degree of TSH deficiency in these dogs is variable, and clinical signs are usually caused primarily by deficiency of growth hormone (rather than thyroid hormone).

In cats, iatrogenic hypothyroidism is the most common form. Hypothyroidism develops in these cats after treatment for hyperthyroidism with radioiodine, surgical thyroidectomy, or use of an antithyroid drug. Although naturally occurring hypothyroidism is an extremely rare disorder in adult cats, congenital or juvenile-onset hypothyroidism does also occur. Recognized causes of congenital hypothyroidism in cats include intrathyroidal defects in thyroid hormone biosynthesis (dysmorphogenesis), an inability of the thyroid gland to respond to TSH, and thyroid dysgenesis. All reported cats with hypothyroidism have had the primary (thyroidal) disorder. Secondary (pituitary) or tertiary (hypothalamic) hypothyroidism has not been well described in either juvenile or adult cats but has been reported after severe head trauma.

In foals, congenital hypothyroidism may develop when pregnant mares graze plants that contain goitrogens, or are fed diets either deficient in or containing excessive amounts of iodine. Most commonly, congenital hypothyroidism develops in association with a specific syndrome of neonatal foals characterized by thyroid gland hyperplasia together with multiple congenital musculoskeletal anomalies. This syndrome, reported most commonly in western Canada, has been referred to as either thyroid hyperplasia and musculoskeletal deformities syndrome or as congenital hypothyroidism and dysmaturity syndrome and may be related to feeding a high nitrate diet to pregnant mares. In adult horses, hypothyroidism appears to be very rare but, as in other species, is commonly misdiagnosed.

Clinical Findings: Although onset is variable, hypothyroidism is most common in dogs 4–10 yr old. It usually affects mid- to large-size breeds and is rare in toy and miniature breeds. Breeds reported to be predisposed include the Golden Retriever, Doberman Pinscher, Irish Setter, Miniature Schnauzer, Dachshund, Cocker Spaniel, and Airedale Terrier. There does not appear to be a sex predilection, but spayed females appear to have a higher risk of developing hypothyroidism than intact females.

A deficiency of thyroid hormone affects the function of all organ systems; as a result, clinical signs are diffuse, variable, often nonspecific, and rarely pathognomonic. Although the disorder should be highly suspect, overdiagnosis should be avoided, because many diseases, especially those of the skin, can easily be misdiagnosed as hypothyroidism.

Many of the clinical signs associated with canine hypothyroidism are directly related to slowing of cellular metabolism, which results in development of mental dullness, lethargy, exercise intolerance, and weight gain without a corresponding increase in appetite. Mild to marked obesity develops in some dogs. Difficulty maintaining body temperature may lead to frank hypothermia; the classic hypothyroid dog is a heat-seeker. Alterations in the skin and coat are common. Dryness, excessive shedding, and retarded regrowth of hair are usually the earliest dermatologic changes. Nonpruritic hair thinning or alopecia (usually bilaterally symmetric) that may involve the ventral and lateral trunk, the caudal surfaces of the thighs, dorsum of the tail, ventral neck, and the dorsum of the nose is seen in about two-thirds of dogs with hypothyroidism. Alopecia, sometimes associated with hyperpigmentation, often starts over points of wear. Occasionally, secondary pyoderma (which may produce pruritus) is seen.

In moderate to severe cases, thickening of the skin occurs secondary to accumulation of glycosaminoglycans (mostly hyaluronic acid) in the dermis. In such cases, myxedema is most common on the forehead and face, resulting in a puffy appearance and thickened skin folds above the eyes. This puffiness, together with slight drooping of the upper eyelid, gives some dogs a "tragic" facial expression. These changes also have been described in the GI tract, heart, and skeletal muscles.

In intact dogs, hypothyroidism may cause various reproductive disturbances: in females, failure to cycle (anestrus) or

sporadic cycling, infertility, abortion, or poor litter survival; and in males, lack of libido, testicular atrophy, hypospermia, or infertility.

A variety of neurologic disorders, including megaesophagus, laryngeal paralysis, facial nerve paralysis, and vestibular disease, have been related to hypothyroidism. However, all such peripheral and central nervous disease is uncommon, at least compared with the metabolic and dermatologic changes commonly seen in hypothyroid dogs. In addition, such neurologic signs do not always resolve after thyroid hormone replacement therapy.

Myxedema coma, a rare syndrome, is the extreme expression of severe hypothyroidism. The course can develop rapidly; lethargy progresses to stupor and then coma. The common signs of hypothyroidism (eg, hair loss) are usually present, but other signs, such as hypoventilation, hypotension, bradycardia, and profound hypothermia, are usually seen as well.

During the fetal period and in the first few months of postnatal life, thyroid hormones are crucial for growth and development of the skeleton and CNS. Therefore, in addition to the well-recognized signs of adult-onset hypothyroidism, disproportionate dwarfism and impaired mental development (cretinism) are prominent signs of congenital and juvenile-onset hypothyroidism. In primary congenital hypothyroidism, enlargement of the thyroid gland (goiter) also may be detected, depending on the cause of the hypothyroidism. Radiographic signs of epiphyseal dysgenesis (underdeveloped epiphyses throughout the long bones), shortened vertebral bodies, and delayed epiphyseal closure are common.

In dogs with congenital hypopituitarism (pituitary dwarfism, *see p 549*), there may be variable degrees of thyroidal, adrenocortical, and gonadal deficiency, but clinical signs are primarily related to growth hormone deficiency. Signs include proportionate dwarfism (rather than the disproportionate form of dwarfism characteristic of congenital hypothyroidism), loss of primary guard hairs with retention of the puppy coat, hyperpigmentation of the skin, and bilaterally symmetric alopecia of the trunk.

In adult cats, clinical signs associated with advanced or severe hypothyroidism include lethargy, dullness, nonpruritic seborrhea sicca, hypothermia, decreased appetite, and occasionally bradycardia. Obesity may develop, especially in cats with

iatrogenic hypothyroidism, but it is not a consistent sign. Bilaterally symmetric alopecia, except for pinnal involvement, does not appear to develop, but focal areas of alopecia over the craniolateral carpi, caudal hocks, and dorsal and lateral tailbase have occasionally been seen. However, in many cats with mild iatrogenic hypothyroidism, very mild or no obvious clinical signs are seen. In young cats with congenital or juvenile-onset hypothyroidism, the clinical signs are more obvious and include disproportionate dwarfism, severe lethargy, mental dullness, constipation, inappetence, and bradycardia.

Diagnosis of Hypothyroidism:

Hypothyroidism is probably one of the most overdiagnosed diseases in dogs. Many diseases and conditions can mimic hypothyroidism, and some of the clinical signs, even in dogs with normal thyroid function, can improve after administration of exogenous thyroid hormone. In addition, a variety of nonthyroidal factors (eg, nonthyroidal illness and prior administration of certain drugs) can lead to low serum thyroid hormone measurements in euthyroid dogs, cats, and other species. Definitive diagnosis of canine hypothyroidism requires careful attention to clinical signs and results of routine laboratory testing. Tests that may confirm the diagnosis include measurement of the serum concentrations of total T_4 , free T_4 , and TSH; provocative thyroid function tests (eg, TSH stimulation test); thyroid gland imaging; and response to thyroid hormone supplementation. Choice and interpretation of diagnostic tests is based heavily on the index of suspicion for hypothyroidism.

There are well-recognized clinicopathologic abnormalities associated with hypothyroidism, the severity of which usually correlates with the severity and chronicity of the hypothyroid state. These changes are nonspecific and may be associated with many other diseases in dogs. Their presence, however, adds supportive evidence for a diagnosis of hypothyroidism in a dog with relevant clinical signs. The classic hematologic finding associated with hypothyroidism, found in 40%–50% of cases, is a normocytic, normochromic, nonregenerative anemia. The classic serum biochemical abnormality is hypercholesterolemia, which occurs in ~80% of dogs with hypothyroidism. The value of serum cholesterol determination as a screening test for hypothyroidism cannot be overemphasized, because cholesterol concentrations are a sensitive and inexpensive

biochemical marker for this disease in dogs. Other clinicopathologic abnormalities may include high serum concentrations of triglycerides, alkaline phosphatase, and CK.

Total T_4 concentration is the most commonly performed static thyroid hormone measurement and is a good initial screening test for hypothyroidism, with a diagnostic sensitivity of ~90%. A dog or cat with a T_4 concentration well within reference range limits may be assumed to have normal thyroid function. However, a subnormal basal T_4 concentration alone is not diagnostic; it may indicate an animal that is normal, hypothyroid, or suffering from a nonthyroidal illness with a secondary decrease in the basal T_4 concentration (sick euthyroid syndrome; see below).

Because only the unbound fraction of serum T_4 is biologically active, measurement of free T_4 has been hypothesized to be more useful to differentiate euthyroid dogs from hypothyroid dogs than total T_4 concentrations. However, most single-stage solid phase (analogue) commercial assays for free T_4 do not appear to be superior to measurement of total T_4 in dogs, probably because of differences in serum binding proteins. A free T_4 assay that uses an equilibrium dialysis step (direct dialysis) has better accuracy than the analogue methods. Compared with the total T_4 assay, the free T_4 assay by dialysis has greater diagnostic sensitivity and specificity.

Because T_3 is the most potent thyroid hormone at the cellular level, it would seem logical to measure its concentration for diagnostic purposes. However, serum T_3 concentrations may be low, normal, or (occasionally) high in dogs with documented hypothyroidism. The diagnostic value of a serum T_3 determination is particularly weak during early thyroid failure because the "failing" thyroid tends to increase the relative synthesis and secretion of T_3 versus T_4 . In hypothyroid dogs in which values for serum T_3 are high, anti- T_3 antibodies, which produce spurious results in most T_3 radioimmunoassays, should be suspected.

Determination of serum TSH concentrations by use of a valid species-specific TSH assay can be a useful adjunctive test for hypothyroidism in dogs, cats, and horses. Animals with primary hypothyroidism (by far the most common type) would be expected to have low serum T_4 and/or free T_4 concentrations with high endogenous TSH concentrations. Unfortunately, serum TSH concentrations remain within the reference range in 20%–40% of dogs with confirmed hypothyroidism. Although a few dogs with normal serum TSH concentra-

tions have secondary hypothyroidism, pituitary TSH deficiency is extremely rare, and most dogs with normal TSH concentrations (ie, a false-negative result) have primary hypothyroidism. In contrast, falsely high serum TSH concentrations (ie, a false-positive result) are occasionally found in euthyroid dogs with nonthyroidal illness. Thus, serum TSH determinations should never be evaluated alone but always in conjunction with the dog's history, routine laboratory abnormalities, and total or free T_4 concentrations.

The TSH stimulation test evaluates the response of the thyroid gland to exogenously administered TSH and is a test of thyroid reserve. It is an accurate test of thyroid function in dogs but its use is limited by the expense and limited availability of TSH. The protocol requires collection of a serum sample for measurement of a basal T_4 , followed by administration of bovine TSH given IV at a dosage of 0.1 U/kg (maximum dose 5 units). A second sample for measurement of T_4 is collected 6 hr later. Human recombinant TSH is available, although expensive, and may be frozen for at least 8 wk with no loss of potency. The recommended dose is 75 mcg, IV, with collection of 0- and 6-hr samples. Results are similar to those obtained using the bovine product. Results may reveal a normal response, a blunted response (sick euthyroid syndrome), or no response (hypothyroidism).

Both ultrasonography and scintigraphy of the thyroid gland have been evaluated as diagnostic tests for hypothyroidism in dogs. With an experienced radiologist, use of thyroid sonography (ie, decreased echogenicity and decreased thyroid volume) can be an effective ancillary diagnostic tool to differentiate between canine hypothyroidism and euthyroid sick syndrome. The best imaging technique may be the use of technetium 99m (^{99m}Tc) uptake and imaging of the thyroid gland. With quantitative measurement of thyroidal ^{99m}Tc uptake, there is little to no overlap between dogs with primary hypothyroidism and dogs with nonthyroidal illness.

In some cases, the most practical approach to confirming the diagnosis of hypothyroidism is a therapeutic trial using appropriate guidelines. Every attempt should be made to exclude nonthyroidal illness before starting a therapeutic trial. There is no evidence that thyroid hormone supplementation is beneficial in dogs with sick euthyroid syndrome, and it may be detrimental. Thyroxine supplementation should be started at a dosage of 20 mcg/kg

(administered without food, on an empty stomach), once to twice daily. Objective criteria should be used to assess the response to treatment. If response to treatment is positive, the clinician should be prepared to withdraw therapy to confirm that clinical signs return. This will ensure that dogs with thyroid-responsive diseases (ie, those in which the clinical signs improve because of the nonspecific effects of thyroid hormone or unrelated to therapy) do not remain on thyroid supplementation for life. If therapy is unsuccessful, therapeutic monitoring should be performed to identify the cause of treatment failure. Because an incorrect diagnosis is the most common cause of treatment failure, the clinician should be prepared to withdraw therapy and pursue other diagnoses.

In cats, hypothyroidism can also be diagnosed on the basis of finding low to low-normal serum concentrations of total T_4 , free T_4 , and T_3 , with high serum TSH concentrations. A feline-specific TSH assay is not available, but the canine TSH assay can be used as a test for feline hypothyroidism.

Diagnosis of Thyroiditis: Circulating antithyroglobulin antibodies can be detected in as many as half of dogs with hypothyroidism and are believed to reflect a state of autoimmune thyroiditis. Measurement of these antibodies in breeding studs and bitches has been proposed as a method to identify dogs with autoimmune thyroid disease. Serum thyroglobulin autoantibody determinations may be a useful adjunctive diagnostic aid for hypothyroidism. However, the test can never be used alone to confirm a diagnosis of hypothyroidism, because a positive antithyroglobulin antibody titer may occur in euthyroid dogs with early stages of lymphocytic thyroiditis. Identification of these autoantibodies supports the diagnosis if the dog has clinical signs and other laboratory data consistent with the disorder.

Although extremely rare in dogs, circulating thyroid hormone autoantibodies (anti- T_3 or anti- T_4 antibodies) are occasionally detected and also are believed to reflect a state of autoimmune thyroiditis. These antibodies, which can be formed against either T_3 or T_4 (or both), produce a spurious increase in the apparent T_3 or T_4 concentrations, into the hyperthyroid range in most dogs. Of all the thyroid hormones, only measurement of free T_4 (by dialysis) is not affected by autoantibodies directed at T_4 or T_3 , because the serum autoantibodies are removed in the dialysis step. Therefore, if

hypothyroidism is suspected in a dog with circulating thyroid hormone autoantibodies, serum free T_4 concentration should be determined to help confirm the diagnosis.

Nonthyroidal Factors That Affect Interpretation of Thyroid Function Tests:

Certain breeds have normal thyroid hormone ranges that differ from most other breeds. Few have been evaluated, but Greyhounds have serum total T_4 and free T_4 concentrations that are considerably lower than those of most other breeds. Scottish Deerhounds also have total T_4 concentrations that are well below the mean concentration of dogs in general, and other sight hounds may have similar findings. Alaskan sled dogs have serum total T_4 , T_3 , and free T_4 concentrations that are below the reference range of most pet dogs, particularly during periods of intense training or racing.

Illness not involving the thyroid gland can alter thyroid function tests and has been labeled "nonthyroidal illness" or "euthyroid sick syndrome." Any illness can alter thyroid function tests, causing a fairly consistent decrease in total T_4 and T_3 concentrations in proportion to the severity of illness. Serum TSH concentration is increased in 8%–10% of dogs with nonthyroidal illness. Serum free T_4 measured by equilibrium dialysis is less likely to be affected but can be increased or decreased. However, in dogs with substantial nonthyroidal illness, the free T_4 is likely to be decreased. Testing of thyroid function should be postponed until the nonthyroidal illness is resolved. If this is not possible, measurement of T_4 , TSH, and free T_4 are indicated.

Glucocorticoids, phenobarbital, sulfonamides, clomipramine, and aspirin are known to commonly alter thyroid function tests. Glucocorticoids suppress total T_4 and sometimes free T_4 concentrations. Phenobarbital causes decreased total T_4 and mildly increased TSH. Sulfonamides can induce overt primary hypothyroidism with clinical signs and thyroid function tests that support the diagnosis. All changes are reversible when the medication is discontinued. Dozens of drugs affect thyroid function and thyroid function tests in people, so many others likely affect animals as well.

Treatment: Thyroxine (T_4) is the thyroid hormone replacement compound of choice in dogs and cats. With few exceptions, replacement therapy is necessary for the remainder of the animal's life; careful initial

diagnosis and tailoring of treatment is essential. The reported replacement dosages for T_4 in dogs and cats range from a total dosage of 0.01–0.02 mg/lb (0.02–0.04 mg/kg), daily, given once or divided bid without food (on an empty stomach).

The most important indicator of the success of therapy is clinical improvement. Reversal of changes in coat and body weight should be assessed only after 1–2 mo of therapy. When clinical improvement is marginal or signs of thyrotoxicosis are seen, the clinical observations can be supported by therapeutic monitoring of serum thyroid hormone concentrations ("post-pill testing"). With once-daily administration of T_4 , the peak serum concentration of T_4 generally should be slightly high to high-normal 4–6 hr after dosing and should be low-normal to normal 24 hr after dosing. Animals on bid administration probably can be checked at any time, but peak concentrations can be expected at the middle of the dosing interval (4–6 hr) and the nadir just before the next dose. After the dosage is stabilized, serum T_4 (with or without T_3) concentrations should be checked 1–2 times per year.

If clinical signs of hypothyroidism remain despite the use of reasonable doses of thyroid hormone, the following must be considered: 1) the dosage or frequency of administration is improper; 2) the owner is not complying with instructions or is not successfully administering the medication; 3) the animal is not absorbing the medication well, or is metabolizing and/or excreting it too rapidly; 4) the medication is outdated; or 5) the diagnosis is incorrect.

NON-NEOPLASTIC ENLARGEMENT OF THE THYROID GLAND

(Goiter)

An enlarged thyroid gland is, by definition, a goiter. Non-neoplastic and noninflammatory enlargements of the thyroid gland develop in all domestic mammals as well as birds. The major causes of goiter include iodine deficiency, ingestion of goitrogenic substances, dietary iodine excess, and inherited enzyme defects in the biosynthesis of thyroid hormones. Many animals with goiter appear to remain euthyroid, but clinical signs of hypothyroidism may develop in some, especially in newborns.

Iodine Deficiency: Thyroid hyperplasia due to iodine deficiency was common in

many goitrogenic areas throughout the world before the widespread supplementation of iodized salt to animal diets. Although outbreaks of iodine-deficient goiter are now sporadic and fewer animals are affected, iodine deficiency is still responsible for most non-neoplastic goiters seen in large domestic animals.

Iodine atoms are a part of the thyroid hormones thyroxine and triiodothyronine; thus, insufficient iodine reduces the ability of the thyroid to make these hormones. With reduced circulating thyroid hormone levels, the pituitary secretes more thyroid-stimulating hormone (TSH), which acts as a stimulus for hyperplasia of the thyroid gland and subsequent development of a goiter. The hyperplastic gland may, and usually does, compensate for the reduced availability of iodine; therefore, goiter is in no way synonymous with hypothyroidism. Fetal thyroid glands are more susceptible to the effects of high or low iodine intake; animals born to females on iodine-deficient diets are more likely to develop severe thyroid enlargement and have clinical signs of hypothyroidism.

Goiter caused by iodine deficiency is most common in newborn pigs, lambs, and calves in iodine-deficient areas. The thyroid lobes of the young animal usually are at least twice normal size, soft, and dark red. In severe cases, there is an accompanying lack of hair (especially in pigs) or wool (lambs). The neck is usually grossly enlarged, and the skin and other tissue may be thickened, flabby, and edematous. In mildly affected animals, treatment with iodized salt (containing >0.007% iodine) may resolve the goiter and associated clinical signs, but many die before or soon after birth. Prophylaxis is more effective than treatment. Using stabilized iodized salt or ensuring that the ration is balanced for iodine content is recommended in all areas known or suspected to be iodine deficient.

Iodine Toxicity: Goiter and hypothyroidism occur in foals of dams fed excess iodine during gestation. Mares supplemented with iodine at ≥ 35 mg/day may produce affected foals. Foals receive the excess iodine both in utero and via the milk, because mares on high-iodine diets secrete higher than normal amounts of iodine in their milk. Clinical signs vary and may include goiter, weakness, and musculoskeletal abnormalities. Mares are invariably asymptomatic. Foals may improve or recover once the excess iodine is removed.

Goitrogenic Substances: Certain plants may produce goiter when ingested in sufficient amounts, especially in the absence of adequate iodine intake. Soybeans are most notable, but cabbage, rape, kale, and turnips all contain less potent goitrogens. Cooking or heating (and the usual processing of soybean meal) destroys the goitrogenic substance in these plants. All of the goitrogenic substances act by interfering with production of thyroid hormone. As with iodine deficiency, the pituitary responds to the reduced circulating thyroid hormone levels by increasing its secretion of TSH, which results in thyroid gland enlargement. In adult animals the disease is usually not significant, but severe thyroid enlargement and hypothyroidism may develop in newborns.

Congenital Hypothyroidism and Dismaturity Syndrome of Foals:

Congenital hypothyroidism and dysmaturity syndrome of neonatal foals was first recognized in the early 1980s and is characterized by hyperplasia of the thyroid gland, goiter, and multiple congenital musculoskeletal anomalies. It is most common in western Canada but has been seen in the Pacific Northwest and sporadically in other areas of the USA. There is no sex or breed predilection. Foals with this syndrome are born after a prolonged gestation (340–400 days) but appear dysmature with pliable ears, muscle weakness, and incomplete skeletal development. Common musculoskeletal defects include flexural deformities of the forelimbs, ruptured tendons of the common digital extensor muscles, mandibular prognathia, and immature carpal and tarsal bones. Multiple cases may appear on a farm, with no recurrence in subsequent years. The underlying etiology is unknown but may be the result of diets that contain high levels of nitrate (eg, greenfeed) combined with low iodine intake or ingestion of an unidentified goitrogen. Most affected foals either die or are euthanized within the first week of life.

Familial Dysmorphogenetic

Goiter: Familial dysmorphogenetic goiter has been reported in sheep, cattle, goats, and pigs and appears to be inherited as an autosomal recessive trait. Essentially, it is a genetic enzyme defect in the biosynthesis of thyroid hormones. As with iodine deficiency, reduced thyroid hormone production leads to secretion of increased levels of TSH and subsequent goiter. Clinical signs may include subnormal growth rate, absence of normal wool development or a

sparse coat, myxedematous swelling of subcutaneous tissues, and weakness. Many affected animals die shortly after birth or are very sensitive to adverse environmental conditions.

HYPERTHYROIDISM

Excessive secretion of the thyroid hormones, T_4 and T_3 , results in signs that reflect an increased metabolic rate and produces clinical hyperthyroidism. It is most common in middle-aged to old cats but also develops rarely in dogs.

Functional thyroid adenoma (adenomatous hyperplasia) is the most common cause of feline hyperthyroidism; in ~70% of cases, both thyroid lobes are enlarged. Thyroid carcinoma, the primary cause of hyperthyroidism in dogs, is rare in cats (1%–2% of hyperthyroidism cases).

Clinical Findings and Diagnosis: The most common signs include weight loss, increased appetite, hyperexcitability, polydipsia, polyuria, and palpable enlargement of the thyroid gland. GI signs are also common and may include vomiting, diarrhea, and increased fecal volume. Cardiovascular signs include tachycardia, systolic murmurs, dyspnea, cardiomegaly, and congestive heart failure. Rarely, hyperthyroid cats exhibit apathetic signs (eg, anorexia, lethargy, and depression); weight loss remains a common sign in these cats.

High basal serum total thyroid hormone concentration is the hallmark of hyperthyroidism and confirms the diagnosis. Although serum total T_4 concentrations are high in most cats with hyperthyroidism, ~5%–10% of cats have normal T_4 values. Most cats with normal serum T_4 values have either mild or early hyperthyroidism or hyperthyroidism with concurrent nonthyroidal illness, which has caused suppression of a high total T_4 concentration to within reference range limits. In these cats, a high free T_4 concentration along with consistent history and physical examination findings is diagnostic of hyperthyroidism.

Treatment: Cats with hyperthyroidism can be treated by radioiodine therapy, thyroidectomy, chronic administration of an antithyroid drug, or lifelong nutritional therapy (iodine-deficient diet). Radioactive iodine provides a simple, effective, and safe treatment and is considered the treatment of choice. The radioiodine is concentrated within the thyroid tumor, where it selectively irradiates and destroys hyperfunctioning thyroid tissue.

Surgical thyroidectomy is also an effective treatment for hyperthyroidism in cats. With unilateral thyroid tumors, hemithyroidectomy corrects the hyperthyroid state, and thyroxine supplementation usually is not necessary. For bilateral thyroid tumors, complete thyroidectomy is indicated, but parathyroid function must be preserved to avoid postoperative hypocalcemia. Thyroxine supplementation should be started 1–2 days after complete thyroidectomy. If iatrogenic hypoparathyroidism develops, treatment with vitamin D and calcium is also indicated.

Treatment with methimazole, an antithyroid drug, controls hyperthyroidism by blocking thyroid hormone synthesis. Carbimazole is a similar antithyroid drug available in many European countries, Australia, and Japan; it exerts its effects through immediate conversion to methimazole after administration. Propylthiouracil, another antithyroid drug, is not recommended for use in cats because of the high incidence of serious adverse effects (especially hemolytic anemia and thrombocytopenia). The recommended initial daily dose of methimazole is 2.5–5 mg in two divided doses. The dosage is adjusted to maintain circulating thyroid hormone concentrations within the mid-normal range and is given daily. Adverse effects, the more serious of which are agranulocytosis and thrombocytopenia, develop in <5% of treated cats. If this occurs, methimazole should be discontinued and supportive therapy instituted; these adverse reactions should resolve within 2 wk. To maintain normal levels of thyroid hormone and to monitor for adverse reactions during the first 3 mo of treatment (when the most serious adverse effects associated with methimazole therapy develop), CBCs and serum thyroid hormone determinations should be repeated at 2- to 4-wk intervals, with the drug dosage adjusted as necessary. Subsequently, serum T_4 concentrations should be measured at 3- to 6-mo intervals to monitor dosage requirements and response to treatment.

The use of medical therapy other than methimazole may be required if adverse effects develop. For the most part, these alternative medical therapies are for short-term use and are only recommended before use of a more permanent treatment option.

Propranolol and atenolol are the most frequently used β -adrenoceptor blocking agents in hyperthyroid cats. These drugs do not lower the circulating T_4 concentration but are used to symptomatically control

the tachycardia, tachypnea, hypertension, and hyperexcitability associated with hyperthyroidism.

Oral cholecystographic agents (eg, ipodate, iopanoic acid, or diatrizoate meglumine) acutely inhibit conversion of peripheral T_4 to T_3 . In one study of hyperthyroid cats, administration of calcium ipodate normalized serum total T_3 concentrations and produced clinical improvement in >60% of cats treated. Ipodate (308 mg iodine/500 mg calcium ipodate) is no longer marketed in the USA, but iopanoic acid (333 mg iodine/500 mg iopanoic acid) and diatrizoate meglumine (370 mg iodine/mL) have been used anecdotally in hyperthyroid cats at comparable dosages. None of these drugs provides complete resolution of clinical signs or biochemical features associated with hyperthyroidism. In addition, waning of the thyroid-lowering effect is common after 3 mo of therapy with any of these drugs.

A fourth treatment option for cats with hyperthyroidism is the use of a prescription diet with severely restricted iodine levels (Hill's® y/d Feline Thyroid Health™). The basis for using this diet is that iodine is an essential component of both T_4 and T_3 ; without sufficient iodine, the thyroid cannot produce excess thyroid hormones. This is an iodine-deficient diet, containing iodine levels below the minimum daily requirement for adult cats. A major indication for use of this diet for management of feline hyperthyroidism is in cats that are not candidates for definitive treatment of the underlying thyroid tumor(s) with surgery or radioiodine, which remain the treatments of choice. In addition, nutritional management could be considered in cats whose owners are not able to give oral medication or in cats that develop adverse effects from methimazole or carbimazole.

Most hyperthyroid cats exclusively fed this iodine-restricted diet become euthyroid in 8–12 wk. This therapy appears to be more effective in cats with only moderate increases of T_4 than in cats with severe hyperthyroidism. Despite some advantages, nutritional management has disadvantages: 1) feeding this diet can only control (by withholding "fuel" for the thyroid tumor) but not cure hyperthyroidism; 2) cats fed this diet must not eat any other cat diet, table food, or treats, because even tiny amounts of iodine can render the diet ineffective in controlling hyperthyroidism; and 3) relapse will occur if the diet is stopped, so the cat must eat only this diet for the rest of its life.

In dogs, a thyroid tumor causing hyperthyroidism should always be presumed to be a carcinoma until proved otherwise. This is in contrast to the case in hyperthyroid cats, in which thyroid carcinoma is present in <5%.

Treatment of thyroid neoplasia and hyperthyroidism in dogs is dictated by the size of the primary tumor, extent of local tissue invasion, presence of detectable metastasis, and available treatment options. Surgery, chemotherapy, cobalt irradiation,

and use of radioactive iodine therapy, alone or in combination, may be indicated depending on the individual. The hyperthyroid state can be medically controlled by daily administration of an antithyroid drug such as methimazole or carbimazole (5–15 mg/dog, bid), but such treatment will not prevent tumor growth or metastasis. Because canine hyperthyroidism is almost always associated with thyroid carcinoma, the long-term prognosis in these dogs is poor to grave.

THE PARATHYROID GLANDS AND DISORDERS OF CALCIUM METABOLISM

The physiology and disorders of calcium and phosphate metabolism, the function of vitamin D (which acts more like a hormone than a vitamin), and the formation of bone are all tied together in a common system along with two other regulatory hormones—parathyroid hormone (PTH) and calcitonin. Therefore, PTH, calcitonin, and vitamin D are discussed in this chapter together with the associated disorders of calcium homeostasis.

Because aberrant calcium and phosphorus metabolism is reflected in the skeletal system, specific syndromes are presented in that section. (See also DYSTROPHIES ASSOCIATED WITH CALCIUM, PHOSPHORUS, AND VITAMIN D, p 1050.)

CALCIUM PHYSIOLOGY AND CALCIUM-REGULATING HORMONES

The concentration of calcium in the blood of mammals is ~10 mg/dL, with some variation due to species (eg, as much as 13 mg/dL is normal in horses and rabbits), age, dietary intake, and analytic method. Calcium in plasma or serum exists in three forms or fractions: 1) Protein-bound calcium accounts for approximately one-third of the total serum calcium concentration. Protein-bound calcium cannot diffuse through membranes and thus is not usable by tissues. 2) Ionized or free calcium is the physiologically active form that accounts for 50%–60% of total calcium concentration. 3) Complexed or chelated calcium is bound to phosphate, bicarbonate, sulfate, citrate, and lactate and accounts for ~10% of the total calcium concentration.

The calcium ion is an essential structural component of the skeleton and plays a key role in muscle contraction, blood coagulation, enzyme activity, neural excitability, secondary messengers, hormone release, and membrane permeability. Precise control of calcium ion in extracellular fluids is vital to health. Three major hormones (PTH, vitamin D, and calcitonin) interact to maintain a constant concentration of calcium, despite variations in intake and excretion. Other hormones, such as adrenal corticosteroids, estrogens, thyroxine, somatotropin, and glucagon, may also contribute to the maintenance of calcium homeostasis.

Parathyroid Hormone: PTH is synthesized and stored in the chief cells of the parathyroid glands. Synthesis is regulated by a feedback mechanism involving the level of blood calcium (and, to a lesser degree, that of magnesium). In addition, biological amines, peptides, steroids, and several classes of drugs can influence PTH secretion.

The primary function of PTH is to control calcium concentration in the extracellular fluid, which it does by affecting the rate of transfer of calcium into and out of bone, resorption in the kidneys, and absorption from the GI tract. The effect on the kidneys is the most rapid, causing reabsorption of calcium and excretion of phosphorus. The major initial effect on bone is to mobilize calcium from the bone to the extracellular fluid; later, bone formation may be enhanced. PTH does not directly affect calcium absorption from the gut. Its effect is mediated indirectly by regulation of synthesis of the active metabolite of vitamin D.

Vitamin D: The second major hormone involved in the regulation of calcium metabolism and skeletal remodeling is vitamin D, which includes cholecalciferol (vitamin D₃) of animal origin, as well as ergocalciferol (vitamin D₂) of plant origin. Vitamin D has long been considered an essential dietary ingredient, but in several species, including sheep, cattle, horses, pigs, and people, vitamin D can be formed in the skin from a cholesterol metabolite (7-dehydrocholesterol) after exposure to ultraviolet light. In contrast, dogs and cats are not able to synthesize vitamin D₃ adequately in the skin and mainly depend on dietary intake.

Vitamin D must be metabolically activated before it can function physiologically. The biologic actions of vitamin D depend on hydroxylation in the liver and kidneys to form the biologically active 1,25-dihydroxyvitamin D (calcitriol). This conversion in the kidneys is the rate-limiting step in vitamin D metabolism, and it is partly responsible for the delay between vitamin D administration and expression of its biologic effects. PTH and conditions that stimulate its secretion, as well as hypophosphatemia, increase the formation of the active vitamin D metabolite. High circulating phosphorus concentrations have the opposite effect. Under certain conditions, prolactin, estradiol, placental lactogen, and possibly somatotropin have a similar enhancing effect. Increased secretion of these hormones, either alone or in combination, appears to be important in the efficient adaptation to the major calcium demands of pregnancy, lactation, and growth.

Calcitonin: Calcitonin is a 32-amino acid polypeptide hormone secreted by the parafollicular cells (C-cells) of the thyroid gland in mammals and by ultimobranchial tissue in avian and other nonmammalian species. The concentration of calcium ion in extracellular fluids is the principal stimulus for the secretion of calcitonin by C-cells. In hypercalcemia, the rate of secretion of calcitonin is increased greatly by rapid discharge of stored hormone from C-cells into interfollicular capillaries. Hyperplasia of C-cells occurs in response to long-term hypercalcemia. When blood calcium is lowered, the stimulus for calcitonin secretion is diminished. The storage of large amounts of preformed hormone in C-cells and rapid release in response to a moderate rise in circulating calcium probably reflect the physiologic role of calcitonin as an "emergency"

hormone to protect against development of hypercalcemia.

Calcitonin exerts its effects by interacting with target cells, primarily in bone and kidney. The actions of PTH and calcitonin are antagonistic on bone resorption but synergistic on decreasing the renal tubular reabsorption of phosphorus. The hypocalcemic effects of calcitonin are primarily the result of decreased entry of calcium from the skeleton into plasma, resulting from a temporary inhibition of PTH-stimulated bone resorption. The hypophosphatemia develops from a direct action of calcitonin, which increases the rate of movement of phosphorus out of plasma into soft tissue and bone and inhibits the bone resorption stimulated by PTH and other factors. Although many effects have been attributed to calcitonin at pharmacologic doses, their physiologic relevance is suspect. Physiologically, calcitonin has at best a minor role in regulating blood concentrations of calcium. Neither chronically high (eg, as in animals with medullary thyroid cancer) nor chronically low (eg, as in animals after surgical removal of the thyroid gland) circulating calcitonin concentrations result in any changes in the serum calcium concentration.

HYPERCALCEMIA IN DOGS AND CATS

Hypercalcemia can be toxic to all body tissues, but major deleterious effects occur in the kidneys, nervous system, and cardiovascular system. The development of clinical signs from hypercalcemia depends on the magnitude of the calcium increase, how quickly it develops, and its duration. Serum total calcium concentrations of ≤ 15 mg/dL may not be associated with systemic signs, but serum concentrations of > 18 mg/dL are often associated with severe, life-threatening signs. Polydipsia and polyuria are the most common signs of hypercalcemia and result from an impaired ability to concentrate urine and a direct stimulation of the thirst center. Anorexia, vomiting, and constipation can also develop as a result of decreased excitability of GI smooth muscle. Decreased neuromuscular excitability may lead to signs of generalized weakness, depression, muscle twitching, and seizures.

There are many potential causes of hypercalcemia (see TABLE 1). In hypercalcemic dogs, neoplasia (lymphosarcoma) is

TABLE 1 CAUSES OF HYPERCALCEMIA IN DOGS AND CATS**Acromegaly**

Apocrine gland adenocarcinoma

Carcinoma (squamous cell, mammary, bronchogenic, prostate, thyroid, nasal cavity)

Chronic and acute renal failure

Factitious: lipemia, postprandial, young dog (<6 mo old)

Granulomatous disease

Hematologic malignancies (bone marrow osteolysis)

Humoral hypercalcemia

Hypercalcemia of malignancy

Hyperthyroidism

Hypervitaminosis D: iatrogenic, plants (eg, day-blooming jessamine), rodenticides, antipsoriatic cream

Hypoadrenocorticism (Addison disease)

Iatrogenic disorders: excess calcium or oral phosphate binders

Idiopathic hypercalcemia of cats

Laboratory error

Lymphoma (lymphosarcoma)

Metastatic or primary bone neoplasia

Multiple myeloma

Myeloproliferative disease (rare)

Primary hyperparathyroidism

Skeletal lesions: osteomyelitis, hypertrophic osteodystrophy

the most common cause, followed by hypoadrenocorticism, primary hyperparathyroidism, and chronic renal failure. Other causes of hypercalcemia in dogs, in an approximate incidence order as seen in practice, include vitamin D toxicosis, apocrine gland carcinoma of the anal sac, multiple myeloma, carcinomas (lung, mammary, nasal, pancreas, thymus, thyroid, vaginal, and testicular), and finally, certain granulomatous diseases (blastomycosis, histoplasmosis, schistosomiasis). Approximately 70% of hypercalcemic dogs are also azotemic. However, azotemia is uncommon in dogs with hyperparathyroidism.

In cats, idiopathic hypercalcemia appears to be the most frequent cause of a high total calcium concentration, followed by renal failure and malignancy. Ionized hypercalcemia in conjunction with chronic renal failure is more common in cats than dogs. The most common tumor types associated with hypercalcemia of malignancy in cats

are lymphoma and squamous cell carcinoma. Primary hyperparathyroidism occurs in cats but not as frequently as in dogs. Rarely, hypercalcemia is seen in cats with hyperthyroidism.

Hypercalcemia of Malignancy

Malignancy is the most common cause of persistent hypercalcemia in dogs and is a common cause in cats. In hypercalcemia of malignancy, the hypercalcemia primarily results from increased osteoclastic bone resorption, but increased renal tubular resorption and increased intestinal absorption may also play a role. Factors that may be produced by tumors and result in humoral hypercalcemia of malignancy include PTH, PTH-related protein (PTHrP), transforming growth factor, 1,25-dihydroxyvitamin D, prostaglandin E₂, osteoclast-activating factor, and other cytokines (interleukin-1,

interleukin-2, and γ -interferon). Although many tumors have been associated with hypercalcemia in people, malignancy-associated hypercalcemia in dogs has been most commonly linked to lymphoma, adenocarcinoma of the apocrine glands of the anal sac, and multiple myeloma. Other tumors (thymoma, squamous cell carcinoma, nasal carcinoma, hemangiosarcoma, and undifferentiated adenocarcinoma) have also been associated with hypercalcemia in dogs. In cats, humoral hypercalcemia of malignancy occurs less frequently than in dogs but has been reported with squamous cell carcinoma, multiple myeloma, and lymphoproliferative diseases.

Lymphoma (Lymphosarcoma): The most common tumor associated with hypercalcemia in dogs, lymphoma is also one of the tumors associated with hypercalcemia in cats. The pathogenesis of the hypercalcemia may involve two general mechanisms. One is local elaboration of an osteolytic factor that induces resorption of bone and mobilization of calcium when the bone marrow is infiltrated by tumor cells. The other, probably more important, is humoral hypercalcemia in which neoplastic cells produce a humoral factor that acts at a distance from the tumor. As evidence for secretion of a humoral substance by tumor cells, increased bone resorption, phosphaturia, and urinary excretion of cyclic adenosine monophosphate (cAMP) have been documented in dogs with lymphoma. Serum concentrations of both PTH and 1,25-dihydroxyvitamin D are generally low in these dogs, but PTHrP has been detected in dogs with lymphoma (see TABLE 2).

Of dogs with lymphoma, 10%–40% have concurrent hypercalcemia, and a large number of these cases also have the mediastinal form of lymphoma. Although detectable lymphadenopathy is usually present, hypercalcemia may be the first abnormality noted. A thorough physical examination, together with thoracic and abdominal radiographs, abdominal ultrasonography, multiple lymph node aspirates or biopsies, and multiple bone marrow aspirates may be necessary to make the diagnosis. Treatment with glucocorticoids (eg, prednisone) lowers serum calcium concentrations; however, steroids are lympholytic and make identification of lymphoma difficult.

Although remission rates in dogs with lymphoma and hypercalcemia are not statisti-

cally different from those without hypercalcemia, survival times are considerably less, indicating that hypercalcemic lymphomas have a poorer prognosis. (See also CANINE MALIGNANT LYMPHOMA, p 40, and FELINE LEUKEMIA VIRUS AND RELATED DISEASES, p 790.)

Adenocarcinoma of the Apocrine Glands of the Anal Sac:

This tumor usually occurs in older dogs of either sex, with hypercalcemia developing in ~90% of cases. Humoral mechanisms are most likely responsible for the hypercalcemia, because a PTH-like protein has been identified from tumor tissue in dogs. This tumor is usually malignant and has metastasized to regional lymph nodes by the time of diagnosis. Surgical resection is associated with reduction of serum calcium. Failure to remove all of the tumor or recurrence of the tumor usually results in recurrence of hypercalcemia. Despite surgical excision, radiation, and various chemotherapy protocols, the tumor usually recurs within a few months, and prognosis is poor.

Multiple Myeloma: This malignancy in dogs and cats has been associated with hypercalcemia in 10%–15% of cases. The pathogenesis of the hypercalcemia is most likely multifactorial. Myeloma cells are known to produce osteoclast-activating factor in people, which may partially account for the hypercalcemia. The presence of extensive bony lysis may also contribute to the increased serum calcium. Although serum protein concentration is usually increased in multiple myeloma, increased protein binding of calcium rarely accounts for the hypercalcemia. Treatment of multiple myeloma with chemotherapy has been associated with longterm survival, but the presence of associated hypercalcemia, light chain proteinuria, and extensive bony lesions is associated with a shorter survival time.

Primary Hyperparathyroidism

Primary hyperparathyroidism results from excessive secretion of PTH by one or more abnormal (usually neoplastic) parathyroid glands. It is relatively rare in dogs and cats. Persistent hypercalcemia is characteristic. Solitary adenoma of the external or internal parathyroid gland is the most common cause of primary hyperparathyroidism, whereas parathyroid carcinoma has been infrequently reported. Hyperplasia of one or all four parathyroid glands has been described but is very rare.

Clinical Findings: Polydipsia, polyuria, anorexia, lethargy, and depression are the most common signs, but many animals with milder degrees of hypercalcemia may be asymptomatic. Constipation, weakness, shivering, twitching, vomiting, stiff gait, and facial swelling are less often reported.

Diagnosis: Hypercalcemia, normal to low serum phosphorus, and low urine specific gravity are the most consistent findings. Azotemia commonly develops as a consequence of moderate to severe hypercalcemia. In hypercalcemic animals that still have relatively normal renal function (normal serum creatinine and urea nitrogen concentrations), determination of serum PTH is helpful in diagnosis. The finding of high-normal to high serum PTH concentrations in hypercalcemic animals with normal renal function is consistent with primary hyperparathyroidism, whereas the finding of low PTH concentrations is consistent with hypercalcemia of malignancy. Ultrasonography of the parathyroid glands is a useful diagnostic technique but requires an ultrasound unit with a high frequency transducer in the 7.5- to 10-MHz range to achieve the necessary resolution. Normal parathyroid glands are not always visualized on ultrasonographic examination, but enlarged parathyroid glands appear as rounded hypoechoic or anechoic structures associated with the thyroid gland. Finding a solitary parathyroid gland in a hypercalcemic animal supports a diagnosis of primary hyperparathyroidism, whereas finding multiple enlarged parathyroid glands is compatible with secondary hyperparathyroidism. Ultrasound cannot distinguish a parathyroid adenoma from an adenocarcinoma. Exploratory surgery of the cervical region is a diagnostic alternative if no other cause of hypercalcemia can be determined.

Treatment: The most cost-effective and expedient approach to management is surgical exploration of the neck and removal of the abnormal parathyroid tissue. Percutaneous ultrasound-guided chemical (ethanol) or heat ablation of the parathyroid has been used and may be a feasible alternative to surgery in some cases. Attempts to lower the serum calcium concentration with IV fluids (saline) and furosemide before surgery or ablation may be beneficial (*see* p 568). No medical

treatment exists for primary hyperparathyroidism, although treatment for hypercalcemia can be done if surgery is declined.

Hypercalcemia Associated with Hypoadrenocorticism

Mild hypercalcemia (≤ 15 mg/dL) has been reported in as many as 30% of dogs with hypoadrenocorticism (Addison disease). Multiple factors may result in the hypercalcemia, including increased calcium citrate (complexed calcium), hemoconcentration (relative increase), increased renal resorption of calcium, and increased affinity of serum proteins for calcium. Although total serum calcium concentrations may be increased, the ionized fraction usually is normal. The hypercalcemia resolves quickly with successful treatment for hypoadrenocorticism.

Renal Failure

In cats, chronic renal failure (usually associated with chronic interstitial nephritis) appears to be the most common cause of hypercalcemia. The pathogenesis of the hypercalcemia is not known, but the ionized calcium concentrations remain normal. In dogs, renal failure caused by familial renal disease is more often associated with hypercalcemia than are other forms of chronic renal failure. Hypercalcemia may also be present in acute renal failure during the polyuric phase, but this is rare.

Idiopathic Hypercalcemia of Cats

A syndrome in young to middle-aged cats, first described in the early 1990s, involves hypercalcemia that occurs without obvious explanation. It has been suggested that the feeding of acidifying, magnesium-restricted diets predisposes cats to idiopathic hypercalcemia. Another plausible hypothesis is that excessive dietary vitamin D content in some cat foods may contribute to this condition. Total serum calcium is increased for months to years, often without obvious clinical signs in the early stages. Ionized calcium is increased, sometimes out of proportion to the increase in total serum calcium. Longhaired cats may be over-represented; most are not azotemic at initial diagnosis but may later develop azotemia. PTH levels are either low or remain within the reference range, PTHrP is not detectable, and 25-hydroxyvitamin D and calcitriol levels are within normal limits.

Intensive treatment for idiopathic hypercalcemia is rarely indicated, because hypercalcemia has developed gradually and is relatively longstanding, and dramatic clinical signs are usually absent. Most cats can be treated as outpatients with dietary change either alone or in combination with drug therapy.

Diet modification is recommended as a first-line treatment. If an acidifying diet is being fed, it should be discontinued. A number of different diets have been recommended, including high-fiber diets, kidney diets, or diets developed to prevent calcium oxalate urolithiasis. ● Others recommend feeding canned diets with a composition similar to what cats would eat in the wild (ie, 40%–60% of calories as protein, 30%–50% fat, and <15% carbohydrates). No matter what type of diet is chosen, it is best to feed a wet-only diet to promote urinary dilution and lessen the chance of calcium oxalate stone formation. Administration of prednisone results in long-term decreases in ionized and total calcium concentrations in some cats.

If normocalcemia has not been restored after a dietary feeding trial of 6–8 wk, treatment with glucocorticosteroids or bisphosphonates should be considered. Prednisone is given orally at 5 mg/cat/day for 1 mo before reevaluation. If the serum ionized calcium concentration is normal, this dose is continued for several months. If the ionized calcium value is still increased, the dosage is gradually increased to 10–20 mg/cat/day as needed to restore normocalcemia. Alternatively, treatment with the bisphosphonate alendronate can be instituted, starting at 10 mg orally once weekly; the dosage can be increased to 20–30 mg per week, as needed. It is extremely important to administer alendronate after a 12-hour fast, because food significantly reduces drug absorption; the fast should also be continued for at least 2 hr after alendronate administration. Erosive esophagitis is a known adverse effect of oral bisphosphonates in human patients. Although the risk of development of esophagitis in cats is unknown, the owner can give 5–6 mL of water to the cat with a dosing syringe immediately after administration of the alendronate; a small amount of butter applied to the cat's lips may increase licking and salivation and promote the transit of the pill to the stomach. The long-term safety and efficacy of oral

bisphosphonates in cats are currently unknown, but alendronate appears to be relatively safe for use in cats.

Osteolytic Lesions

Hypercalcemia resulting from tumor invasion or metastasis to bone develops very rarely in animals. Primary bone tumors (eg, osteosarcoma) and neoplastic cells within the bone marrow (eg, multiple myeloma) may occasionally produce hypercalcemia. The mechanisms whereby bony neoplasia may produce hypercalcemia include mechanical destruction by the infiltrating cells (as occurs with metastatic tumors and osteosarcoma) and local production of osteoclast-activating factor (as occurs with multiple myeloma). Bacterial and mycotic osteomyelitis can also occasionally produce hypercalcemia. The hypercalcemia may result from direct bone lysis or may be mediated by bone-resorbing factors (eg, prostaglandins, osteoclast-activating factor).

Other Causes of Hypercalcemia

Hypervitaminosis D: Vitamin D toxicity refers to the effects of excessive intake of bioactive metabolites of vitamin D. Toxicity caused by ergocalciferol (vitamin D₂) or cholecalciferol (vitamin D₃) can occur from excessive dietary supplementation (most common in young growing dogs) for treatment of primary hypoparathyroidism. Both of these forms of vitamin D have a slow onset of action and prolonged duration, making correct dosing difficult. Treatment is directed at discontinuing the supplement or decreasing the dose of vitamin D. Toxicity caused by calcitriol (1,25-dihydroxyvitamin D), the most active form of vitamin D, most commonly occurs after treatment of primary hypoparathyroidism. Calcitriol is also the active ingredient in some rodenticides, but these products are no longer widely available in the USA.

In dogs, a newly emerging cause of vitamin D toxicity is ingestion of the calcitriol analogue, calcipotriene (also called tacalcitol), which is a topical preparation used to treat psoriasis in people. Calcipotriene toxicity in dogs can result in severe metastatic calcification in the GI tract, kidney, and other tissues; the condition is commonly fatal.

Houseplants: Certain house plants (eg, *Cestrum diurnum* [the day-blooming jessamine], *Solanum malacoxylon*, *Trisetum flavescens*) may contain a

substance similar to vitamin D that may cause hypercalcemia when ingested.

Granulomatous Disease: Hypercalcemia associated with granulomatous disease arises from an alteration of endogenous vitamin D metabolism. Macrophages activated in response to granulomatous inflammation can develop the capability to convert vitamin D precursors to the active form of vitamin D (ie, calcitriol) in an unregulated manner. A similar alteration of vitamin D metabolism in people may explain hypercalcemia in non-Hodgkin lymphoma, Hodgkin lymphoma, and lymphomatoid granulomatosis.

In companion animals, hypercalcemia related to granulomatous disease has been reported in disseminated histoplasmosis, blastomycosis, coccidiomycosis, tuberculosis, and schistosomiasis. Animals with hypercalcemia related to granulomatous disease are expected to have high serum concentrations of ionized calcium and low values for PTH. Serum calcium concentrations return to normal with treatment (ie, antifungal drugs and surgical removal).

Diagnostic Tests for Hypercalcemia

The first step in investigating hypercalcemia is to exclude the possibility of spurious test results. Ideally, a fasting sample should be resubmitted, because sample conditions (lipemia or hemolysis) can artifactually increase total serum calcium values reported by colorimetric analyzers.

If the hypercalcemia is repeatable, ionized calcium should be measured, because it is a better reflection of the biologically active form of calcium. Total or adjusted total calcium are not reliable measurements of calcium status.

In some animals with persistent ionized hypercalcemia, identification of the cause will be obvious after analysis of history (vitamin D exposure, drugs, ingestion of houseplants) and physical examination findings (masses, organomegaly, cancer, or granulomatous disease). In other animals, the cause will not be obvious, and hematology, serum biochemistry, body cavity imaging, cytology, and histopathology may be required. In many animals, use of specialized assays, including measurement of PTH, PTHrP, and/or vitamin D is necessary to confirm a diagnosis.

If lymphadenopathy is present, a lymph node aspirate or biopsy should be performed to check for lymphosarcoma. If a tumor of the anal sac is found, surgical removal should be attempted. Any other neoplasm

should be treated by surgical removal, chemotherapy, or radiation therapy. Problems may arise when hypercalcemia is complicated by renal failure, or when primary hyperparathyroidism or occult malignancy is suspected. In these cases, the cause of hypercalcemia may not be obvious, and additional steps must be taken to differentiate primary hyperparathyroidism from occult tumors causing hypercalcemia.

Ionized Calcium: Because the ionized calcium fraction is the biologically active form and the component that regulates production of PTH, measurement of the ionized calcium concentration is the first step in evaluation of calcium abnormalities. If ionized calcium is normal, even if total calcium is increased, no further diagnostics are warranted. If ionized calcium is increased, then PTH and PTHrP determinations should be considered if there are no obvious causes of the hypercalcemia.

In many cases of hyper- or hypocalcemia, the total calcium and ionized calcium concentrations are highly correlated (see TABLE 2). However, in some instances the concentration of total calcium does not reflect the status of ionized calcium. In dogs with renal failure, total calcium is high, but ionized calcium is normal or surprisingly low. In this situation, the total calcium increase seems to reflect increased amounts of calcium complexed to anions, an effect that would not be identified in albumin-adjusted calcium concentrations.

Ionized calcium is measured in serum or heparinized plasma by an instrument using a calcium-specific electrode. Serum ionized calcium may be falsely high when collected in serum separator tubes. There is simultaneous measurement of pH, which affects the binding of calcium to protein in an inverse manner. An increase in pH is accompanied by a decrease in ionized calcium. Serum samples collected and handled in anaerobic conditions provide the best results with ionized calcium assays. Samples collected in EDTA tubes are unsuitable, because EDTA binds available ionized calcium.

Parathyroid Hormone: Assay of PTH is the next step in evaluation of calcium abnormalities, once hypercalcemia has been confirmed by measurement of the ionized calcium concentration. Evaluation of PTH can reveal whether the parathyroid glands are responding appropriately to the change in calcium concentration or whether inappropriate production of PTH is the cause of the disorder. If calcium metabolism is normal, small increases of ionized

calcium inhibit secretion of PTH and small decreases of ionized calcium prompt release of PTH.

Serum or plasma PTH determinations are very useful in evaluation of hypercalcemic dogs and cats. Animals with primary hyperparathyroidism should have mid-normal to high concentrations of PTH, whereas those with most other forms of hypercalcemia have low PTH concentrations (see TABLE 2).

Parathyroid Hormone-related

Protein (PTHrP): Hypercalcemia associated with nonparathyroid neoplasia is often caused by production of a humoral factor, PTHrP, that has parathyroid hormone-like bioactivity. Since its discovery in the 1980s, PTHrP has been found to be associated with a variety of tumors that cause hypercalcemia of malignancy in people.

Assay of PTHrP can be used to confirm hypercalcemia of malignancy (see TABLE 2). There is a relatively high prevalence of positive results in dogs with apocrine gland adenocarcinoma of the anal sac, lymphoma, or other miscellaneous tumors. However, humoral hypercalcemia of malignancy always remains a differential diagnosis in a hypercalcemic dog with a low PTH and a normal or negative PTHrP. In cats, high PTHrP is also consistent with humoral hypercalcemia of malignancy, especially in cats with carcinoma.

Vitamin D Metabolites (Calcidiol and Calcitriol):

Because metabolites of vitamin D are chemically identical in all species, radioimmunoassays developed for use in people are satisfactory for measurement in animals. Calcidiol (25-hydroxyvitamin D) concentration is a good indicator of vitamin D ingestion and can be used to diagnose hypervitaminosis D.

Vitamin D metabolites resulting from the ingestion of cholecalciferol present in rodenticides can be measured with the calcidiol assay. Toxicity from ingestion of cholecalciferol or ergocalciferol would be detected by an increase of calcidiol that may persist for weeks after exposure. Assay of calcidiol also may be used to confirm toxicity from ingestion of rodenticides that contain vitamin D₃ as the active ingredient.

Calcipotriene, the vitamin D analogue found in antipsoriasis creams, is not measured with the assay for calcidiol but would be detected in the assay for calcitriol. Unfortunately, the calcitriol assay is not widely available for clinical use.

See TABLE 2 for a summary of the anticipated PTH, ionized calcium, and PTHrP values in the various disorders causing hypercalcemia. Generally, the PTH level is normal to high with primary, secondary, or tertiary hyperparathyroidism. The PTH level is low with other causes of hypercalcemia (eg, hypervitaminosis D, malignancy associated, renal failure, hypoadrenocorticism).

Treatment of Hypercalcemia

A mild degree of hypercalcemia may not be immediately dangerous; there is time to establish a definitive diagnosis before starting treatment. In animals with severe clinical signs associated with hypercalcemia, diagnostic and therapeutic efforts may proceed concurrently. No single treatment protocol is consistently effective for all causes of hypercalcemia; each animal must be approached individually, and the cause of the hypercalcemia must be determined. The definitive treatment of hypercalcemia is treating or removing the underlying cause. Unfortunately, the cause may not be apparent, and supportive measures must be taken to decrease the serum calcium concentration. The goal of all supportive treatment is to enhance urinary excretion of calcium and to prevent calcium resorption from bone.

Fluid Therapy: Volume expansion with 0.9% saline, ~100–125 mL/kg/day, IV, decreases hemoconcentration and increases renal calcium loss by improving glomerular filtration rate and sodium excretion, which results in less calcium reabsorption.

Diuretics: Loop diuretics such as furosemide (2–4 mg/kg, bid-tid) increase calcium excretion by the kidneys; however, higher dosages may be needed. If dehydration is present, fluid therapy should be instituted first because volume contraction and further hemoconcentration may worsen the hypercalcemia. Thiazide diuretics are contraindicated in hypercalcemia, because these agents decrease calcium excretion by the kidneys and worsen the hypercalcemia.

Glucocorticoids: Glucocorticoids such as prednisone (1–2 mg/kg, bid) or dexamethasone (0.1–0.2 mg, bid) provide a second tier of treatment for hypercalcemic cases that do not respond adequately to IV fluids and furosemide. They reduce bone resorption of calcium, reduce

TABLE 2

CHARACTERISTIC LABORATORY ABNORMALITIES ASSOCIATED WITH COMMON CAUSES OF HYPERCALCEMIA

Diagnosis	Total Calcium	Ionized Calcium	Intact PTH	1,25-Dihydroxy-vitamin D	Phosphorus	PTHrP
Primary hyperthyroidism	High	High	Normal to high	Normal	Normal to low	Negative
Malignant hypercalcemia	High	High	Low to low-normal	Low to normal	Normal to low	Positive (sometimes)
Hypoadrenocorticism (Addison disease)	Low, normal, or high	Normal	Normal	Normal	Normal to high	Negative
Chronic renal failure	Low, normal, or high	Normal to low	Normal to high	Low to normal	High	Negative
Hypervitaminosis D (calcitriol or calcitriol analogue)	High	High	Low to low-normal	Low to normal	Normal to high	Negative
Hypervitaminosis D (D ₂ or D ₃ toxicity)	High	High	Low to low-normal	High	Normal to high	Negative
Granulomatous disease	High	High	Low to low-normal	Low to normal	Normal to high	Negative
Idiopathic hypercalcemia of cats	High	High	Normal	Normal	Normal	Negative

intestinal calcium absorption, increase renal calcium excretion, and are cytotoxic to malignant lymphocytes, leading to substantial reduction in serum calcium concentration in animals with hypercalcemia secondary to lymphoma, myeloma, hypervitaminosis D, granulomatous disease, and hypoadrenocorticism.

However, use of glucocorticoids may make definitive diagnosis of the underlying cause of the hypercalcemia difficult. This is especially true with lymphosarcoma, because steroids are lymphocytolytic and may alter lymph node architecture and patterns of lymphocyte infiltration in bone marrow.

Miscellaneous Agents: The third tier of treatment is to add a bisphosphonate, mithramycin, or calcitonin for more long-term control of hypercalcemia. Bisphosphonates assist in lowering serum calcium by reducing the number and action

of osteoclasts. Pamidronate is the most commonly used parenteral drug; the recommended dosage in dogs is 1–2 mg/kg, IV, mixed in 0.9% saline given throughout 2 hr. In cats, alendronate is the most common oral preparation used to control idiopathic hypercalcemia. Adequate hydration is essential when treating with bisphosphonates, because these drugs may cause nephrotoxicity, especially at higher doses. The drug can be repeated in 3–4 wk if needed.

Mithramycin, an inhibitor of RNA synthesis in osteoclasts, is an effective treatment for hypercalcemia; the dosage is 25 mcg/kg, IV, given throughout 4–6 hr. A single dose is usually successful in normalizing the serum calcium concentration; effects last from a few days to several weeks. Adverse effects may include thrombocytopenia, nephrotoxicity, and hepatotoxicity but are unlikely after a single dose. However, this drug must be used with extreme caution.

Calcitonin inhibits bone resorption by inhibiting the activity and formation of bone osteoclasts. The dose of calcitonin is 4–8 U/kg, SC, bid-tid. Calcitonin is the most rapidly acting hypocalcemia agent, causing serum calcium to decrease within a few hours after administration. Its effect is rather transient, however, and the maximal reduction in calcium is not as great as that seen with bisphosphonates or mithramycin.

Calcimimetics, a new class of drugs, are calcium-sensing receptor agonists. The mostly commonly used drug of this class is cinacalcet. By interacting with the calcium-sensing receptors in the parathyroid glands, these drugs reduce the secretion of PTH and can effectively suppress circulating PTH in all forms of hyperparathyroidism. They have become a major therapy for secondary hyperparathyroidism associated with renal failure as well as for treatment of primary hyperparathyroidism.

HYPERCALCEMIA IN HORSES

Like dogs and cats, horses can develop hypercalcemia due to several disorders, including chronic renal failure, vitamin D toxicosis, and primary hyperparathyroidism. The most common cause of hypercalcemia in horses is chronic renal failure. The equine kidney is important in the excretion of calcium; therefore, impaired renal calcium excretion associated with normal intestinal calcium absorption may explain the hypercalcemia found in these horses.

Humoral hypercalcemia of malignancy has been reported to be associated with gastric squamous cell carcinoma, adrenocortical carcinoma, squamous cell carcinoma of the vulva, lymphosarcoma, and ameloblastoma. These horses have hypercalcemia, hypophosphatemia, increased serum concentrations of PTHrP, and decreased serum concentrations of PTH.

Intoxication with ergocalciferol or cholecalciferol has been reported in horses. Ingestion of plants containing 1,25-dihydroxyvitamin D-like compounds (*Solanum malacoxylon*, *S. sodomaeum*, *Cestrum diurnum*, *Trisetum flavescens*) causes typical clinical signs of vitamin D intoxication, including hypercalcemia.

Primary hyperparathyroidism is a rare disorder in ponies and horses. As in dogs and cats, hypercalcemia, hypophosphatemia, and high serum PTH concentrations

are reported in horses with the disorder. Additional tests to exclude other conditions associated with hypercalcemia may include measurement of PTHrP and vitamin D metabolite concentrations.

As in other species, the definitive treatment of equine hypercalcemia is treating or removing the underlying cause. Unfortunately, the cause may not be readily apparent, and supportive measures (eg, fluid therapy, diuretics, and/or glucocorticoids) must sometimes be used to enhance urinary excretion of calcium and to decrease the serum calcium concentration.

HYPOCALCEMIA IN DOGS AND CATS

Hypocalcemia causes the major clinical manifestations of hypoparathyroidism by increasing the excitability of both the central and peripheral nervous systems. Peripheral neuromuscular signs classically include muscle tremors, twitches, and tetany. Generalized convulsions, resembling those of an idiopathic seizure disorder, are the predominant CNS manifestation of hypoparathyroidism.

Hypoparathyroidism

Hypoparathyroidism is a metabolic disorder characterized by hypocalcemia and hyperphosphatemia and either transient or permanent PTH insufficiency. The spontaneous disorder is uncommon in dogs and rarely reported in cats. Iatrogenic injury or removal of the parathyroid glands during thyroidectomy for treatment of hyperthyroidism is the most common cause in cats. Postoperative hypoparathyroidism secondary to parathyroidectomy for parathyroid tumor may occur because of atrophy of the remaining glands in either dogs or cats.

Diagnosis: Diagnosis is based on history, clinical signs, laboratory evidence of hypocalcemia and hyperphosphatemia, and exclusion of other causes of hypocalcemia (eg, hypoproteinemia, malabsorption, pancreatitis, renal failure). If idiopathic hypoparathyroidism is suspected, it should be confirmed by histologic examination of the parathyroid glands and documentation of parathyroid atrophy or destruction. Because the parathyroid glands are not grossly evident in animals with hypoparathyroidism, a unilateral

thyroidectomy should be performed to ensure that adequate parathyroid tissue is available for examination. Determination of serum PTH concentrations might be helpful in the diagnosis of idiopathic hypoparathyroidism and may thereby eliminate the need for cervical exploratory surgery and histologic verification.

Treatment: Treatment is directed at restoring the serum calcium concentration to the low end of the normal range. This should include use of calcium supplements and vitamin D for either iatrogenic or idiopathic forms of hypoparathyroidism. If hypocalcemic tetany or seizures are present, calcium should be administered IV immediately. For maintenance of normocalcemia, oral calcium should be administered together with a vitamin D preparation.

The major complication associated with treatment of hypoparathyroidism is hypercalcemia, which develops as a consequence of overtreatment with calcium and vitamin D. If this occurs, calcium and vitamin D therapy should be temporarily discontinued; saline and furosemide should be administered if hypercalcemia is severe (*see* p 568). With idiopathic hypoparathyroidism, longterm management with vitamin D (with or without calcium supplementation) is necessary. In contrast, with iatrogenic hypoparathyroidism, spontaneous recovery of parathyroid function or accommodation of calcium-regulating mechanisms to the absence of PTH may occur weeks to months after surgery.

Other Causes of Hypocalcemia

Renal Disease: Chronic renal failure is probably the most frequently encountered cause of hypocalcemia. Azotemia and hyperphosphatemia result from decreased glomerular filtration rates. Mechanisms of hypocalcemia include decreased renal tubular calcium resorption, hyperphosphatemia, decreased formation of 1,25-dihydroxyvitamin D, hypoalbuminemia, and chelation of calcium with oxalate. Parathyroid gland hyperplasia occurs to maintain serum calcium in normal ranges. High PTH concentrations result in increased bone resorption. The hypocalcemia associated with renal failure, however, is rarely clinically significant (ie, muscle tremors, twitches, tetany, or convulsions do not develop). In addition, most animals with chronic renal failure have normal serum calcium concentrations. Treatment

should be directed at lowering the serum phosphate concentrations by dietary restriction of phosphorus and intestinal phosphate binders. (*See also* RENAL DYSFUNCTION IN SMALL ANIMALS, p 1512.)

Hypoproteinemia: Animals with hypoalbuminemia may be hypocalcemic because of a decrease in the protein-bound fraction of calcium, but the ionized calcium fraction may remain normal. Clinical signs of hypocalcemia do not usually develop. The magnitude of hypocalcemia is usually mild.

Pancreatitis: When hypocalcemia occurs in animals with pancreatitis (*see* p 407), it is usually mild and subclinical. The exact mechanism is unknown, but a commonly accepted theory is that calcium is precipitated in the form of insoluble soaps through saponification of peripancreatic fatty acids formed subsequent to release of the pancreatic enzyme lipase. More recent work suggests that hypocalcemia may result from a shift of calcium into soft tissues, especially muscle.

Puerperal Tetany: Puerperal tetany (eclampsia, *see* p 992) is an acute, life-threatening disease caused by an extreme fall in circulating calcium concentrations in the lactating bitch or queen. Severe hypocalcemia associated with eclampsia develops during the nursing period (several days to several weeks postpartum). The pathophysiology remains poorly understood but appears to result from an imbalance between the rate of inflow (eg, bone resorption, GI absorption) and outflow (eg, mammary gland) from the extracellular calcium pool. Treatment consists of slow IV administration of calcium (*see* below) and weaning of the litter, if possible.

Phosphate Enema Toxicity: Hypertonic sodium phosphate (eg, Fleet®) enemas may result in severe biochemical abnormalities, especially when administered to dehydrated cats with colonic atony and mucosal disruption. Hypernatremia and hyperphosphatemia result from the colonic absorption of sodium and phosphate from the enema solution, as well as transfer of intravascular water to the colonic lumen (because of the hypertonic enema). Hyperphosphatemia leads to precipitation of serum calcium with resultant hypocalcemia. Clinical signs of phosphate enema toxicosis, which result from these electrolyte and fluid alterations, include shock and neuromuscular irritability. Treatment consists of IV volume expansion with an electrolyte-poor solu-

tion (eg, 5% dextrose in water), as well as treatment of hypocalcemia (*see* below).

Chelating Agents: EDTA (ethylenediaminetetraacetic acid), citrated blood, and oxalic acid (a metabolite of the ethylene glycol in antifreeze) all complex calcium and can cause hypocalcemia. Animals with ethylene glycol intoxication (*see* p 3046) also have severe metabolic acidosis, azotemia, and hyperphosphatemia from the oliguric renal failure, which results from calcium oxalate crystal precipitation in the renal tubules.

Treatment of Hypocalcemia

The definitive treatment for hypocalcemia is to eliminate the underlying cause. Supportive measures, including the following, to restore normocalcemia can be administered pending the diagnosis.

Parenteral Calcium: Hypocalcemic tetany or convulsions are indications for the immediate IV administration of 10% calcium gluconate (1–1.5 mL/kg), which should be slowly infused throughout a 10-min period. Close monitoring is mandatory; if bradycardia or shortening of the QT interval occurs, the IV infusion should be slowed or temporarily discontinued.

Once the life-threatening signs of hypocalcemia have been controlled, calcium can be added to the IV fluids and administered as a slow continuous infusion (eg, 10% calcium gluconate, 2.5 mL/kg every 6–8 hr). The rate of calcium administration should be adjusted as necessary to maintain a normal serum calcium concentration, and the infusion should be continued for as long as necessary to prevent recurrence of hypocalcemia. Although this continuous calcium infusion will maintain normocalcemia, its effects are short-lived; hypocalcemia will recur within hours of stopping the infusion unless other treatment is given.

Oral Calcium: Oral calcium supplementation may be beneficial in some conditions (eg, hypoparathyroidism, puerperal tetany). The daily requirements are 1–4 g for dogs and 0.5–1 g for cats. The daily dose of calcium should be based on the amount of elemental calcium in the product, rather than on the weight of the calcium salt.

Vitamin D: In some conditions, vitamin D supplementation is necessary to increase calcium absorption from the intestines. There are three main

preparations of vitamin D available, including vitamin D₂ (ergocalciferol), dihydrotachysterol, and 1,25-dihydroxyvitamin D (calcitriol). The dosage and duration of response of these drugs depends on the form used. For vitamin D₂, the initial required dosages are generally 4,000–6,000 IU/kg/day, whereas the final dosages required to maintain normocalcemia range from 1,000–2,000 IU/kg, once daily to once weekly. For dihydrotachysterol, initial loading dosages of 0.02–0.03 mg/kg/day are usually administered, with maintenance dosages of 0.01–0.02 mg/kg given every 24–48 hr. For 1,25-dihydroxyvitamin D, a daily dosage of 0.025–0.06 mcg/kg (25–60 ng/kg/day) is generally required. Because the available capsule sizes (250 and 500 ng) are not well formulated for the small body size of most dogs and cats, and these capsules cannot be readily divided, it may be desirable to contact a pharmacist who can reformulate these products to a size that is appropriate for the individual pet. With all vitamin D preparations and dosage regimens, the development of iatrogenic hypercalcemia is a common complication of treatment.

HYPOCALCEMIC DISORDERS OF HORSES

Primary hypoparathyroidism is a rare but well documented disorder in horses. Affected horses have clinical signs consistent with hypocalcemia (ataxia, seizures, hyperexcitability, synchronous diaphragmatic flutter, tachycardia, tachypnea, muscle fasciculation, and ileus). As in other species, the diagnosis is based on the finding of low serum concentrations of calcium and PTH with high levels of phosphorus. As described above, treatment with intravenous and subsequently oral calcium combined with large doses of vitamin D should result in the remission of clinical signs associated with hypoparathyroidism.

Sepsis is one of the most common causes of hypocalcemia in horses admitted to veterinary hospitals. Total and ionized hypocalcemia are common in horses with severe GI disease and sepsis. Hypocalcemia with inappropriately low serum PTH concentrations also has been reported in foals. The underlying cause of hypocalcemia in foals remains to be determined. However, these foals may possibly have some form of hypoparathyroidism associated with sepsis.

THE ADRENAL GLANDS

The adrenal glands of mammals are located near the cranial pole of the kidneys. They consist of two distinct parts, the outer cortex and inner medulla, that differ in morphology, function, and origin.

ADRENAL CORTX

The adrenal cortex is subdivided into three layers, or zones, although the demarcation between zones often is indistinct. The zona glomerulosa, the outer zone, is responsible for the secretion of mineralocorticoid hormones. The zona fasciculata, the middle zone, comprises ~70% of the cortex and is composed of cells that contain abundant cytoplasmic lipid and the glucocorticoid hormones. The zona reticularis, the inner zone, is responsible for the secretion of sex steroids.

Mineralocorticoids, of which the most potent naturally occurring one is aldosterone, are adrenal steroids that have their principal effects on ion transport by epithelial cells, resulting in a loss of potassium and retention of sodium. Sweat glands and the electrolyte "pumps" in epithelial cells of the renal tubule respond similarly. In the distal convoluted tubule of the mammalian nephron, a cation-exchange mechanism resorbs sodium from the glomerular filtrate and secretes potassium into the lumen. These reactions are accelerated by mineralocorticoids and proceed more slowly in their absence. A lack of secretion of mineralocorticoids (Addison disease) may result in a lethal retention of potassium and loss of sodium.

Cortisol and lesser amounts of corticosterone are the most important glucocorticoid hormones secreted by the adrenal gland in many species. In general, the actions of glucocorticoids on carbohydrate, protein, and lipid metabolism result in sparing of glucose and a tendency to result in hyperglycemia and increased glucose production. In addition, they decrease lipogenesis and increase lipolysis in adipose tissue, which results in release of glycerol and free fatty acids.

Glucocorticoids also suppress inflammatory and immunologic responses, thereby attenuating associated tissue destruction and fibroplasia. However, high levels of glucocorticoids reduce resistance to bacteria, viruses, and fungi, which favors

the spread of infection. Glucocorticoids may impair the immunologic response at any stage, from the initial interaction and processing of antigens by cells of the reticuloendothelial system, through the induction and proliferation of immunocompetent lymphocytes and subsequent antibody production. Inhibition of a number of lymphocyte functions forms part of the basis for immunosuppression.

Glucocorticoids may have a profound negative effect on wound healing. High therapeutic doses of adrenal corticosteroids or the syndrome of hyperadrenocorticism may cause wound dehiscence after surgery. The inhibition of fibroblast proliferation and collagen synthesis leads to a decrease in scar tissue formation.

Progesterone, estrogens, and androgens are adrenal sex hormones. Excess secretion may be associated with a neoplasm of the zona reticularis. The manifestation of virilism, precocious sexual development, or feminization depends on which steroid is secreted in excess, sex of the individual, and age of onset. In addition, a syndrome termed atypical hyperadrenocorticism has been reported in association with excessive production of adrenal sex steroids. The symptoms mirror those of Cushing syndrome (*see* p 543), despite normal or low levels of cortisol concentrations after provocative testing. Dogs with this syndrome have increased concentrations of one of several adrenal steroids, which lead to the clinical signs. Treatment options are similar to those used in the management of Cushing syndrome.

HYPERADRENOCORTICISM

(Cushing syndrome)

Hyperadrenocorticism may be the most frequent endocrinopathy in adult to aged dogs but is infrequent in other domestic animals. The clinical signs and biochemical abnormalities result primarily from chronic excess production of cortisol. Increased cortisol levels in dogs may result from one of several mechanisms. The most common is an adenoma or hyperplasia of the adrenocorticotrophic hormone (ACTH)-containing cells of the pituitary gland (pars distalis or pars intermedia), which results in bilateral adrenal cortical

hypertrophy and hyperplasia. This form of the disease is referred to as pituitary-dependent hyperadrenocorticism (Cushing disease) and is seen in ~90% of cases. Functional adrenal tumors, a far less frequent cause of hyperadrenocorticism in dogs, may secrete cortisol or sex steroids, resulting in a variety of clinical signs. Many of the clinical signs and biochemical abnormalities seen with naturally occurring hyperadrenocorticism can be induced by longterm, daily administration of large doses of corticosteroids. Dogs develop a spectrum of clinical signs and laboratory abnormalities as a result of the combined glucocorticogenic, lipolytic, protein catabolic, and anti-inflammatory effects of the glucocorticoid hormones on many organ systems. The disease is insidious and slowly progressive. (For discussion of the clinical signs, laboratory abnormalities, diagnosis, and treatment of hyperadrenocorticism, see p 543.)

HYPOADRENOCORTICISM

(Addison disease)

A deficiency in adrenocortical hormones is seen most commonly in young to middle-aged dogs and occasionally in horses. The disease may be familial in Standard Poodles, West Highland White Terriers, Great Danes, Bearded Collies, Portuguese Water Dogs, and a variety of other breeds. The cause of primary adrenocortical failure usually is unknown, although most cases probably result from an autoimmune process. Other causes include destruction of the adrenal gland by granulomatous disease, metastatic tumor, hemorrhage, infarction, adrenolytic agents (mitotane), or adrenal enzyme inhibitors (trilostane).

Clinical Findings: Many of the functional disturbances of chronic adrenal insufficiency are not highly specific; they include recurrent episodes of gastroenteritis, a slowly progressive loss of body condition, and failure to respond appropriately to stress. Although hypoadrenocorticism is seen in dogs of any breed, sex, or age, idiopathic adrenocortical insufficiency is most common in young female adult dogs. This may be related to its suspected immune-mediated pathogenesis.

A reduction in secretion of aldosterone, the principal mineralocorticoid, results in marked alterations of serum levels of potassium, sodium, and chloride. Potassium

excretion by the kidneys is reduced and results in a progressive increase in serum potassium levels. Hyponatremia and hypochloremia result from renal tubular loss. Severe hyperkalemia may result in bradycardia and an irregular heart rate with changes in the ECG. Some dogs develop a pronounced bradycardia (heart rate ≤ 50 bpm) that predisposes to weakness or circulatory collapse after minimal exertion.

Although the development of clinical signs is often unnoticed, acute circulatory collapse and evidence of renal failure frequently occur. A progressive decrease in blood volume contributes to hypotension, weakness, and microcardia. Increased excretion of water by the kidneys, because of decreased reabsorption of sodium and chloride, results in progressive dehydration and hemoconcentration. Emesis, diarrhea, and anorexia are common and contribute to the animal's deterioration. Weight loss is frequently severe. Similar clinical signs are seen in cats with hypoadrenocorticism.

Decreased production of glucocorticoids results in several characteristic functional disturbances. Decreased gluconeogenesis and increased sensitivity to insulin contribute to the development of moderate hypoglycemia. In some dogs, hyperpigmentation of the skin is seen because of the lack of negative feedback on the pituitary gland and increased ACTH release. Atypical Addison disease has been reported in dogs and is associated with hypocortisolemia with normal electrolytes. Clinical signs are similar to those seen in dogs with both glucocorticoid and mineralocorticoid insufficiency.

Lesions: The most common abnormality in dogs is bilateral idiopathic adrenocortical atrophy, in which all layers of the cortex are markedly reduced in thickness. The adrenal cortex is reduced to one-tenth or less of its normal thickness and consists primarily of the adrenal capsule. The adrenal medulla is relatively more prominent and, with the capsule, makes up the bulk of the remaining adrenal glands.

All three zones of the adrenal cortex are involved, including the zona glomerulosa, which is not under ACTH control; however, no obvious pituitary lesions have been seen in dogs with idiopathic adrenal cortical atrophy.

A destructive pituitary lesion that decreases ACTH secretion is characterized by severe atrophy of the inner two cortical zones of the adrenal gland; the zona glomerulosa remains intact.

Diagnosis: A presumptive diagnosis is based on the history and supportive (although not specific) laboratory abnormalities, including hyponatremia, hyperkalemia, a sodium:potassium ratio of $<25:1$, azotemia, mild acidosis, and a normocytic, normochromic anemia. Severe GI blood loss has also been reported. Occasionally, mild hypoglycemia is present. The hyperkalemia results in ECG changes: an elevation (spiking) of the T wave, a flattening or absence of the P wave, a prolonged PR interval, and a widening of the QRS complex. Ventricular fibrillation or asystole may occur with potassium levels >11 mEq/L.

Differential diagnoses include primary GI disease (especially whipworm infection), renal failure, acute pancreatitis, and toxin ingestion. For definitive diagnosis, evaluation of adrenal function is required. After obtaining a baseline blood sample, ACTH (gel or synthetic) is administered. Gel preparations are administered IM, and a second blood sample is obtained 2 hr later. Synthetic preparations are administered IM or IV with a second blood sample 1 hr later. Baseline (resting) cortisol concentrations >2.5 mcg/dL effectively exclude the diagnosis of hypoadrenocorticism, whereas values <2.5 mcg/dL require the use of ACTH stimulation testing to confirm the diagnosis. Affected dogs have low baseline cortisol levels, and there is little response to ACTH administration in classic and atypical cases. This test can be completed in most animals before replacement hormone therapy is started.

Treatment: An adrenal crisis is an acute medical emergency. An IV catheter should be inserted, and an infusion of 0.9% saline begun. If the dog is hypoglycemic, the saline should include 2.5%–5% dextrose. The hypovolemia is corrected rapidly by administering 0.9% saline (60–70 mL/kg over the first 1–2 hr). Urine output should be assessed to determine whether the dog is becoming anuric. Fluids should be continued, at a rate appropriate to match ongoing losses, until the clinical signs and laboratory abnormalities have resolved.

Prednisolone sodium succinate (22–30 mg/kg) or dexamethasone sodium phosphate (0.2–1 mg/kg) may be used in the initial management of shock. Dexamethasone will not interfere with cortisol measurements during the ACTH stimulation test. Prednisolone or prednisone should be given at 1 mg/kg, bid, for the first few days of therapy and then at 0.25–0.5 mg/kg/day. Mineralocorticoid replacement therapy (*see below*) is also begun to help with electrolyte imbalances and hypovolemia. Electrolytes, renal

function, and glucose should be monitored regularly to assess response to therapy.

In cases of severe, nonresponsive hyperkalemia, 10% glucose in 0.9% saline can be given for 30–60 min to increase potassium movement into the cells. Regular insulin (0.25–1 U/kg) administered IM will enhance glucose and potassium uptake, but 10% glucose (20 mL per unit of insulin) should be administered IV concurrently to avoid hypoglycemia.

For long-term maintenance therapy, the mineralocorticoid desoxycorticosterone pivalate (DOCP) is administered at 2.2 mg/kg, IM or SC, every 25–28 days. Electrolytes should be measured at 3 and 4 wk after the first few injections to determine the duration of action. Alternatively, fludrocortisone acetate is administered PO at 10–30 mcg/kg/day. Serum electrolytes should be monitored weekly until the proper dose is determined. Some dogs (especially dogs on DOCP) also require daily oral glucocorticoid therapy to adequately control clinical signs. Replacement doses of prednisone (0.2–0.4 mg/kg/day) are required in ~50% of dogs. Additional glucocorticoid supplementation may be required (2–5 times maintenance) during times of illness or stress. Dogs with atypical Addison disease require only replacement doses of prednisone, although it is recommended that electrolytes be monitored every 3 mo for the first year after diagnosis. Dogs with chronic hypoadrenocorticism should be reexamined every 3–6 mo.

Treatment of horses with hypoadrenocorticism is similar—aggressive replacement of fluids, steroids, and glucose if needed in an adrenal crisis. Supportive therapy and resf are indicated in cases of chronic Addison disease.

ADRENAL MEDULLA

The adrenal medulla, although apparently not essential to life, plays an important role in response to stress or hypoglycemia. It secretes epinephrine and norepinephrine, which increase cardiac output, blood pressure, and blood glucose, and decrease GI activity.

Pheochromocytomas (*see below*) may develop in domestic animals, most often in cattle and dogs. These secrete epinephrine, norepinephrine, or both. Clinical signs are often absent, and tumors may be incidental findings during evaluation for other conditions or at necropsy.

Other adrenal tumors, such as neuroblastomas and ganglioneuromas, may arise in the chromaffin cells of the sympathetic nervous system.

NEUROENDOCRINE TISSUE TUMORS

Neuroendocrine cells are characterized by their ability to produce and secrete a neuromodulator, transmitter, or hormone. In addition, these cells contain dense core secretory granules, the storage site for the secreted product(s). Neuroendocrine cells are capable of releasing this product in a regulated manner by classic exocytosis. Neuroendocrine cells differ from classic neurons in that they lack axons and synapses. Certain molecules, particularly those of the granin family (eg, chromogranin) are synthesized and stored in neuroendocrine cells and serve as immunohistologic markers.

Previously, neuroendocrine cells were classified as amine precursor uptake and decarboxylation (APUD) cells and were believed to be solely derived from neuroectoderm. However, more recent evidence supports a more diverse embryologic origin.

Tumors that arise from this cell type comprise a family of neuroendocrine tumors, or NETs. Because of the diffuse distribution of cells, particularly within the GI tract, NETs are found in a wide variety of locations. Overall, NETs are rare tumors in people and animals. Some NETs oversecrete their normal product, and the excessive levels result in the observed signs. Other NETs are nonfunctional, and clinical signs instead result from physical forces associated with expansion and/or metastasis.

Examples of NETs include carcinoids, gastroenterohepatic tumors (gastrinoma, insulinoma, glucagonoma), pheochromocytoma of the adrenal gland, medullary carcinoma of the thyroid gland, some pituitary tumors, small-cell lung cancer, multiple endocrine neoplasia (MEN types 1 and 2), and tumors of the chemoreceptor organs. Interestingly, devil facial tumor disease, a devastating transmissible cancer affecting Tasmanian devils (*see* p 2044), appears to be an NET. NETs are identified and classified by their microscopic appearance, the immunohistologic identification of classic neuroendocrine cell markers (such as chromogranin A), and staining for their characteristic transmitter or hormonal product.

Insulinoma and Gastrinoma: Insulinoma (functional islet cell tumor) is the most common NET in domestic species.

For discussions of insulinoma and gastrinoma, *see* p 582 and p 583.

Carcinoids: Carcinoids are a heterogeneous group of NETs that occur in various regions of the GI tract. In dogs and cats, carcinoids have been reported to occur in the stomach. The most common sign reported in affected animals is chronic vomiting. In people (but not yet documented in companion animals), carcinoids serve as a source of serotonin or histamine. Excessive release of these transmitters can cause a syndrome of flushing, hypotension, wheezing, and diarrhea.

Glucagonoma: Glucagonomas have been found in a small number of dogs. Interestingly, affected animals show cutaneous lesions characterized by a superficial necrolytic dermatitis affecting mucocutaneous junctions, footpads, elbows, or the abdomen.

TUMORS OF THE ADRENAL MEDULLA

Pheochromocytomas: Pheochromocytomas occur in domestic species, including dogs and cats. Incidental masses in the area of the adrenal glands are being discovered with greater frequency because of the increased use of abdominal ultrasound and other imaging techniques. Pheochromocytoma, although rare, should be a differential diagnosis whenever such a mass is identified. Pheochromocytomas arise from the adrenal medullary chromaffin cells that normally synthesize and secrete the catecholamines epinephrine and norepinephrine. These tumors have been identified more often in dogs than in cats, usually affect only one gland, and tend to occur in older animals. They are often locally invasive (may result in thrombus formation in the adjacent vena cava) and metastasize in ~25% of cases. Diagnosis of pheochromocytoma is challenging. Clinical signs are nonspecific and may appear sporadically, possibly related to periodic or intermittent release of catecholamines. In addition, signs may vary depending on which catecholamine predominates. Signs reported in most dogs

include weight loss, anorexia, depression, weakness, and occasional collapse. Dyspnea and tachycardia may be seen, and hypertension is common; indirect blood pressure measurement can help establish the diagnosis. Imaging, such as ultrasonography or CT scans, is very useful in confirmation of a suspected adrenal mass. Although surgical removal is the treatment of choice, animals with pheochromocytoma present an anesthetic risk secondary to the cardiovascular effects of the catecholamines. Surgery is additionally complicated by the tendency toward local invasion of these tumors and their proximity to large vessels.

Adrenal Medullary Hyperplasia:

Diffuse or nodular adrenal medullary hyperplasia appears to precede the development of pheochromocytomas in bulls with C-cell tumors of the thyroid gland. This diffuse proliferation of chromaffin cells is nonencapsulated but compresses the surrounding adrenal cortex. In bulls with prominent diffuse medullary hyperplasia, there are often a few small foci of intense nodular proliferation of medullary cells.

THYROID C-CELL TUMORS

Tumors derived from C-cells (parafollicular, ultimobranchial cells) of the thyroid gland are most common in adult to aged bulls and horses and in certain strains of laboratory rats. A high percentage of aged bulls has been reported to develop C-cell tumors ($\geq 30\%$) or hyperplasia of C-cells and ultimobranchial derivatives ($\geq 15\%$ – 20%). These have not been seen in cows fed similar diets. The incidence in bulls increases with advancing age and is often associated with development of increased vertebral density. Multiple endocrine tumors, especially bilateral pheochromocytomas and occasionally pituitary adenomas, are detected coincidentally in bulls with C-cell tumors. A high frequency of thyroid C-cell tumors and pheochromocytomas has been reported in a family of Guernsey bulls, which suggests an autosomal dominant pattern of inheritance. A diffuse or nodular hyperplasia of secretory cells in the adrenal medulla often precedes the development of pheochromocytoma.

In dogs, C-cell tumors of the thyroid occur as a small percentage of all thyroid tumors (estimates range from 0.1%–12%), but the incidence may be higher. Distin-

guishing these tumors from other thyroid carcinomas is challenging with light microscopy alone, and confirmation requires immunohistologic staining. These tumors are usually well encapsulated and do not show the tendency for metastasis other thyroid carcinomas exhibit. Oversecretion of calcitonin has not been clearly documented in affected animals. Perhaps related to excessive release of prostaglandins or serotonin, diarrhea is a common clinical sign in dogs with C-cell tumors of the thyroid.

Adenomas: C-cell adenomas appear in one or both thyroid lobes as discrete, single or multiple, gray to tan nodules. Adenomas are smaller (~1–3 cm in diameter) than carcinomas and are separated from the thyroid parenchyma by a thin, fibrous connective tissue capsule. The adjacent thyroid is compressed but not invaded by the tumor. In horses, C-cell adenomas may result in a palpable enlargement in the anterior cervical region. Larger C-cell adenomas incorporate most of the thyroid lobe, but a rim of dark brown-red thyroid often is present on one side.

Carcinomas: Thyroid C-cell carcinomas cause extensive multinodular enlargements of one or both thyroid lobes and may incorporate the entire thyroid gland. If present, metastases in anterior cervical lymph nodes usually are large and have areas of necrosis and hemorrhage. Pulmonary metastases are infrequent and appear as discrete tan nodules throughout all lobes of the lung.

The chronic stimulation of C-cells by longterm dietary intake of excess calcium may be related to the high incidence of these tumors in bulls; adult bulls frequently were fed diets with 3.5–6 times the amount of calcium normally recommended for maintenance, and incidence of the tumors declined significantly when calcium intake was reduced.

Syndromes associated with abnormalities in the secretion of calcitonin are recognized much less frequently than disorders involving parathyroid hormone (PTH). Hypersecretion of calcitonin has been reported in people, bulls, and laboratory rats with medullary (ultimobranchial) thyroid neoplasms derived from C-cells. Osteosclerotic changes have been reported in bulls with this syndrome, but the relationship of longterm excess calcitonin secretion to the pathogenesis of the skeletal

lesions and their occurrence in other species is unclear.

In dogs, the histologic grading of thyroid carcinoma has been important in prognosis, although histologic type has not. ● Of greater importance is the volume of tumor and its relation to the potential for metastasis; also, the more deeply fixed the tumor is to underlying structures, the less likely surgical resection will be complete. Surgery is the primary therapy, but some form of adjuvant therapy is reasonable because of the potential for metastatic spread and residual nonresectable tissue. A combination of radiotherapy and chemotherapy would be ideal in theory, and there is increasing interest in such combined therapy. For the rather rare functional thyroid carcinoma in dogs, treatment with ¹³¹I would be a reasonable choice.

CHEMORECEPTOR ORGANS

Chemoreceptor organs are sensitive barometers of changes in the carbon dioxide and oxygen content and pH of the blood and aid in the regulation of respiration and circulation. Although chemoreceptor tissue appears to be widely distributed in the body, tumors (chemodectomas) develop principally in the aortic (more frequent in animals) and carotid (more frequent in people) bodies. These tumors are found primarily in dogs and rarely in cats and cattle. Brachycephalic breeds of dogs, such as the Boxer and Boston Terrier, are predisposed to tumors of the aortic and carotid bodies.

Aortic body tumors appear most frequently as single masses or as multiple nodules within the pericardial sac near the base of the heart. They vary considerably in size (0.5–12.5 cm), with carcinomas generally larger than adenomas. Solitary, small adenomas either are attached to the adventitia of the pulmonary artery and ascending aorta or are embedded in the adipose connective tissue between these major vascular trunks. Larger adenomas may indent the atria or displace the trachea, are multilobular, and partially surround the major arterial trunks at the base of the heart.

In dogs, malignant aortic body tumors occur less frequently than adenomas. Carcinomas may infiltrate the wall of the pulmonary artery to form papillary projections into the lumen or invade through the wall into the lumen of the atria. Although tumor cells often invade blood vessels, metastases to the lungs and liver

are infrequent in dogs with aortic body carcinomas. Nonetheless, the local and physiologic effects are important, including those of adenomas.

Aortic body tumors in animals are not functional (ie, they do not secrete excess hormone into the circulation) but, as space-occupying lesions, may result in various functional disturbances. These include manifestations of cardiac decompensation due to pressure on the atria or vena cava (or both) associated with larger aortic body adenomas and carcinomas. Aortic body tumors tend to be more benign than carotid body tumors. They grow slowly by expansion and exert pressure on the vena cava and atria. Aortic body carcinomas may invade locally into the atria, pericardium, and adjacent large, thin-walled vessels.

Carotid body tumors arise near the bifurcation of the common carotid artery, usually as a unilateral, slow-growing mass. Adenomas are usually 1–4 cm in diameter. The bifurcation of the carotid artery is incorporated in the mass, and tumor cells are firmly adherent to the tunica adventitia. Complete excision or biopsy often is difficult because of the high degree of vascularity and intimate relationship with major arterial trunks in the neck.

Malignant carotid body tumors are larger and more coarsely multinodular than adenomas. Although carcinomas appear to be encapsulated, tumor cells invade the capsule and penetrate into the walls of adjacent vessels and lymphatics. The external jugular vein and several cranial nerves may be incorporated by the neoplasm. Metastases of carotid body tumors occur in ~30% of cases and have been found in the lung, bronchial and mediastinal lymph nodes, liver, pancreas, and kidneys. Multicentric neoplastic transformation of chemoreceptor tissue occurs frequently in brachycephalic breeds of dogs.

The histologic characteristics of chemodectomas are essentially similar whether derived from the carotid or aortic body.

Although the etiology of carotid and aortic body tumors is unknown, it has been suggested that a genetic predisposition aggravated by chronic hypoxia may account for the higher risk in certain brachycephalic breeds. Carotid bodies of several mammalian species, including dogs, have undergone hyperplasia when subjected to chronic hypoxia by living in a high-altitude environment.

THE PANCREAS

The endocrine function of the pancreas is performed by small groups of cells, the islets of Langerhans, that are completely surrounded by acinar (exocrine) cells that produce digestive enzymes. The endocrine and exocrine portions of the pancreas are closely related during development, and evidence suggests that islet, acinar, and ductal cells arise from a common multipotential precursor cell.

Pancreatic islets contain α , β , and δ cells, each of which synthesize a unique polypeptide hormone. β cells account for 60%–70% of the islet-cell population and secrete insulin, α cells secrete glucagon, and δ cells secrete somatostatin.

The pancreatic islets function as discrete microendocrine organs. They are distributed throughout the pancreas with a characteristic pattern of cellular interrelationships to assure an appropriate balance of hormones. Afferent vessels and nerves enter the islet in the peripheral tricellular region. The close anatomic relationship of α , β , and δ cells in this heterogeneous cortical region allow it to function as a local glucose sensor, permitting a coordinated output of insulin and glucagon in response to fluctuations in blood glucose. Specialized tight junctions between membranes of adjacent endocrine cells tend to partition the intercellular space and may permit somatostatin to exert a direct local (paracrine) inhibitory effect on glucagon and insulin release.

Insulin is formed initially as a single polypeptide chain of 81–86 amino acid residues. This prohormone (proinsulin) contains the A and B chains of the insulin molecule, plus a connecting peptide. Proinsulin is converted enzymatically to insulin before storage in membrane-limited secretory granules.

The major physiologic stimulus for the release of insulin from β cells is an increase in the concentration of glucose in the extracellular fluid. Specific glucoreceptors that bind with glucose exist on the plasma membrane of β cells. An appropriate level of extracellular calcium is required for insulin secretion. Other sugars (fructose, mannose, ribose), amino acids (leucine, arginine), hormones (glucagon, secretin), drugs (sulfonylurea, theophylline), short-chain fatty acids, and ketone bodies may also stimulate insulin secretion under certain

conditions. Pancreatic β cells are able to respond to a specific physiologic stimulus with release of stored hormone in a modulated fashion, rather than releasing all of the stored hormone at once.

Insulin affects, either directly or indirectly, the function of every organ in the body. Tissues that are especially responsive to insulin include skeletal and cardiac muscle, adipose tissue, fibroblasts, liver, WBCs, mammary glands, cartilage, bone, skin, aorta, pituitary gland, and peripheral nerves. The main function of insulin is to stimulate anabolic reactions involving carbohydrates, fats, proteins, and nucleic acids. Liver, adipose cells, and muscle are three principal target sites for insulin. Insulin catalyzes the formation of macromolecules used in cell structure and energy stores, and it regulates many cell functions. In general, insulin increases the transfer of glucose and certain other monosaccharides, some amino acids and fatty acids, and potassium and magnesium ions across the plasma membrane of target cells. It also decreases the rate of lipolysis, proteolysis, ketogenesis, and gluconeogenesis.

Glucagon is secreted in response to a reduction in blood glucose. It promotes mobilization of stores of energy-yielding nutrients by increasing glycogenolysis, gluconeogenesis, and lipolysis. At physiologic concentrations, glucagon increases both hepatic glycogenolysis and gluconeogenesis, thereby increasing blood glucose.

Insulin and glucagon act in concert to maintain the concentration of glucose in extracellular fluids within relatively narrow limits. A glucose sensor in the pancreatic islets controls the relative amounts of insulin and glucagon secreted. Glucagon controls glucose release from the liver into the extracellular space, and insulin controls glucose transport from the extracellular space into insulin-sensitive tissues such as fat, muscle, and liver.

DIABETES MELLITUS

Diabetes mellitus is a chronic disorder of carbohydrate metabolism due to relative or absolute insulin deficiency. Most cases of spontaneous diabetes occur in middle-aged dogs and middle-aged to older cats. In dogs, females are affected twice as often as males,

and incidence appears to be increased in certain small breeds such as Miniature Poodles, Dachshunds, Schnauzers, Cairn Terriers, and Beagles, but any breed can be affected. In one study, obese male cats were more commonly affected than females; no breed predilection is seen in cats.

Etiology and Pathogenesis: The pathogenic mechanisms responsible for decreased insulin production and secretion are multiple, but usually they are related to destruction of islet cells, secondary to either immune destruction or severe pancreatitis (dogs) or amyloidosis (cats). Chronic relapsing pancreatitis with progressive loss of both exocrine and endocrine cells and their replacement by fibrous connective tissue results in diabetes mellitus. The pancreas becomes firm and multinodular and often contains scattered areas of hemorrhage and necrosis. Later in the course of disease, a thin, fibrous band of tissue near the duodenum and stomach may be all that remains of the pancreas. In other cases, the numbers of β cells are decreased, and the cells become vacuolated; in chronic cases, the islets are difficult to find. Insulin resistance and secondary diabetes mellitus are also seen in many dogs with spontaneous hyperadrenocorticism and after chronic administration of glucocorticoids or progestins. Pregnancy and diestrus also can predispose to diabetes mellitus. In dogs, but not cats, progesterone leads to release of growth hormone from mammary tissue, resulting in hyperglycemia and insulin resistance. Obesity also predisposes to insulin resistance in both dogs and cats.

Cats with diabetes mellitus usually have specific degenerative lesions localized selectively in the islets of Langerhans, whereas the remainder of the pancreas appears to be normal. The selective deposition of amyloid in islets, with degenerative changes in β cells, is the most common pancreatic lesion in many cats with diabetes. The amyloid appears to arise from islet-associated polypeptide (IAPP), which is secreted together with insulin from the β cells. Cats are unable to process IAPP normally, which leads to excessive accumulation and conversion into amyloid. As cats age, a greater percentage of their islets contain amyloid. Cats with diabetes have a greater percentage of their islets affected with larger amounts of amyloid than age-matched cats without diabetes. The amyloid or IAPP (or both) lead to physical disruption of the β cell and insulin resistance, resulting in diabetes.

Infection with certain viruses in people may cause selective islet damage or pancreatitis and has been suggested to be responsible for certain cases of rapidly developing diabetes mellitus. This has yet to be documented in dogs or cats. The selective degeneration and necrosis of β cells is accompanied by infiltration of the islets by lymphocytes and macrophages. Stress, obesity, and administration of corticosteroids or progestogens may increase the severity of clinical signs.

Complete expression of the complex metabolic disturbances in diabetes mellitus appears to be the result of a bihormonal abnormality. Although a relative or absolute deficiency of insulin action in response to a rising extracellular glucose concentration has long been recognized as the major hormonal abnormality, the importance of an absolute or relative increase of glucagon secretion has been appreciated more recently. Hyperglucagonemia in diabetes may be the result of increased secretion of pancreatic glucagon, enteroglucagon, or both. Increased glucagon appears to contribute to development of severe hyperglycemia by mobilizing hepatic stores of glucose and to development of ketoacidosis by increasing the oxidation of fatty acids in the liver.

Clinical Findings: The onset of diabetes is often insidious, and the clinical course chronic. Common signs in dogs include polydipsia, polyuria, polyphagia with weight loss, bilateral cataracts, and weakness. The disturbances in water metabolism develop primarily because of an osmotic diuresis. The renal threshold for glucose is ~180 mg/dL in dogs and ~280 mg/dL in cats.

Diabetic animals have decreased resistance to bacterial and fungal infections and often develop chronic or recurrent infections such as cystitis, prostatitis, bronchopneumonia, and dermatitis. This increased susceptibility to infection may be related in part to impaired chemotactic, phagocytic, and antimicrobial activity associated with decreased neutrophil function. Radiographic evidence of emphysematous cystitis (rare) due to infections with glucose-fermenting organisms (such as *Proteus* sp, *Aerobacter aerogenes*, and *Escherichia coli*), which results in gas formation in the wall and lumen of the bladder, is suggestive of diabetes mellitus. Emphysema also may develop in the wall of the gallbladder in diabetic dogs.

Hepatomegaly due to lipid accumulation is common in diabetic dogs and cats. The

fatty liver results from increased fat mobilization from adipose tissue. Individual liver cells are greatly enlarged by the accumulation of multiple droplets of neutral lipid. In cats, hepatic lipidosis may occur in conjunction with diabetes mellitus.

Cataracts develop frequently in dogs (not cats) with poorly controlled diabetes mellitus. The lenticular opacities appear initially along the suture lines of lens fibers and are stellate ("asteroid") in shape. Cataract formation in dogs is related to the unique sorbitol pathway by which glucose is metabolized in the lens, which leads to edema of the lens and disruption of normal light transmission. Although the same sorbitol pathway seems to be present in cats, the development of cataracts is rare. Other extrapancreatic lesions associated with diabetes mellitus in people, such as nephropathy, retinopathy, and micro- and macrovascular angiopathy, are rare in dogs and cats.

Diagnosis: A diagnosis of diabetes mellitus is based on persistent fasting hyperglycemia and glycosuria. The normal fasting value for blood glucose in dogs and cats is 75–120 mg/dL. In cats, stress-induced hyperglycemia is a frequent problem, and multiple blood and urine samples may be required to confirm the diagnosis. Measurement of serum fructosamine can assist in differentiating between stress-induced hyperglycemia and diabetes mellitus. In cases of stress-induced hyperglycemia, the fructosamine concentrations are normal. In all cases, a search should be made for drugs or diseases that predispose to diabetes.

Treatment: Longterm success depends on the understanding and cooperation of the owner. Treatment involves a combination of weight reduction, diet, insulin, and possibly oral hypoglycemics. Intact females should be neutered. In cats, recent evidence has supported the use of high-protein, low-carbohydrate diets. In dogs, diets that are high in fiber and complex carbohydrates are preferred. Diet and weight reduction alone will not control the disease, so initial therapy with insulin is required. Most dogs require two doses of insulin a day. In general, NPH or lente is the initial insulin of choice at a dose of 0.5 U/kg, bid. With twice daily injections, two meals of equal calories are given at the time of insulin administration. Diets high in simple sugars (semimoist foods) should be avoided. Clinical signs and serial blood glucose determinations are used to monitor therapy after initial stabilization at home for 5–7 days.

In dogs with poor glycemic control on NPH or lente insulin, use of the basal insulin detemir should be considered. Because of its potency, the starting dosage of detemir is 0.1 U/kg, bid, with reassessment of clinical signs and glycemic control in 1 wk.

It is usually preferable to have blood glucose testing performed at home to avoid changes in the pet's routine and the stress of in-hospital testing. Studies in both dogs and cats have shown that at-home monitoring improves glycemic control and increases the likelihood of obtaining remission in diabetic cats. In cats, high-protein diets along with insulin therapy are initiated, with reevaluation in 5–7 days. In newly diagnosed cats, insulin glargine is the insulin of choice. Glargine is a long-acting basal insulin. Used in conjunction with high-protein, low-carbohydrate diets, it is associated with remission of diabetes and discontinuation of insulin therapy in 80%–90% of cases within the first 3–4 mo of treatment. NPH, lente, or PZI insulins may also be used in cats, with starting dosages ranging from 1 to 3 units, bid. However, these insulins are not associated with high rates of diabetic remission.

The use of oral hypoglycemic agents (glipizide) has been evaluated in diabetic cats. Glipizide is a sulfonylurea that stimulates the release of insulin from functional β cells. Glipizide should not be used in thin or ketonuric cats when absolute insulin deficiency is likely and exogenous insulin administration is required. Glipizide is administered at an initial dose of 2.5 mg, bid, PO, in conjunction with dietary management. Clinical response is seen at 3–4 wk. Short-term success is seen in 50% of treated cats, with longterm success rates (>1 yr) of ~15%. Alternatively, glimepiride and glyburide (other sulfonylureas) may be administered to cats at 2 mg/day (glimepiride) or 0.625 mg/day (glyburide). Acarbose, an oral α -glucosidase inhibitor, has also been used in cats at a dose of 12.5–25 mg, bid-tid, in conjunction with diet and/or insulin to control hyperglycemia.

Ketoacidosis is a serious complication of diabetes mellitus and should be regarded as a medical emergency. Therapy includes correcting dehydration by administration of IV fluids, such as 0.9% NaCl or lactated Ringer's solution; reducing hyperglycemia and ketosis by administration of crystalline zinc (regular) insulin; maintaining serum electrolyte levels, especially potassium, through supplemental administration of appropriate electrolyte solutions; and identifying and treating underlying and

complicating diseases, such as acute pancreatitis or infections.

Numerous insulin regimens have been used in treatment of ketoacidotic diabetes mellitus. In the intermittent insulin regimen, regular insulin at 0.2 U/kg, IM, is the initial dosage, followed by hourly administration of 0.1 U/kg. Once the serum glucose is <250 mg/dL, the insulin is administered SC at 0.25–0.5 U/kg, every 4–6 hr, with careful monitoring of the serum glucose at 1- to 2-hr intervals. During aggressive treatment with insulin, blood glucose levels may fall rapidly, and the addition of 2.5%–5% dextrose to the IV fluids may be required.

When insulin therapy has been instituted, the blood glucose should be checked frequently until an adequate maintenance dose has been determined. Once the animal is on maintenance therapy and its condition is stable, it should be reassessed every 4–6 mo.

FUNCTIONAL ISLET CELL TUMORS

The most frequent pancreatic islet tumor is an islet cell carcinoma derived from insulin-secreting β cells. These neoplasms frequently are hormonally active and secrete excessive amounts of insulin, which causes hypoglycemia. Endocrine pancreatic tissue appears to be derived from multipotential ductal epithelial cells, which differentiate into one of the several cell types present within the islets. Gastrin, somatostatin, pancreatic polypeptide, and vasoactive intestinal peptide may also be produced in excess in islet cell tumors. β -cell neoplasms of the pancreatic islets (insulinomas) are seen most frequently in dogs 5–12 yr old. They are common in ferrets and have also been less frequently reported in cats and in older cattle.

Clinical Findings: The clinical signs seen with insulinomas result from excessive insulin secretion, which leads to an increased rate of transfer of glucose from the extracellular fluid to body tissues and thus to severe hypoglycemia. The clinical signs are a reflection of the hypoglycemia and are not specific for hyperinsulinism associated with β -cell neoplasms. Initial signs include posterior weakness, fatigue after exercise, generalized muscular twitching and weakness, ataxia, mental confusion, and changes of temperament. Dogs are easily agitated, and there are intermittent periods of excitability and

restlessness. Periodic seizures may occur, and episodes of collapse resembling syncope have also been reported.

Clinical signs are characteristically episodic and occur initially at widely spaced intervals but become more frequent and prolonged as the disease progresses. Hypoglycemic attacks may be precipitated by physical exercise (increased use of glucose) or fasting (decreased availability of glucose), as well as by ingestion of food (stimulation of insulin release). Administration of glucose rapidly alleviates the signs.

The predominance of clinical signs relating to the CNS demonstrates the primary dependence of the brain on the metabolism of glucose for energy. When the brain is not supplied with glucose, cerebral oxidation decreases and manifestations of anoxia appear. Because clinical signs are compatible with primary disease of the CNS, functional islet cell tumors may be misdiagnosed as idiopathic epilepsy, brain tumors, or other organic neurologic disease. Repeated episodes of prolonged and severe hypoglycemia may result in irreversible neuronal degeneration throughout the brain. Permanent neurologic disability probably accounts for the terminal coma, unresponsiveness to glucose, and eventual death of some dogs.

Lesions: Insulinomas usually appear as single, yellow to dark red, spherical, small (1–3 cm) nodules visible from the serosal surface. They occur as single or occasionally multiple nodules in the same or different lobes of the pancreas. They are of similar consistency to or slightly firmer than the surrounding pancreatic parenchyma. A thin layer of fibrous connective tissue separates the neoplasm from the adjacent parenchyma. Insulinomas frequently metastasize to regional lymph nodes or the liver (or both) before diagnosis. True benign adenomas of islet cells are rare.

Diagnosis: A blood glucose determination should be done on all older dogs with a history of periodic weakness, collapse, or seizures. Fasting hypoglycemia (≤ 60 mg/dL) in a middle-aged to older dog is strong support for an insulinoma. Serum insulin concentrations taken at the time of hypoglycemia are normal to increased in animals with an insulinoma. Differential diagnoses for hypoglycemia include hypoadrenocorticism, hepatic failure, large extrapancreatic neoplasms, sepsis, polycythemia, insulin overdosage, and laboratory error.

Treatment: Although insulinomas are usually solitary in dogs, the entire pancreas should be examined carefully for multiple tumors. Complete excision of the tumor ameliorates the hypoglycemia and associated neurologic signs, unless there have been irreversible changes in the CNS. If there are nonvisible metastases, hypoglycemia may persist after surgery. Even though the potential for malignancy of insulinomas is high, many dogs live >1 yr with acceptable quality of life if all visible tumors are debulked at surgery. Dogs with inoperable tumors may be managed fairly well with multiple feedings per day and glucocorticoid administration (0.5–1 mg/kg/day). Diazoxide (20–80 mg/kg/day, divided into three equal doses) may also alleviate clinical signs in some dogs, although problems with availability have limited its use. The chemotherapeutic agent streptozotocin has been investigated for the treatment of islet cell tumors in dogs and may be considered after surgical resection.

GASTRIN-SECRETING ISLET CELL TUMORS

Gastrinomas of the pancreas have been reported in people, dogs, and a cat. Hypersecretion of gastrin in people results in the Zollinger-Ellison syndrome, consisting of hypersecretion of gastric acid and recurrent peptic ulceration in the GI tract. The tumors, derived from ectopic amine precursor uptake decarboxylase (APUD) cells in the pancreas, produce an excess of the hormone gastrin, which normally is secreted by cells of the antral and duodenal mucosa.

Clinical Findings: These tumors are rare; they occur less frequently than the insulin-

secreting β -cell neoplasms. The few documented cases have had anorexia, hematemesis, intermittent diarrhea (usually with dark blood present), progressive weight loss, and dehydration. The prominent functional disturbances appear to result from multiple ulcerations of the GI mucosa that develop from gastrin hypersecretion.

Lesions: Animals studied with the Zollinger-Ellison-like syndrome have had single or multiple tumors of varying size in the pancreas. The tumors were firm on palpation because of an increase of fibrous connective tissue in the stroma, and all had evidence of metastasis before diagnosis.

Diagnosis: Serum gastrin levels have been evaluated in a limited number of dogs with gastrinomas. Gastrin levels in a dog with a Zollinger-Ellison-like syndrome varied from 155 to 2,780 pg/mL, whereas the mean serum gastrin in clinically normal (control) dogs was 70.9 pg/mL. Recurrent gastric or duodenal ulcers in dogs with no identified cause warrants exploratory surgery and careful inspection of the pancreas.

Treatment: Excision of the gastrin-secreting mass in the pancreas can be attempted. However, all such tumors that have been studied in dogs have had evidence of local invasion into adjacent parenchyma and had metastasized to regional lymph nodes and liver. The dogs had either single or multiple ulcerations in the gastric or duodenal mucosa associated with free blood in the lumen. Medical management with H_2 -receptor antagonists (famotidine or ranitidine) or the proton-pump inhibitor omeprazole may temporarily alleviate clinical signs in animals with inoperable disease.

ACTINOBAICILLOSIS

Actinobacillosis refers to a group of diseases caused by gram-negative coccobacilli in the genus *Actinobacillus*. Although there are >22 different bacterial species in this genus, only four (*A. pleuropneumoniae*, *A. suis*, *A. equuli*, and *A. lignieresii*) are frequently associated with disease in animals.

A. pleuropneumoniae causes contagious pleuropneumonia in pigs (see p 1469). Disease ranges from acute, severe fibrinous pleuropneumonia to subacute or chronic infection with pleuritis and pulmonary abscessation. Immune complexes formed as a result of host response may damage endothelial cells, resulting in vasculitis and thrombosis, with edema, necrosis, infarction, and hemorrhage. Infection is usually restricted to pigs <5 mo old. *A. pleuropneumoniae* may be normal mucosal flora in pigs, cattle, and sheep. Diagnosis is by culture of the organism from nasal swabs or lung tissue at necropsy. Molecular techniques such as PCR have also been developed to detect the presence of *A. pleuropneumoniae* in tissue samples. Treatment involves use of antibiotics, including penicillin, tetracycline, spectinomycin, cephalosporins, or fluoroquinolones. Control focuses on good management combined with the use of vaccines or eradication of the infection from the herd by depopulation.

A. suis is part of the normal flora of the oral cavity of pigs. It causes septicemia in young pigs and arthritis, pneumonia, and pericarditis in older pigs. It may also cause septicemia, arthritis, pneumonia, and purulent nephritis in neonatal and post-natal foals. Disease follows a break in the integrity of the oral mucosa or may be associated with immunosuppression. The organism is typically susceptible to sulfonamides and cephalosporins.

The natural host of *A. equuli* is the horse, and infections are seen in both foals and adult horses. Disease in foals may manifest as diarrhea, followed by meningitis, pneumonia, purulent nephritis, or septic polyarthritis (sleepy foal disease or joint-ill). Infection may be acquired through a contaminated umbilicus or by inhalation or ingestion. The incidence of foal infection is reduced with greater attention to sanitation in the foaling environment, and maternal antibodies in colostrum are often protective. Abortions, septicemia, nephritis, peritonitis, and endocarditis may result from *A. equuli* infection in adult horses. A syndrome of acute peritonitis in adult horses associated with *A. equuli* has been described in Australia as well as sporadically in other parts of the world. *A. equuli* isolates have also been recovered from fetuses of mares affected with mare reproductive loss syndrome; however, it is not clear whether the bacteria is directly associated with the pregnancy loss. In both foals and adult horses, several other bacteria can cause the same clinical disease syndromes as *A. equuli*. Therefore, definitive diagnosis of *A. equuli* relies on isolating the bacteria by culture. Infected horses may be treated with chloramphenicol, gentamicin, or third-generation cephalosporins, depending on the nature of the infection and the ability to achieve therapeutic concentrations at the site of infection. β -Lactam antibiotics and potentiated sulfonamides have been recommended; however, resistance to both of these types of antibiotics is occasionally reported.

A. arthritidis, previously classified as Bisgaard taxon 9, has been isolated from horses with arthritis and septicemia.

A. lignieresii causes tumorous abscesses of the tongue, usually referred to as wooden tongue. It is seen primarily in cattle but also

Actinobacillosis in a cow. Note the characteristic large granulomas in the substance of the tongue. Courtesy of Dr John Prescott.

in sheep, horses, pigs, and dogs. It is a rare cause of disease in chickens. The organism may also cause pyogranulomatous lesions in soft tissues associated with the head, neck, limbs, and occasionally the lungs, pleura, udder, and subcutaneous tissue. *A. lignieresii* is part of the normal mucosal flora of the upper GI tract and causes disease when it gains access to adjacent soft tissue via penetrating wounds. It causes localized infections and can spread via the lymphatics to other tissues. The primary lesion associated with *A. lignieresii* infection in cattle is a very hard, diffusely swollen, painful tongue. This leads to excessive salivation, the inability to prehend food normally, and sometimes a visibly enlarged tongue that protrudes from the mouth. On palpation, the tongue will feel very hard. Diagnosis requires culture and biopsy of the lesion. Pus from an abscess crushed between two glass slides may show club-like spicules of calcium phosphate, giving the appearance of sulfur granules <1 mm diameter. No reliable serologic tests are available for actinobacillosis, and the hematologic and clinical

chemistry findings are generally normal. Gross pathology generally reveals a firm, pale tongue containing multifocal nodules. These nodules are often filled with thick yellow-white pus. Histologically, the primary lesion is a granulomatous abscess.

This form of actinobacillosis is found worldwide but is sporadic and thus difficult to prevent. Herd outbreaks are possible and are generally associated with consumption of coarse, abrasive feeds that encourage formation of lesions in the mouth. Sodium iodide is the treatment of choice in actinobacillosis in ruminants. IV sodium iodide (70 mg/kg of a 10%–20% solution) is given once and then repeated once or twice at 7- to 10 day intervals. If clinical signs of iodine toxicity develop (including dandruff, diarrhea, anorexia, coughing, and excessive lacrimation), iodine administration should be discontinued. Clinical improvement is often seen within 48 hr of therapy, and treatment is usually successful when only the tongue is involved. Systemic antibacterial agents, such as ceftiofur, penicillin, ampicillin, florfenicol, and tetracyclines may be effective and are primarily recommended in severe cases of actinobacillosis or in cases refractory to sodium iodide therapy. Surgical debulking of lesions, especially if they interfere with breathing, may be useful. This is particularly true when large granulomatous masses that do not respond to medical therapy are present. Prevention of actinobacillosis in ruminants primarily relies on avoidance of coarse, stemmy feedstuffs and pastures full of hard, penetrating plant awns (ie, foxtails or thistles).

A. ureae has caused upper respiratory tract infections in people and abortions in pigs. In addition, *A. actinoides* has occasionally been associated with suppurative pneumonia in calves and seminal vesiculitis in bulls.

ACTINOMYCOSIS

Members of the genus *Actinomyces* are gram-positive, anaerobic, non-acid-fast rods, many of which are filamentous or branching. Branches are <1 μ m in diameter, as opposed to fungal filaments, which are >1 μ m in diameter. Although they are normal flora of the oral and nasopharyngeal membranes, several species are associated with diseases in animals.

A. bovis is the etiologic agent of lumpy jaw in cattle. It has also been isolated from nodular abscesses in the lungs of cattle and infrequently from infections in sheep, pigs, dogs, and other mammals, including chronic fistulous withers and chronic poll evil in horses. Lumpy jaw is a localized, chronic, progressive, granulomatous abscess that most frequently involves the mandible, the

maxillae, or other bony tissues in the head. Disease is seen when *A. bovis* is introduced to underlying soft tissue via penetrating wounds of the oral mucosa from wire or coarse hay or sticks. Involvement of adjacent bone frequently results in facial distortion, loose teeth (making chewing difficult), and dyspnea from swelling into the nasal cavity. Any part of the head can be affected; however, the alveoli around the roots of the cheek teeth are frequently involved. The primary lesion appears as a slow-growing, firm mass that is attached to or part of the mandible. Ulceration forms in some cases, with or without fistulous tracts, and drainage of purulent exudate may occur. Presumptive diagnosis is often based on clinical signs. The diagnosis can be confirmed by culture of the organism from the lesion; however, this requires anaerobic conditions and is frequently negative. A Gram stain of purulent material will reveal gram-positive, club-shaped rods and filaments (sulfur granules). Radiology of the head is also useful; the primary radiographic lesion consists of multiple, centrally radiolucent areas of osteomyelitis surrounded by periosteal new bone and fibrous tissue. As a last resort, a biopsy sample can be taken with a trephine and submitted for histopathology.

The goal of treatment is to kill the bacteria and stop the spread of the lesion. However, the hard mass will usually not regress significantly. Sodium iodide is the treatment of choice in ruminant actinomycosis. Sodium iodide (70 mg/kg of a 10%–20% solution, IV) is given once and repeated several times at 7- to 10-day intervals. If signs of iodine toxicity develop (eg, dandruff, diarrhea, anorexia, coughing, and excessive lacrimation), iodine administration should be discontinued or treatments given at longer intervals. Sodium iodide has been shown to be safe for use in pregnant cows and presents little risk of causing abortion. Concurrent administration of antimicrobials, including penicillin, florfenicol, or oxytetracycline, is recommended. Surgery to debride large mandibular lesions has also been described in conjunction with iodine and antimicrobial therapy. Because *A. bovis* is part of the normal oral flora in ruminants, control focuses on avoiding coarse, stemmy feeds or feeds with plant awns that might damage the mucosal epithelium. When multiple cases are seen in a herd, it is not from the contagious nature of the pathogen but the widespread exposure to a risk factor (eg, coarse feed).

A. actinoides is occasionally found as a secondary invader in enzootic pneumonia of calves and seminal vasculitis in bulls.

A. israelii is primarily associated with chronic granulomatous infections in people but has also been isolated rarely from pyogranulomatous lesions in pigs and cattle. Treatment involves surgical debridement and administration of penicillin.

A. naeshundii has been isolated from suppurative infections in several animal species, the most common being aborted porcine fetuses.

A. suis causes pyogranulomatous porcine mastitis, characterized by small abscesses containing thick, yellow pus surrounded by a wide zone of dense connective tissue. Yellow "sulfur granules" may be scattered throughout the pus, as in *A. bovis* in cattle. Chronic, deep-seated abscesses may fistulate. Sows may also develop ventral subcutaneous granulomatous lesions, and occasional pyogranulomatous infections develop in lungs, spleen, kidneys, and other organs. Diagnosis is based on clinical signs and on isolation and identification of the etiologic agent. Treatment is rarely successful, primarily due to the inability of an antibacterial agent to penetrate the infected tissue. Infected tissue may be surgically removed to salvage sows for slaughter.

A. hordeovulneris is a rare cause of canine actinomycosis, which can present with either localized abscesses or systemic infections such as pyogranulomatous pleuritis, peritonitis, visceral abscesses, or septic arthritis. A common predisposing factor is the presence of tissue-migrating foxtail grass (*Hordeum* spp) particles, and the primary route of infection appears to be via inhalation of the bacteria. History and clinical signs may contribute to the diagnosis, but demonstration of the causative agent by Gram stain and bacteriologic culture is necessary for confirmation. Treatment includes surgical debridement and/or long-term treatment with penicillin, cephalosporins, or sulfonamides. Pyothorax is frequently seen in canine actinomycosis and requires repeated drainage of the chest in addition to antimicrobial therapy.

A. viscosus causes cutaneous actinomycosis in dogs, which appears as localized subcutaneous abscesses. These usually occur secondary to perforating injuries caused by bite wounds or foreign bodies. The most common sites for abscesses are the head, neck, thorax, and abdomen. *A. viscosus* can also cause pneumonia, pyothorax, and rarely pyogranulomatous meningoencephalitis. Diagnosis may be based on history and clinical signs, including the presence of soft, grayish

white granules in the pus or exudate. Cytology (of pus or pleural fluid) is useful and will reveal gram-positive, filamentous organisms. Definitive diagnosis is based on isolation and identification of *A viscosus*. Treatment of pyothorax with penicillin,

sulfonamides, or cephalosporins may be successful if begun early in the clinical course. A successful outcome is more likely with cutaneous infections, which should also be treated with the same antimicrobials.

AMYLOIDOSES

The amyloidoses are diseases that result from errors in protein folding. When new proteins are made, their peptide chains normally fold into the correct shape. Sometimes, however, the peptide chains fold incorrectly and form highly stable β -sheets that are insoluble and resistant to proteolytic digestion. When this insoluble protein is deposited in tissues, it is called amyloid. Amyloid proteins may be deposited in a localized fashion or widely distributed throughout the body. They cause damage by displacing normal cells. If critical organs such as the kidneys, liver, or heart are extensively disrupted, the disease may be fatal. Amyloidosis can affect all domestic mammals, and minor, asymptomatic deposition of amyloid proteins is common in aged animals.

The most common form of amyloid is generated by misfolding of the major acute-phase protein, serum amyloid A (SAA). Levels of SAA in the blood climb significantly in animals with severe inflammation. If SAA fails to fold correctly, it forms a very stable protein called AA amyloid. Amyloidosis thus develops as a result of chronic inflammatory diseases, chronic bacterial infections, and malignant tumors. It is a common cause of death in horses aggressively immunized for antiserum production. AA amyloid is usually deposited in parenchymal organs, such as the spleen, where it may not cause clinical signs. If the kidneys are involved, the presence of amyloid in glomeruli may lead to severe proteinuria, eventually resulting in renal failure and death. There is no practical treatment for this form of amyloidosis, although removal of the source of inflammation may slow amyloid deposition and hence progression of the disease.

Misfolding of immunoglobulin light chains generates a second form of amyloid, AL amyloid. This commonly results from the overproduction of monoclonal light chains in animals with plasma cell tumors (myelomas). AL amyloid tends to be

deposited in mesenchymal tissues, especially nervous tissues and joints. It is rare in domestic animals.

At least 20 other proteins have been shown to misfold, form β -sheets, and become deposited in the tissues as amyloid. There are also hereditary amyloidoses, such as those described in Abyssinian cats and Chinese Shar-Pei dogs, in which mutations result in protein misfolding. Some amyloid is formed in all aged animals (senile systemic amyloidosis); eg, in aged dogs, amyloid is commonly deposited in the media of meningeal and cortical arteries. Tumorlike amyloid nodules and subcutaneous amyloid have been reported in horses.

Some forms of amyloid may be transmitted between animals. The most important of these are the transmissible spongiform encephalopathies, such as bovine spongiform encephalopathy (see p 1284) and scrapie (see p 1288). These are caused by the production of misfolded prion proteins. Indeed, even AA amyloid is somewhat transmissible, because experimental administration of small amounts of amyloid protein to an animal can accelerate its development. Cheetahs are especially prone to amyloidosis and shed an infectious form of amyloid protein in their feces.

Because of its diffuse distribution and insidious onset, amyloidosis is difficult to diagnose clinically. However, amyloidosis should be suspected if progressive renal or hepatic failure develops in animals subsequent to chronic infections or inflammation. There is no specific therapy that can prevent the development of amyloidosis or promote the resorption of fibrils. Animals with persistent inflammation should be treated to reduce the severity of their inflammatory response and hence the availability of SAA. Amyloidosis is readily recognized at necropsy and in histologic sections by its affinity for dyes such as Congo red.

ANTHRAX

(Splenic fever, Siberian ulcer, Charbon, Milzbrand)

Anthrax is a zoonotic disease caused by the sporeforming bacterium *Bacillus anthracis*. Anthrax is most common in wild and domestic herbivores (eg, cattle, sheep, goats, camels, antelopes) but can also be seen in people exposed to tissue from infected animals, to contaminated animal products, or directly to *B anthracis* spores under certain conditions. Depending on the route of infection, host factors, and potentially strain-specific factors, anthrax can have several different clinical presentations. In herbivores, anthrax commonly presents as an acute septicemia with a high fatality rate, often accompanied by hemorrhagic lymphadenitis. In dogs, people, horses, and pigs, it is usually less acute although still potentially fatal.

B anthracis spores can remain viable in soil for many years. During this time, they are a potential source of infection for grazing livestock but generally do not represent a direct risk of infection for people. Grazing animals may become infected when they ingest sufficient quantities of these spores from the soil. In addition to direct transmission, biting flies may mechanically transmit *B anthracis* spores from one animal to another. The latter follows when there have been rains encouraging a high fly hatch and reporting has been delayed on the index ranch, such that there are 4–6 moribund or dead cattle for the flies to feed on. Feed contaminated with bone or other meal from infected animals can serve as a source of infection for livestock, as can hay muddy with contaminated soil. Raw or poorly cooked contaminated meat is a source of infection for zoo carnivores and omnivores; anthrax resulting from contaminated meat consumption has been reported in pigs, dogs, cats, mink, wild carnivores, and people.

Epidemiology: Underdiagnosis and unreliable reporting make it difficult to estimate the true incidence of anthrax worldwide. However, anthrax has been reported from nearly every continent and is most common in agricultural regions with neutral or alkaline, calcareous soils. In these regions, anthrax periodically emerges as epizootics among susceptible domesticated and wild animals. These epizootics

are usually associated with drought, flooding, or soil disturbance, and many years may pass between outbreaks. During interepidemic periods, sporadic cases may help maintain soil contamination. But it is now absent from some countries in western Europe, north Africa, and east of the Mississippi in the USA.

Human cases may follow contact with contaminated carcasses or animal products. The risk of human disease in these settings is comparatively small in developed countries, partly because people are relatively resistant to infection. However, in developing countries, each affected cow can result in up to 10 human cases because of home slaughter and sanitation issues. In cases of natural transmission, people exhibit primarily cutaneous disease (>95% of all cases). GI anthrax (including pharyngeal anthrax) may be seen among human populations after consumption of contaminated raw or undercooked meat. Under certain artificial conditions (eg, laboratories, animal hair processing facilities, exposure to weaponized spore products), people may develop a highly fatal form of disease known as inhalational anthrax or woolsorter's disease. Inhalational anthrax is an acute hemorrhagic lymphadenitis of the mediastinal lymph nodes, often accompanied by hemorrhagic pleural effusions, severe septicemia, meningitis, and a high mortality rate. Of late, injection anthrax has emerged in conjunction with contaminated heroin.

The precise incidence of anthrax among animals in the USA is unknown. Throughout the past hundred years, animal infections have been seen in nearly all states, with highest frequency from the Midwest and West. Presently, anthrax is enzootic in west Texas and northwest Minnesota; sporadic in south Texas, Montana, eastern North and South Dakota; and only occasionally seen elsewhere. The annual incidence of human anthrax in the USA has declined from ~130 cases annually in the beginning of the last century to no reported cases in 2004–2005.

In addition to causing naturally occurring anthrax, *B anthracis* has been manufactured as a biologic warfare agent. *B anthracis* was used successfully as a weapon of terrorism in 2001, killing 5 people and causing disease in 22. Probably because of the method of

delivery (via mail), no known animal disease resulted from this attack. Weaponized spores represent a threat to both human and animal populations. The World Health Organization has estimated that 50 kg of *B anthracis* released upwind of a population center of 500,000 could result in 95,000 deaths and 125,000 hospitalizations. The effect on animal populations has not been estimated, but because livestock are more susceptible to *B anthracis* infection than primates, the outcome of an aerosol attack with *B anthracis* spores against livestock would result in higher and earlier mortality and morbidity rates than among a human population. Subsequent to the 1979 Severdlovsk incident, human cases were seen up to 4 km from the source, but dead sheep were noted 64 km downwind, and in villages between.

Pathogenesis: After wound inoculation, ingestion, or inhalation, spores infect macrophages, germinate, and proliferate. In cutaneous and GI infection, proliferation can occur at the site of infection and in the lymph nodes draining the site of infection. Lethal toxin and edema toxin are produced by *B anthracis* and respectively cause local necrosis and extensive edema, which are frequent characteristics of the disease. As the bacteria multiply in the lymph nodes, toxemia progresses and bacteremia may ensue. With the increase in toxin production, the potential for disseminated tissue destruction and organ failure increases. After vegetative bacilli are discharged from an animal after death (by carcass bloating, scavengers, or postmortem examination), the oxygen content of air induces sporulation. Spores are relatively resistant to extremes of temperature, chemical disinfection, and dessication. Necropsy is discouraged because of the potential for blood spillage and vegetative cells to be exposed to air, resulting in large numbers of spores being produced. Because of the rapid pH change after death and decomposition, vegetative cells in an unopened carcass quickly die without sporulating.

Clinical Findings: Typically, the incubation period is 3–7 days (range 1–14 days). The clinical course ranges from peracute to chronic. The peracute form (common in cattle and sheep) is characterized by sudden onset and a rapidly fatal course. Staggering, dyspnea, trembling, collapse, a few convulsive movements, and death may occur in cattle, sheep, or goats with only a brief evidence of illness.

In acute anthrax of cattle and sheep, there is an abrupt fever and a period of excitement followed by depression, stupor, respiratory or cardiac distress, staggering, convulsions, and death. Often, the course of disease is so rapid that illness is not observed and animals are found dead. Body temperature may reach 107°F (41.5°C), rumination ceases, milk production is materially reduced, and pregnant animals may abort. There may be bloody discharges from the natural body openings. Some infections are characterized by localized, subcutaneous, edematous swelling that can be quite extensive. Areas most frequently involved are the ventral neck, thorax, and shoulders.

The disease in horses may be acute. Signs may include fever, chills, severe colic, anorexia, depression, weakness, bloody diarrhea, and swellings of the neck, sternum, lower abdomen, and external genitalia. Death usually occurs within 2–3 days of onset.

Although relatively resistant, pigs may develop an acute septicemia after ingestion of *B anthracis*, characterized by sudden death, oropharyngitis, or more usually a mild chronic form. Oropharyngeal anthrax is characterized by rapidly progressive swelling of the throat, which may cause death by suffocation. In the chronic form, pigs show systemic signs of illness and gradually recover with treatment. Some later show evidence of anthrax infection in the cervical lymph nodes and tonsils when slaughtered (as apparently healthy animals). Intestinal involvement is seldom recognized and has nonspecific clinical characteristics of anorexia, vomiting, diarrhea (sometimes bloody), or constipation.

In dogs, cats, and wild carnivores, the disease resembles that seen in pigs. In wild herbivorous animals, the expected course of illness and lesions varies by species but resembles, for the most part, anthrax in cattle.

Lesions: Rigor mortis is frequently absent or incomplete. Dark blood may ooze from the mouth, nostrils, and anus with marked bloating and rapid body decomposition. If the carcass is inadvertently opened, septicemic lesions are seen. The blood is dark and thickened and fails to clot readily. Hemorrhages of various sizes are common on the serosal surfaces of the abdomen and thorax as well as on the epicardium and endocardium. Edematous, red-tinged effusions commonly are present under the serosa of various organs, between skeletal muscle groups, and in the subcutis.

Hemorrhages frequently occur along the GI tract mucosa, and ulcers, particularly over Peyer's patches, may be present. An enlarged, dark red or black, soft, semifluid spleen is common. The liver, kidneys, and lymph nodes usually are congested and enlarged. Meningitis may be found if the skull is opened.

In pigs with chronic anthrax, the lesions usually are restricted to the tonsils, cervical lymph nodes, and surrounding tissues. The lymphatic tissues of the area are enlarged and are a mottled salmon to brick-red color on cut surface. Diphtheritic membranes or ulcers may be present over the surface of the tonsils. The area around involved lymphatic tissues generally is gelatinous and edematous. A chronic intestinal form involving the mesenteric lymph nodes is also recognized.

Diagnosis: A diagnosis based on clinical signs alone is difficult. Confirmatory laboratory examination should be attempted if anthrax is suspected. Because the vegetative cell is not robust and will not survive 3 days in transit, the optimal sample is a cotton swab dipped in the blood and allowed to dry. This results in sporulation and the death of other bacteria and contaminants. For carcasses dead >3 days, either the nasal turbinates should be swabbed or turbinate samples removed. Pigs with localized disease are rarely bacteremic, so a small piece of affected lymphatic tissue that has been collected aseptically should be submitted. Before submission, the receiving reference laboratory should be contacted regarding appropriate specimen labelling, handling, and shipping procedures.

Bacillus anthracis, methylene blue stain of tissue smear, high power. Note the intense red stain of the large capsule of this organism. Courtesy of the Department of Pathobiology, University of Guelph.

Specific diagnostic tests include bacterial culture, PCR tests, and fluorescent antibody stains to demonstrate the agent in blood films or tissues. Western blot and ELISA tests for antibody detection are available in some reference laboratories. Lacking other tests, fixed blood smears stained with Loeffler's or MacFadean stains can be used and the capsule visualized; however, this can result in ~20% false positives.

In livestock, anthrax must be differentiated from other conditions that cause sudden death. In cattle and sheep, clostridial infections, bloat, and lightning strike (or any cause of sudden death) may be confused with anthrax. Also, acute leptospirosis, bacillary hemoglobinuria, anaplasmosis, and acute poisonings by bracken fern, sweet clover, and lead must be considered in cattle. In horses, acute infectious anemia, purpura, colic, lead poisoning, lightning strike, and sunstroke may resemble anthrax. In pigs, acute classical swine fever, African swine fever, and pharyngeal malignant edema are diagnostic considerations. In dogs, acute systemic infections and pharyngeal swellings due to other causes must be considered.

Treatment, Control, and Prevention:

Anthrax is controlled through vaccination programs, rapid detection and reporting, quarantine, treatment of asymptomatic animals (postexposure prophylaxis), and burning or burial of suspect and confirmed cases. In livestock, anthrax can be controlled largely by annual vaccination of all grazing animals in the endemic area and by implementation of control measures during epizootics. The nonencapsulated Sterne-strain vaccine is used almost universally for livestock immunization. Vaccination should be done at least 2–4 wk before the season when outbreaks may be expected. Because this is a live vaccine, antibiotics should not be administered within 1 wk of vaccination. Before vaccination of dairy cattle during an outbreak, all of the procedures required by local laws should be reviewed and followed. Human anthrax vaccines currently licensed and used in the USA and Europe are based on filtrates of artificially cultivated *B. anthracis*.

Early treatment and vigorous implementation of a preventive program are essential to reduce losses among livestock. Livestock at risk should be immediately treated with a long-acting antibiotic to stop all potential incubating infections. This is followed by vaccination ~7–10 days after antibiotic

treatment. Any animals becoming sick after initial treatment and/or vaccination should be retreated immediately and revaccinated a month later. Simultaneous use of antibiotics and vaccine is inappropriate, because available commercial vaccines for animals in the USA are live vaccines. Animals should be moved to another pasture away from where the bodies had lain and any possible soil contamination. Suspected contaminated feed should be immediately removed. Domestic livestock respond well to penicillin if treated in the early stages of the disease. Oxytetracycline given daily in divided doses also is effective. Other antibacterials, including amoxicillin, chloramphenicol, ciprofloxacin, doxycycline, erythromycin, gentamicin, streptomycin, and sulfonamides also can be used, but their effectiveness in comparison with penicillin and the tetracyclines has not been evaluated under field conditions.

In addition to therapy and immunization, specific control procedures are necessary to contain the disease and prevent its spread. These include the following: 1) notification of the appropriate regulatory officials; 2) rigid enforcement of quarantine (after vaccination, 2 wk before movement off the farm, 6 wk if going to slaughter); 3) prompt disposal of dead animals, manure, bedding, or other contaminated material by cremation (preferable) or deep burial; 4) isolation of sick animals and removal of well animals from the contaminated areas; 5) cleaning and disinfection of stables, pens, milking barns, and equipment used on livestock; 6) use of insect repellents; 7) control of scavengers that feed on animals dead from the disease; and 8) observation of general sanitary procedures by people who handle diseased animals, both for their own safety and to prevent spread of disease. Contaminated soils are very difficult to completely decontaminate, but formaldehyde will be successful if the level is not excessive. The process generally requires removal of soil.

Human infection is controlled through reducing infection in livestock, veterinary supervision of animal production and slaughter to reduce human contact with potentially infected livestock or animal products, and in some settings either pre- or postexposure prophylaxis. In countries where anthrax is common and vaccination coverage in livestock is low, people should avoid contact with livestock and animal products that were not inspected before and after slaughter. In general, consumption of meat from animals that have exhibited sudden death, meat obtained via emergency

slaughter, and meat of uncertain origin should be avoided. Routine vaccination against anthrax is indicated for individuals engaged in work involving large quantities or concentrations of *B anthracis* cultures or activities with a high potential for aerosol production. Laboratory workers using standard Biosafety Level 2 practices in the routine processing of clinical samples are not at increased risk of exposure to *B anthracis* spores. The risk for workers who come into contact with imported animal hides, furs, bone meal, wool, animal hair, or bristles has been reduced by improvements in industry standards and import restrictions. Routine preexposure vaccination is recommended for people in this group only when these standards and restrictions are insufficient to prevent exposure to anthrax spores. Routine vaccination of veterinarians in the USA is not recommended because of the low incidence of animal cases. However, vaccination may be indicated for veterinarians and other high-risk individuals handling potentially infected animals in areas where there is a high incidence of anthrax cases.

The CDC has recommended that those at risk of repeated exposure to *B anthracis* spores in response to a bioterrorism attack should be vaccinated. Those groups include some emergency first responders, federal responders, and laboratory workers. Vaccination in anticipation of a terrorist attack is not recommended for other populations.

For people, postexposure prophylaxis against *B anthracis* is recommended after an aerosol exposure to *B anthracis* spores. Prophylaxis may consist of antibiotic therapy alone or the combination of antibiotic therapy and vaccination, if vaccine is available (most human vaccines are not live). Although there is no approved regimen, the CDC has suggested that antibiotics may be discontinued after three doses of vaccine have been administered according to the standard schedule (0, 2, and 4 wk). Because of availability and ease of dosing, doxycycline or ciprofloxacin may be chosen initially for antibiotic chemoprophylaxis until the susceptibility of the infecting organism is determined. Penicillin and doxycycline are approved by the FDA for treatment of anthrax in people and have traditionally been considered the drugs of choice. Both ciprofloxacin and ofloxacin have demonstrated in vitro activity against *B anthracis*. Although naturally occurring *B anthracis* resistance to penicillin is infrequent, it is reported; resistance to other antibiotics has been noted. Antibiotics are

effective against the germinated form of *B anthracis* but are not effective against the spore form of the organism. Spores may survive in the mediastinal lymph nodes in the lungs for months without germination in nonhuman primates.

There are currently no approved vaccination regimens for postexposure prophylaxis after *B anthracis* exposures. Although postexposure chemoprophylaxis using antibiotics alone has been effective in animal models, the definitive length of treatment remains unclear. Antibiotic chemoprophylaxis may be switched to penicillin VK or amoxicillin in children or pregnant women once antibiotic susceptibilities are known and the organism is found to be susceptible to penicillin. The safety and efficacy of anthrax vaccine in children or pregnant women has not been studied; therefore, a recommendation for use of vaccine in these groups cannot be made. Although the shortened vaccine regimen has been effective when used in a postexposure regimen that includes antibiotics, the duration of protection from vaccination is not known. The existing evidence suggests that vaccine protection is adequate for

12 mo. If subsequent exposures occur, additional vaccinations may be required.

There are no definitive recommendations for postexposure prophylaxis after cutaneous or GI exposures of people to *B anthracis*. Based on the slow progression of disease, low fatality rate, and ease of antibiotic treatment of cutaneous anthrax, and the general low risk of cutaneous disease after natural exposure, postexposure prophylaxis is not recommended after direct cutaneous exposure to contaminated animals or animal products. However, immediate washing of the exposed areas is advised. Those exposed should be advised of the signs of cutaneous anthrax (ie, an inflamed but painless area with or without circumferential small vesicles, enlargement of the regional lymph nodes) and should seek medical assistance if illness develops. Because of the high fatality rate and rapid progression of GI anthrax, serious consideration should be given to initiating postexposure antibiotic prophylaxis for those who consume contaminated undercooked or raw meat. There is no current indication for vaccination after either cutaneous exposure or ingestion.

BESNOITIOSIS

Besnoitiosis (originally named globidiosis) is a cyst-forming, usually nonfatal disease caused by a number of different species of the apicomplexan protozoa *Besnoitia*. Lesions are commonly seen in the dermis and in mucous and serous membranes, as well as in other tissues. These *Besnoitia* species tend to be confined to specific animal hosts that include large and small mammals, as well as reptiles.

Etiology and Transmission: The most significant condition in domestic animals is that of cattle, in which *B besnoiti* causes economic loss through reduced milk production, infertility and sterility, skin lesions, and increased mortality; similar effects are likely with *B caprae* in goats in Africa, southern Europe, and New Zealand. Recent studies indicate that infection is being detected more commonly in cattle in Europe (ie, Spain, Portugal, Italy, Germany, Switzerland, Hungary, and Greece). *B bennetti* has been reported to be present

in donkeys in Africa, southern France, Mexico, and in a number of locations in the USA. *B bennetti* is also found in horses, especially, but not only, those living in the tropics. *B jellisoni* and *B wallacei* have been described from rodents; *B tarandi* from reindeer or caribou; *B darlingi* from lizards, opossums, and snakes; and *B sauriana* from lizards. Viscerotropic strains of *B besnoiti* have been isolated from African antelopes; and serologic evidence of infection was detected in red and roe deer. Wildlife in Australia and blue duiker, impala, and blue wildebeest in Africa have been affected; to date it has not been reported in cattle in North America. A recent addition to these species and their hosts is *B oryctofelisi* in Argentinian rabbits.

It is thought that these parasites may have both definitive and intermediate hosts, and although the cat is often named as the likely candidate for the role of definitive host, this has not yet been clearly defined for most *Besnoitia* sp. Various animals,

usually rodents or small mammals, such as woodrats and opossums, have been suggested as intermediate hosts.

These *Toxoplasma/Neospora*-like organisms multiply in endothelial, macrophage, and other cells and produce characteristic large, thick-walled cysts filled with bradyzoites. These, along with the oocyst stage in cats and the tachyzoite stage in other animals, are the infectious forms.

The true route(s) of transmission remains unclear despite many experimental and epidemiologic attempts. Experimental cyclic transmission with intestinal sexual stages in a definitive host—the cat—has been reported for *B besnoiti*, *B wallacei*, and *B darlingi*, and experimental transmission using genetically modified mice and tissue culture has been achieved with *B oryctofelisi*. Transmission of *B besnoiti* from cattle to cats has not been substantiated by subsequent studies. The suggestion that biting insects may transmit *B besnoiti* mechanically remains a possibility but has not been substantiated; *Besnoitia* spp can be transmitted artificially to suitable hosts by needle inoculation of tissues that contain cysts. Water or feed contaminated by infected cat feces are other possible routes of transmission.

Clinical Findings: Infected cattle often show no clinical signs other than a few cysts in the scleral conjunctiva or a localized, scaly, papular dermal change. Illness begins with fever followed by warm, painful swellings ventrally (anasarca). Swollen lymph nodes, diarrhea, anorexia, photophobia, rhinitis, and orchitis also are seen. Anasarca gives way to sclerodermatitis. The skin becomes hard, thick, and wrinkled and develops cracks that allow secondary bacterial infection and myiasis to develop; movement is painful. There is loss of hair and epidermis. In addition to the skin lesions, there may be focal, disseminated myositis, keratitis,

periostitis, endostitis, lymphadenitis, pneumonia, periorchitis, orchitis, epididymitis, arteritis, and perineuritis. Severely affected animals become emaciated. Although mortality is low, convalescence is slow in severe cases. Severely affected bulls can become permanently sterile. Affected animals remain carriers for life. The disease in goats is similar to that in cattle. In horses, the clinical signs are similar but tend to be less severe or invasive. Infected donkeys, which are most commonly young (<2 yr old), also present with similar signs and symptoms, which are often more severe than those seen in horses.

The appearance of cysts in the scleral conjunctiva and nasal mucosa are useful diagnostic indicators. Parasitologic diagnosis is made by finding the crescent-shaped bradyzoites in biopsies or skin/conjunctival scrapings.

Prevention and Treatment: *B besnoiti* infections are economically important to cattle owners in endemic areas because of mortality (although usually <10%), sterility (which may be temporary or permanent), loss of condition, lower market value, and damage to the hide.

Although the route of transmission remains unclear, cattle are usually isolated and protected from biting insects and ticks to reduce transmission, and then treated symptomatically. In some countries, cattle are immunized with a live, tissue culture-adapted vaccine. Chemotherapy remains very limited and only minimally effective. Both antimony and sulfanilamide complex prevented cyst development by *B besnoiti* in rabbits, and oxytetracycline may have some therapeutic value if given early in the disease course. Clindamycin has been used to treat cats, but this has no positive effect on the stages present in other animals. Ponazuril has been found to be generally ineffective in infected donkeys.

CHLAMYDIOSIS

Bacteria of the order Chlamydiales are ubiquitous, obligate intracellular gram-negative bacteria. Within the host cell, they replicate via a unique developmental cycle competing with the host for intracellular nutrient pools. Virtually any chlamydial

organism can infect any eukaryotic host cell, resulting in various infections.

Chlamydial taxonomy with two genera, *Chlamydia* and *Chlamydophila*, was proposed in 1999 but is no longer valid. A single genus, *Chlamydia*, is now used, as

well as nine species (*abortus*, *caviae*, *felis*, *muridarum*, *pecorum*, *pneumoniae*, *psittaci*, *suis*, and *trachomatis*). Genome comparison revealed a high level of sequence conservation and synteny across taxa with the major exception of the human pathogen *C trachomatis*. Two additional new species have been discovered recently, ie, *C avium* and *C gallinacea*.

Etiology and Epidemiology: Traditional classification of chlamydiae was based on host and/or disease association, without a high degree of consistency. Different efficiencies in infectivity and replication determine consistent, but not absolute, associations between chlamydial strain, host, and disease manifestation. The *Chlamydia* species known so far were traditionally attributed to their main hosts.

C abortus (formerly *C psittaci* serotype 1) is an agent causing primarily abortion in small ruminants, mainly sheep (ovine enzootic abortion, now ovine chlamydiosis; see p 1338) and goats (see p 1340). *C caviae* was found in guinea pigs and was related to ocular and urogenital infections. *C felis* is associated with acute or chronic conjunctivitis (see p 506), rhinitis, and bronchopneumonia in both stray and domestic cats. *C muridarum* was isolated from a mouse colony with pneumonia. Infections with *C pecorum* are ubiquitous in cattle herds with multiple organ manifestations (see also ABORTION IN LARGE ANIMALS, p 1332). *C pneumoniae* is a respiratory pathogen in people and is involved in community-acquired respiratory tract infections as well as exacerbations of chronic obstructive airway diseases. *C psittaci* is the causative agent of avian chlamydiosis (see p 2808), formerly called psittacosis or ornithosis in psittacine birds or poultry/fowl, respectively. In swine, *C suis* (former porcine serovar of *C trachomatis*) is the most prevalent chlamydial agent that might be involved in multiple infection sites of the body. *C trachomatis* causes a variety of diseases in people, such as trachoma, urogenital infection, and lymphogranuloma venereum. With respect to the two new species, *C avium* has already been identified as a pathogen in pigeons and in psittacines, whereas the role of *C gallinacea* in poultry has yet to be defined.

With the availability of molecular diagnostic tools, the presence of chlamydiae has been frequently noticed in clinically inconspicuous animals (pets and farm animals). Epidemiologic data indicate that chlamydial infections are disseminated worldwide, but the epidemiologic importance of these findings is still unknown.

Transmission and Zoonotic Risk:

Recent studies indicate that host specificity of different species is not as clear as previously thought. Most members of the genus *Chlamydia* have shown to be transmissible among species, including people. Zoonotic transmission from animals to people is well known for *C psittaci*, *C abortus*, and *C felis*. Conversely, chlamydial species of people have been detected in numerous animal species.

Transmission of avian *C psittaci* strains to people may result in atypical pneumonia or even life-threatening acute illness (ie, psittacosis in people). Transmission between companion parrots and dogs or cats, respectively, has also been associated with clinical cases. Furthermore, *C psittaci* has been found in numerous other mammalian species (eg, cattle, swine, horses, small ruminants, rodents, wildlife). An association between *C psittaci* genotypes with host species has recently been detected, but the pathogenetic relevance as well as the zoonotic potential of non-avian *C psittaci* strains have yet to be defined.

C abortus may cause abortion and fetal death in pregnant women after transmission from goats or sheep. It has also been found in other animals (cattle, swine, wild suidae, horses, and birds). Zoonotic risks resulting from these hosts and the role of this pathogen in these hosts are unknown.

Natural transmission of *C felis* mostly occurs through close contact with other infected cats, their aerosol, and fomites, but the pathogen has also been found in dogs. With respect to people, there is clear evidence that *C felis* acquired from cats may occasionally cause keratoconjunctivitis. Reports are rare, attributing this pathogen to serious systemic disease or atypical pneumonia.

The known human pathogen *C pneumoniae* was detected in cats with conjunctivitis and also infects koalas, horses, and frogs. *C trachomatis*, the other human pathogen, was found in pigs and birds so far.

The risk of zoonotic transmission of other chlamydial species found in numerous animal species beside their main hosts, including the two new species *C avium* and *C gallinacea*, has yet to be defined.

Clinical Findings: Chlamydial infections do not present a typical clinical picture. In general, they affect multiple organs and can generate a variety of clinical manifestations, ranging from acute to chronic inflammation and from a severe to a mild or even subclinical course. Because aerosol

transmission of the pathogen is one of the main infection routes, the respiratory system is often involved.

In birds, avian chlamydiosis is accompanied by conjunctivitis, serositis, fibrinopericarditis, hepato- or splenomegaly, anemia, and leukocytosis or monocytosis. Dogs infected by *C psittaci* (most likely transmitted from birds) present a clinical picture of bronchopneumonia that may include fever and dry cough, but also keratoconjunctivitis, GI signs (vomiting, diarrhea), and even neurologic signs. In cats, infections with *C felis* clinically result in rhinitis, conjunctivitis, and/or bronchopneumonia, but seropositive cats are often asymptomatic. Lambs delivered by ewes with *C abortus* infection may develop acute chlamydial pneumonia. They become febrile, lethargic, and dyspneic and develop a serous and later mucopurulent nasal discharge.

In cattle and pigs, chlamydial infections must be regarded as widespread but often underdiagnosed. Chlamydiae detected so far in cattle herds include mainly *C pecorum*, but also *C abortus*, *C psittaci*, and *C suis*. In pig herds, *C suis* dominates, but *C psittaci*, *C abortus*, *C pecorum*, and even *C trachomatis* have been found in parallel. Mixed infections are common in herds and even in individual animals. Clinical pictures of bovine and porcine chlamydioses are highly variable, although most infections remain clinically inapparent. Current knowledge suggests these infections manifest clinically when they coincide with additional risk factors. In acute infection, clinical symptoms include fever and depression. Respiratory disorders may affect upper airways as well as the lower respiratory tract and result in pneumonia with the typical signs (nasal secretions, dry hacking cough, and dyspnea). In reproducing cows and sows, chlamydial infections might be associated with abortion, disorders in fertility, and mastitis. Other disease manifestations of acute chlamydiosis include enteritis and diarrhea, polyarthritis (see p 1065), keratoconjunctivitis, encephalomyelitis (see p 1308), pericarditis, or hepatitis. In chlamydia-positive herds, newborns are free of chlamydiae but start to acquire chlamydial infections within 2 wk of birth. Thus, young animals develop more clinical signs than older ones.

Equine chlamydiosis has been described as variable. Bronchopneumonia may be accompanied by abortions in mares, polyarthritis in foals, hepatitis, and fatal cases of encephalomyelitis. Recent data indicate a role of *C psittaci* and/or

C abortus in equine recurrent airway obstruction as trigger factors of inflammation or indicators of severe disease.

Based on serologic data, most chlamydial infections in farm animals do not necessarily result in clinical illness. However, they may lead to chronic-persistent or recurrent chlamydial infections on a subclinical level. Because of the potential role of chlamydiae as bystanders, copathogens, or etiologic agents of latent persisting infections, clinically inapparent chlamydial infections are probably economically more important than rare outbreaks of severe chlamydial disease.

Lesions: Acute pulmonary lesions include bronchiolitis, severe focal pneumonia, and dystelektases. Dissemination of chlamydial bodies in lung tissue is usually accompanied by an influx of macrophages, granulocytes, and activated T cells. Pulmonary edema may occur. Disturbances in gas exchange and acid-base status (hypoxemia and/or respiratory acidosis) or even acute respiratory distress are attributed to multiple disorders in pulmonary functions.

Bronchointerstitial pneumonia and alveolitis may be accompanied by progression to type II pneumocyte hyperplasia and interstitial thickening due to ingress of mixed inflammatory cells. Lymphocytic aggregates are frequently seen around airways and pulmonary vessels.

In chronic (often subclinical) chlamydial infections, macroscopic examination of the respiratory tract reveals only mild lesions or a few foci of atelectasis, predominantly affecting the apical lobes. Histologic lesions may include neutrophil inflammation, follicular bronchiolitis, and active lymphoid tissues (tonsils, tracheobronchial and pulmonary lymph nodes, etc). Both activated bronchus-associated lymphoid tissue of bronchioles (bronchiolar cuffing) and hyperplastic bronchial and bronchiolar epithelium contribute to chronic small airway obstruction and persistent airflow limitation.

Diagnosis: Neither clinical signs nor lesions allow a definitive diagnosis of chlamydiosis. Detection of *Chlamydia* species is not part of routine veterinary bacteriologic diagnosis, and infections caused by these intracellular pathogens have long been underestimated because of the requirement for special laboratory facilities. Isolation of the pathogen strictly depends on cell culture techniques.

Confirmation of chlamydial infection requires collection of an appropriate clinical sample from the animal, followed by direct

detection of the organism using a suitable diagnostic test. In vivo, swabs (nasal, ocular, rectal, vaginal), tracheal washing, or bronchoalveolar lavage fluid are useful. Chlamydial inclusion bodies may be detected in affected tissues. Appropriate tests include direct impression smears and cytologic staining, cell culture isolation of the agent, immunofluorescence tests, and nucleic acid amplification-based tests (PCR and microarray techniques).

Because most chlamydial infections do not elicit sufficiently high changes in antibody levels, serologic detection is generally more suitable for prevalence surveys than for the retrospective diagnosis of chlamydial infection. Species-specific serologic tests are still lacking. Most commercially available ELISA methods may detect infections caused by the family Chlamydiaceae but do not differentiate between chlamydial species. Sensitivity and specificity of these serologic tests are much lower than direct detection of the antigen by PCR.

Prevention and Treatment: The classic concept of prophylactic immunization that

elicits sterilizing immunity and virtually 100% protection from disease does not apply to chlamydiae. However, therapeutic vaccination may nevertheless provide substantial health and economic benefits. To prevent abortion in small ruminants, *C. abortus* live vaccines are available. There is, however, an ongoing and controversial discussion whether the vaccine strain might even be involved in enzootic abortion. Vaccines against *C. felis* are available for pet cats, but little has been reported about their efficacy.

Several antimicrobials (eg, tetracyclines, quinolones, macrolides, lincosamides, rifamycins) can interfere with chlamydial replication. Tetracyclines or fluoroquinolones (eg, enrofloxacin) are generally the drugs of choice. Treatment must start as early as possible and continue for at least 7 days.

No antibiotic treatment for chlamydiae is bactericidal. It is suspected that antibiotics frequently induce persistent chlamydial infections by reducing antichlamydial immunity due to suppression of antigen production while not completely eliminating chlamydiae.

CLOSTRIDIAL DISEASES

Clostridia are relatively large, anaerobic, sporeforming, rod-shaped, gram-positive organisms. They are found either as living cells (vegetative forms) or as dormant spores. Their natural habitats are soils and intestinal tracts of animals, including people. Dormant spores of several clostridial species have been found in healthy muscular tissue of horses and cows. The endospores are oval, sometimes spherical, and are located centrally, subterminally, or terminally. The vegetative forms of clostridia in tissue fluids of infected animals occur singly, in pairs, or rarely in chains. Differentiation of the various pathogenic and related species is based on cultural characteristics, spore shape and position, biochemical reactions, and the antigenic specificity of toxins or surface antigens. The genomes of many clostridia have been sequenced and are available online. Pathogenic strains or their toxins may be acquired by susceptible animals by either wound contamination or ingestion. Diseases thus produced are a

constant threat to successful livestock production in many parts of the world.

Clostridial diseases can be divided into two categories: 1) those in which the organisms actively invade or when locally dormant spores are activated and reproduce in the tissues of the host, with the production of toxins that enhance the spread of infection (the gas-gangrene group, the clostridial cellulitides group); and 2) those characterized by toxemia resulting from the absorption of toxins produced by organisms within the digestive system (the enterotoxemias), in devitalized tissue (tetanus), or in food or carrion outside the body (botulism). Clostridial diseases are not spread from animal to animal.

BACILLARY HEMOGLOBINURIA

(Red water disease)

Bacillary hemoglobinuria is an acute, infectious, toxemic disease caused by *Clostridium haemolyticum*. It affects

primarily cattle but has also been found in sheep and rarely in dogs. It occurs in the western part of the USA, along the Gulf of Mexico, in South America, Great Britain, the Middle East, India, Japan, and other parts of the world.

Etiology: *C haemolyticum* is a soilborne organism naturally found in the GI tract of some cattle. It can survive for long periods in contaminated soil or in bones from carcasses of infected animals. After ingestion, latent spores ultimately become lodged in the liver. The incubation period is extremely variable, and onset depends on the presence of a locus of anaerobiosis in the liver. Such a nidus for germination is most often caused by liver fluke (*Fasciola hepatica*) infection, rarely by high nitrate content of the diet, accidental liver puncture, liver biopsy, or any other cause of localized necrosis. When conditions for anaerobiosis are favorable, the spores germinate, and the resulting vegetative cells multiply and produce β toxin (phospholipase C). This causes intravascular hemolysis, resulting in hemolytic anemia and hemoglobinuria.

Clinical Findings: Cattle may be found dead without premonitory signs. Usually, there is a sudden onset of severe depression, fever, abdominal pain, dyspnea, dysentery, and hemoglobinuria. Anemia and jaundice are present in varying degrees. Edema of the brisket may occur. Hgb and RBC levels are quite low. The duration of clinical signs varies from ~12 hr in pregnant cows to ~3–4 days in other cattle. Mortality in untreated animals is ~95%. Some cattle suffer from subclinical attacks of the disease and thereafter act as immune carriers.

Lesions: Dehydration, anemia, and sometimes subcutaneous edema are seen. There is bloody fluid in the abdominal and thoracic cavities. The lungs are not grossly affected, and the trachea contains bloody froth with hemorrhages in the mucosa. The small intestine and occasionally the large intestine are hemorrhagic; their contents often contain free or clotted blood. An ischemic infarct in the liver is characteristic; it is slightly elevated, lighter in color than the surrounding tissue, and outlined by a bluish red zone of congestion. The kidneys are dark, friable, and usually studded with petechiae. The bladder contains purplish red urine. After death, rigor mortis sets in quickly.

Diagnosis: The general clinical picture and postmortem findings usually permit a

tentative diagnosis. The most striking sign is the typical port-wine-colored urine, which foams freely when voided or on agitation. The presence of the typical liver infarct is sufficient for a presumptive diagnosis. The normal size and consistency of the spleen serve to exclude anthrax and anaplasmosis. Bracken fern poisoning and leptospirosis also should be considered. Diagnosis can be confirmed by isolating *C haemolyticum* from the liver infarct, but the organism is difficult to culture. Rapid and accurate diagnosis can be made by demonstrating the organism in the liver tissue by a fluorescent antibody or immunohistochemical test or by demonstrating the toxin in the fluid in the peritoneal cavity or in a saline extract of the infarct. PCR has also been used to diagnose clinical bacillary hemoglobinuria in a cow in Japan.

Control: Early treatment with penicillin or tetracyclines at high doses is essential. Whole blood transfusions and fluid therapy also are helpful early in the disease. *C haemolyticum* bacterin prepared from whole cultures confers immunity for ~6 mo. In areas where the disease is seasonal, one preseasonal dose is usually adequate; where the disease occurs throughout the year, semiannual vaccination is necessary. Cattle in contact with animals from areas where this disease is endemic should be vaccinated, because the latter may be carriers.

BIG HEAD

(Swollen head)

Big head is an acute, infectious disease, caused by *Clostridium novyi*, *C sordellii*, or rarely *C chauvoei*, characterized by a nongaseous, nonhemorrhagic, edematous swelling of the head, face, and neck of young rams. This infection is initiated in young rams by fighting or continual butting of one another. It has also been associated with the practice of dipping immediately after shearing. The bruised and battered subcutaneous tissues provide conditions suitable for growth of pathogenic clostridia, and the breaks in the skin offer an opportunity for their entrance. Treatment is with broad-spectrum antibiotics or penicillin.

BLACKLEG

Blackleg is an acute, febrile, highly fatal disease of cattle and sheep caused by *Clostridium chauvoei* and characterized by emphysematous swelling, commonly affecting heavy muscles (clostridial myositis). It is found worldwide.

Etiology: *C chauvoei* is found naturally in the intestinal tract of animals. Spores remain viable in the soil for years and are purported to be a source of infection. Outbreaks of blackleg have occurred in cattle on farms in which recent excavations have occurred or after flooding. The organisms probably are ingested, pass through the wall of the GI tract, and after gaining access to the bloodstream, are deposited in muscle and other tissues (spleen, liver, and alimentary tract) and may remain dormant indefinitely.

In cattle, blackleg infection is endogenous. Lesions develop without any history of wounds, although bruising or excessive exercise may precipitate disease in some cases. Commonly, the animals that contract blackleg are of the beef breeds, in excellent health, and gaining weight. Outbreaks occur in which a few new cases are found each day, sometimes for several days. Most cases are seen in cattle from 6–24 mo old, but thrifty calves as young as 6 wk and cattle as old as 10–12 yr may be affected. The disease usually occurs in summer and fall and is uncommon during the winter. Interestingly, in sheep, the disease is almost always the result of a wound infection and often follows some form of injury such as shearing cuts, docking, crutching, or castration. The case fatality rate approaches 100%. In New Zealand, blackleg is seen more frequently in sheep.

Clinical Findings and Lesions: Usually, onset is sudden, and a few cattle may be found dead without premonitory signs. Acute, severe lameness and marked depression are common. Initially, there is a fever but, by the time clinical signs are obvious, body temperature may be normal or subnormal. Characteristic edematous and crepitant swellings develop in the hip, shoulder, chest, back, neck, or elsewhere. At first, the swelling is small, hot, and painful. As the disease rapidly progresses, the swelling enlarges, there is crepitation on palpation, and the skin becomes cold and insensitive with decreased blood supply to affected areas. General signs include prostration and tremors. Death occurs within 12–48 hr. In some cattle, the lesions are restricted to the myocardium and the diaphragm.

Diagnosis: A rapidly fatal, febrile disease in well-nourished young cattle, particularly of the beef breeds, with crepitant swellings of the heavy muscles suggests blackleg. The affected muscles are dark red to black and dry and spongy, have a sweetish odor, and are infiltrated with small bubbles but little

edema. The lesions may be seen in any muscle, even in the tongue or diaphragm. In sheep, because the lesions of the spontaneously occurring type are often small and deep, they may be overlooked. Occasionally, the tissue changes caused by *C septicum*, *C novyi*, *C sordellii*, and *C perfringens* may resemble those of blackleg. At times, both *C septicum* and *C chauvoei* may be isolated from blackleg lesions, particularly when the carcass is examined ≥ 24 hr after death, which allows time for postmortem invasion of the tissues by *C sordellii*. Field diagnoses are confirmed by laboratory demonstration of *C chauvoei* in affected muscle (standard methods: culture and biochemical identification). The samples of muscle should be taken as soon after death as possible. The fluorescent antibody test for *C chauvoei* is rapid and reliable. A PCR is available and reported to be very good for clinical samples but not for environmental samples.

Control: A multivalent vaccine containing *C chauvoei*, *C septicum* and, where needed, *C novyi* antigens is safe and reliable for cattle and sheep. Calves 3–6 mo of age should be vaccinated twice, 4 wk apart, followed by annual boosters before the anticipated danger period (usually spring or early summer). In an outbreak, all susceptible cattle should be vaccinated and treated prophylactically with penicillin (10,000 IU/kg, IM) to prevent new cases for as long as 14 days. Cattle should be moved from affected pastures. Vaccine failure has been observed locally and attributed to a deficient spectrum of antigens in the vaccine. In such instances, a bacterin vaccine is produced with local, previously identified clostridial strains of *C chauvoei*.

Naive ewes should be vaccinated twice 1 mo before lambing and then with yearly boosters. In outbreaks in flocks of ewes, prophylactic penicillin and antiserum treatments are recommended. Young sheep should be vaccinated before going to pasture. Immunity in young sheep is relatively short. Clostridial vaccines are reported to create a weaker immune response in sheep and goats than in cattle. Carcasses should be destroyed by burning or buried deeply in a fenced-off area to limit heavy spore contamination of the soil.

INFECTIOUS NECROTIC HEPATITIS

(*Clostridium novyi* infection, Black disease)

Infectious necrotic hepatitis is an acute toxemia of sheep that is sometimes seen in cattle and is rare in pigs and horses.

Etiology and Pathogenesis: The etiologic agent, *Clostridium novyi* type B, is soilborne and present in the intestines and livers of herbivores; it may be present on skin surfaces and dormant in muscles and is a potential source of wound infections. Fecal contamination of pasture by carrier animals is the most important source of infection. The organism multiplies in areas of liver necrosis caused by migration of liver flukes and produces a powerful necrotizing toxin (α toxin). The disease is distributed worldwide, wherever sheep and liver flukes are both found, and is increasing in cattle where liver flukes are accidentally introduced.

C novyi has been suspected but not yet confirmed as a cause of sudden death in cattle and pigs fed high-level grain diets, and in which preexisting lesions of the liver were not detectable. The lethal and necrotizing toxins damage hepatic parenchyma, thereby permitting the bacteria to multiply and produce a lethal amount of toxin.

Clinical Findings: Usually, death is sudden with no well-defined signs. Affected animals often are 2–4 yr old, tend to lag behind the flock, assume sternal recumbency, and die within a few hours. Most cases occur in the summer and early fall when liver fluke infection is at its peak. The disease is most prevalent in well-nourished adult sheep and seems to be limited to animals infected with liver flukes. Differentiation from acute fascioliasis may be difficult, but peracute deaths of animals that show typical lesions on necropsy should arouse suspicion of infectious necrotic hepatitis.

Lesions: The most characteristic gross lesions are grayish yellow, necrotic foci in the liver along migratory tracks of the young flukes. Histologically, the liver lesions include central eosinophilic inflammation (flake induced) surrounded by coagulation necrosis with an outer rim of neutrophils. The lesion is positive for gram-positive rods. Other common findings are an enlarged pericardial sac filled with straw-colored fluid and excess fluid in the peritoneal and thoracic cavities. Usually, there is extensive rupture of the capillaries in the subcutaneous tissue, which causes the adjacent skin to turn black (hence the common name, black disease).

Control: The incidence may be lowered by reducing the numbers of *Lymnaea* spp snails, the intermediate hosts for the liver

flukes, or by otherwise reducing the fluke infection of sheep. However, these procedures are not always practical, and active immunization with *C novyi* aluminum-precipitated toxoid seems more effective and can be also performed during outbreaks. Longterm immunity is produced by one vaccination. After this, only new introductions to the flock (lambs and sheep brought in from other areas) need to be vaccinated. This is best done in early summer. Pasture contamination can be minimized by proper disposal of carcasses (burning).

MALIGNANT EDEMA

Malignant edema is an acute, generally fatal toxemia affecting all species and ages of animals and is usually caused by *Clostridium septicum*. Other clostridial species have been isolated, indicating mixed infections. Additional clostridia implicated in wound infections include *C chauvoei*, *C perfringens*, *C novyi*, and *C sordellii*. The disease occurs worldwide.

Etiology and Pathogenesis: *C septicum* is found in soil and intestinal contents of animals throughout the world. Infection ordinarily occurs through contamination of wounds containing devitalized tissue, soil, or some other tissue debilitant or through activation of dormant spores. Wounds caused by accident, castration, docking, insanitary vaccination, and parturition may become infected. Potent clostridial toxins cause local and systemic signs, often resulting in death. Local exotoxins cause excessive inflammation, resulting in severe edema, necrosis, and gangrene. Risk factors include IM injections in horses; shearing, docking, and lambing in sheep; and traumatic parturition and castration in cattle. Horses and probably cows have dormant spores present in muscle tissues.

Clinical Findings: General signs, such as anorexia, intoxication, and high fever, as well as local lesions, develop within 6–48 hr after predisposing injury or activation of dormant spores. The local lesions are soft swellings that pit on pressure and extend rapidly because of the formation of large quantities of exudate that infiltrate the subcutaneous and intramuscular connective tissue of the affected areas. The muscle in such areas is dark brown to black. Accumulations of gas in subcutaneous tissue and along muscle fascias may or may not be present. These muscle infections are extremely painful, and systemic toxemia may evolve. Extensive local sloughing of

Clostridial myonecrosis due to *C perfringens* type A in a horse. Courtesy of Dr. Henry Stämpfli.

skin and tissues is often seen in progressed states of malignant edema. Severe edema of the head of rams develops after infection of wounds inflicted by fighting. Malignant edema associated with lacerations of the vulva at parturition is characterized by marked edema of the vulva, severe toxemia, and death in 24–48 hr.

Diagnosis: Similarity to blackleg (*see* p 602) is marked, and differentiation made on necropsy is unreliable; laboratory confirmation is the only certain procedure. Horses and pigs are susceptible to malignant edema but not to blackleg. An important differential diagnosis in these species is anthrax (*see* p 593).

C septicum also causes **braxy** in sheep, a highly fatal infection characterized by toxemia and inflammation of the abomasal wall. This disease seems to be confined mostly to European sheep fed on “frosted” pasture.

Diagnosis can be confirmed rapidly on the basis of fluorescent-antibody staining of *C septicum* from a tissue smear. However, *C septicum* is an extremely active post-mortem invader from the intestine, and its presence in a specimen taken from an animal that has been dead for ≥ 24 hr is not significant. PCR can be used for direct identification and differentiation of clostridia associated with malignant edema. The presence of type III echinocytes or spherioechinocytes in blood smears may help diagnose immune-mediated hemolytic anemia associated with clostridial infections in horses. Fine-needle aspirates and Gram stain may confirm the presence of gram-positive rods before confirmation by anaerobic culture.

Control: Bacterins are used for immunization. *C septicum* usually is combined with

C chauvoei in a blackleg/malignant edema vaccine and is available in multivalent vaccines. In endemic areas, animals should be vaccinated before they are castrated, dehorned, or docked. Calves should be vaccinated at ~ 2 mo of age. Two doses 2–3 wk apart generally give protection. In high-risk areas, annual vaccination is indicated, as is revaccination after severe trauma.

Treatment with high doses of parenteral penicillin, tetracyclines, or broad-spectrum antibiotics is indicated early in the disease. Although injection of penicillin directly into the periphery of the lesion may minimize spread of the lesion, the affected tissues usually slough. Supportive therapy with NSAIDs (flunixin meglumine for cattle and horses) is recommended. Local treatment includes surgical incision of skin and fascia to allow drainage. Animals with systemic toxic signs will need supportive treatments such as IV perfusion.

BOTULISM

(Lamziekte)

Botulism is a rapidly fatal motor paralysis caused by ingestion of the toxin produced by *Clostridium botulinum* types A–G. The spore-forming anaerobic organism proliferates in decomposing animal tissue and sometimes in plant material.

Etiology: Botulism is in most cases an intoxication, not an infection, and results from ingestion of toxin in food. There are seven types of *C botulinum*, differentiated on the antigenic specificity of the toxins: A, B, C₁, D, E, F, and G. Types A, B, and E are most important in people; C₁ in most animal species, notably wild ducks, pheasants, chickens, mink, cattle, and horses; and D in cattle. In horses, the most common type in North America and Europe is type B ($>85\%$ of USA cases), and in the western USA type A has been reported in only two outbreaks, both in people, known to have been caused by type F. Type G, isolated from soil in Argentina, is not known to have been involved in any outbreak of botulism. The usual source of the toxin is decaying carcasses or vegetable materials such as decaying grass, hay, grain, or spoiled silage. Toxins of all types have the same pharmacologic action. Like tetanus toxin, botulinum toxin is a zinc-binding metalloprotease that cleaves specific proteins in synaptic vesicles. Motor neuron surface receptors vary for the different botulinum toxins, explaining some of the species differences in susceptibility to the different toxins.

The exact incidence of botulism in animals is not known, but it is relatively low in cattle and horses, probably more frequent in chickens, and high in wild waterfowl. Probably 10,000–50,000 birds are lost in most years, with losses reaching 1 million or more during the great outbreaks in the western USA. Most affected birds are ducks, although loons, mergansers, geese, and gulls also are susceptible. (See also BOTULISM IN POULTRY, p 2889.) Dogs, cats, and pigs are comparatively resistant to all types of botulinum toxin when challenged orally; however, there are recent individual case reports mentioning botulism in dogs.

Most botulism in cattle occurs in South Africa and South America, where a combination of extensive agriculture, phosphorus deficiency in soil, and *C botulinum* type D in animals creates conditions ideal for the disease. The phosphorus-deficient cattle chew any bones with accompanying bits of flesh they find on the range; if these came from an animal carrying type D strains of *C botulinum*, intoxication is likely to result. Any animal eating such material also ingests spores, which germinate in the intestine and, after death of the host, invade the musculature, which in turn becomes toxic for other cattle. Type C strains also cause botulism in cattle in a similar fashion. This type of botulism in cattle is rare in the USA, although a few cases have been reported from Texas under the name of **loin disease**, and a few cases have occurred in Montana. Hay or silage contaminated with toxin-containing carcasses of birds or mammals and poultry litter fed to cattle have also been sources of type C or type D toxin for cattle ("forage botulism"). Big bale silage and haylage seem to be a particular risk and result in botulism problems if fermentation fails to produce a low and stable pH (<4.5). Botulism in sheep has been encountered in Australia, associated not with phosphorus deficiency as in cattle, but with protein and carbohydrate deficiency, which results in sheep eating carcasses of rabbits and other small animals found on the range. Botulism in horses often results from forage contaminated with type C or D toxin. In six out of eight outbreaks of equine botulism associated with type A, the source of infection was confirmed to be hay or silage.

Toxicoinfectious botulism is the name given the disease in which *C botulinum* grows in tissues of a living animal and produces toxins there. The toxins are liberated from the lesions and cause typical botulism. This has been suggested as a means of producing the **shaker foal**

syndrome. Gastric ulcers, foci of necrosis in the liver, abscesses in the navel and lungs, wounds of the skin and muscle, and necrotic lesions of the GI tract are predisposing sites for development of toxicoinfectious botulism. This disease of foals and adult horses appears to resemble "wound botulism" in people. Type B toxin is often implicated in botulism in horses and foals in the eastern USA. Toxicoinfection is also suggested as a cause of equine grass sickness (equine dysautonomia, see p 1257).

Botulism in mink usually is caused by type C strains that have produced toxin in chopped raw meat or fish. Type A and E strains are occasionally involved. Botulism has not been reported in cats but occurs sporadically in dogs. Type C toxin is usually responsible, but there have been reports in which type D was incriminated.

Clinical Findings and Lesions: The signs of botulism are caused by flaccid muscle paralysis and include progressive motor paralysis, disturbed vision, difficulty in chewing and swallowing, and generalized progressive paresis. Death is usually due to respiratory or cardiac paralysis. The toxin prevents release of acetylcholine at motor endplates (neuromuscular junction). Passage of impulses down the motor nerves and contractility of muscles are not hindered. No characteristic gross and histologic lesions develop, and pathologic changes may be ascribed to the general paralytic action of toxin, particularly in the muscles of the respiratory system, rather than to the specific effect of toxin on any particular organ.

Epidemics have occurred in dairy herds in which up to 65% of adult cows developed clinical botulism and died 6–72 hr after the onset of recumbency. Major clinical findings included drooling, decreased tongue tone, dysphagia, inability to urinate, and sternal recumbency that progressed to lateral recumbency just before death. Skin sensation is usually normal, and withdrawal reflexes of the limbs are weak. Initially, clinical signs resemble second-stage parturient paresis (see p 988), but the cows do not respond to parenteral calcium therapy.

Reported clinical signs in horses are very similar, with progressive muscle paresis, recumbency, dysphagia, and decreased muscle tone (tail, tongue, jaw), respiratory distress, and death.

In the shaker foal syndrome, foals are usually <4 wk old. They may be found dead without premonitory signs; most often, they exhibit signs of progressive symmetric motor

paralysis. Stilted gait, muscular tremors, and the inability to stand for >4–5 min are salient features. Other clinical signs include dysphagia, constipation, mydriasis, and frequent urination. As the disease progresses, dyspnea with extension of the head and neck, tachycardia, and respiratory arrest occur. Death ensues most often 24–72 hr after the onset of clinical signs due to respiratory failure. The most consistent necropsy findings are pulmonary edema and congestion and excessive pericardial fluid, which contains free-floating strands of fibrin.

Diagnosis: Although sporadic cases of botulism often are suspected because of the characteristic motor paralysis, it is difficult to establish the diagnosis by demonstrating the toxin in animal tissues or sera or in the suspect feed. Commonly, the diagnosis is made by eliminating other causes of motor paralysis (flaccid paralysis). Filtrates of the stomach and intestinal contents should be tested for toxicity in mice, but a negative answer is unreliable. Primary supportive evidence is provided by feeding suspect material to susceptible animals. In peracute cases, the toxin may be detectable in the blood by mouse inoculation tests but usually is not detectable in the average field case in farm animals. Use of ELISA methodology for detection of the toxin makes it feasible to test large numbers of samples, increasing the chances of diagnosis confirmation. In toxicoinfectious botulism, the organism may be cultured from tissues of affected animals.

Treatment and Control: Any dietary deficiencies in range animals should be corrected and carcasses disposed of, if possible. Decaying grass or spoiled silage should be removed from the diet. Immunization of cattle with types C and D toxoid has proved successful in South Africa and Australia. Toxoid is also effective in immunizing mink and has been used in pheasants.

Botulinum antitoxin has been used for treatment with varying degrees of success, depending on the type of toxin involved and the species of host. Treatment of ducks and mink with type C antitoxin is often successful; however, such treatment is rarely used in cattle. Early administration of antitoxin (type B) specific or polyvalent to foals before recumbency (30,000 IU, IV) is reported to be successful. Supportive care in valuable animals is essential; prognosis is poor in recumbent animals. In endemic areas (eg, Kentucky), vaccination with type B toxoid appears to be effective.

CLOSTRIDIUM DIFFICILE AND C PERFRINGENS INFECTIONS

Clostridium difficile is a large, gram-positive, anaerobic, spore-forming motile rod and is the major cause of antibiotic-associated colitis in people. *C difficile*-associated diarrhea and disease develops spontaneously in a variety of other species including horses, pigs, calves, dogs, cats, hamsters, guinea pigs, rats, and rabbits. *C difficile* produces protein toxins A, B, and/or the binary toxin CDT in the intestine. Toxin A is an enterotoxin that causes hypersecretion of fluid into the intestinal lumen and also causes tissue damage. Toxin B is a potent cytotoxin that induces inflammation and necrosis. The mechanism of action of CDT is not known. Disruption of colonic microflora together with the presence of toxigenic *C difficile* strains that overgrow in the intestines are the prerequisites for disease. Diagnostic tests for *C difficile* toxins include cell cytotoxicity assays and ELISA on fecal samples, anaerobic culture, and PCR to discriminate between toxigenic and nontoxigenic strains. *C perfringens* is widely distributed in the soil and the GI tract of animals and is characterized by its ability to produce potent exotoxins, some of which are responsible for specific enterotoxemias. Five types (A, B, C, D, and E) have been identified and produce one or more of four major toxins (alpha, beta, epsilon, and iota). *C perfringens* type A is most common and the most variable strain in toxigenic properties. Alpha toxin production is associated with gas gangrene, traumatic infections, avian and canine necrotic enteritis, colitis in horses, and diarrhea in pigs. *C perfringens* types B and C cause severe enteritides, dysentery, toxemia, and high mortality in young lambs, calves, pigs, and foals (beta toxin). Type C causes enterotoxemia in adult cattle, sheep, and goats. The diseases are listed below, categorized as to cause and host.

Clostridia-associated Enterocolitides in Horses

Clostridium difficile and *C perfringens* have been implicated in this acute, sporadic disease of horses characterized by diarrhea and colic. Because of uncertainty about the etiology, the condition has also been referred to as idiopathic colitis, but there is now good evidence that these organisms are responsible for enterocolitis in horses in approximately 20%–30% of cases of acute diarrhea. (See also p 285.)

Etiology: *C difficile* may be found in low concentrations in the feces of as many as 10% of healthy horses. *C difficile* and *C perfringens* organisms may be present in soil or the environment and be ingested by horses. The factors that trigger disease are not well known, but it is presumed that some alteration in the normal flora permits excessive multiplication of the bacteria, which produce toxins capable of causing intestinal damage and systemic effects.

Predisposing factors that have been suggested include change in diet and antibiotic therapy. Other host factors that may determine whether disease develops include age, immunity, and presence or absence of intestinal receptors for the clostridial toxins. Recent antibiotic therapy is a common feature of the history of horses with *C difficile*-induced diarrhea. Certain antibiotics, notably macrolides and especially erythromycin ethylsuccinate, β -lactam antibiotics, and trimethoprim/sulfonamide, are more likely than others to be associated with *C difficile* colitis. Mares with foals that are being treated with erythromycin ethylsuccinate appear to be at high risk. Elimination of roughage from the diet before surgery is also reported to predispose to *C difficile* colitis. Acute diarrhea has been reproduced in healthy neonatal foals using *C difficile* spores and vegetative cell forms. Acute anterior enteritis (duodenitis-jejunitis, *see* p 285) has also been associated with *C difficile* in a case-control study.

C perfringens type A is believed to cause diarrhea by elaboration of an enterotoxin (CPE), which is released during sporulation and stimulates intestinal epithelial cells to secrete excess fluid into the lumen. A novel necrotizing toxin, called β_2 , produced by some strains of *C perfringens*, has recently been strongly associated with colitis in horses.

Clinical Findings: Foals and adult horses may be affected. Typically, there are signs of abdominal pain and diarrhea with or without blood. There may be abdominal distention, especially in cases of *C difficile*-induced diarrhea. Dehydration, toxemia, and shock may develop, and the mortality rate is variable. One or several animals on a farm may be affected. Horses with anterior enteritis have associated severe recurrent nasogastric reflux, fever, and malaise.

Lesions: The characteristic lesion is a necrotizing enterocolitis-typhlitis. There is severe loss of colonic and cecal mucosal epithelial cells, hemorrhagic colitis and typhlitis, and thrombosis in capillaries of

the intestinal mucosa. Horses with anterior enteritis will mostly have hemorrhagic duodenitis.

Diagnosis: Clinical features of the disease are similar to those of acute salmonellosis (*see* p 195), Potomac horse fever (*see* p 283), or monocytic ehrlichiosis. The identification of *C perfringens* as the cause of diarrhea in horses depends on demonstration of the presence of enterotoxin or the gene for CPE in the feces or intestinal fluid and the absence of other likely etiologic agents. Most *C perfringens* found in the intestine of horses lack the gene for CPE expression. Large numbers of *C perfringens* in anaerobic fecal culture of horses with diarrhea is not diagnostically significant. The diagnosis of *C difficile* diarrhea is suggested by a history of recent treatment with antibiotics and is supported by demonstration of the presence of *C difficile* toxin A and/or B in a freshly passed or frozen fecal sample submitted to a laboratory using a human ELISA validated in horses, with good sensitivity and specificity. The toxin gene may be identified by PCR ribotyping.

Control: Steps may be taken to reduce the opportunity for *C difficile* infections in horses. Proper isolation procedures and infectious disease control should be applied to high-risk horses receiving antibiotics. The environmental load of *C difficile* spores may be reduced by surface disinfection with sporicidal disinfectants, and the spread may be reduced by hand washing and by isolation of infectious horses and foals. There are no control measures available for prevention of *C perfringens*-induced diarrhea. Oral metronidazole (15 mg/kg, tid) is recommended for treatment of either of these clostridial infections. Metronidazole might be teratogenic, so its use should be avoided if possible in pregnant mares.

Clostridium difficile in Swine

Clostridium difficile has emerged as an important cause of diarrhea in neonatal swine. In some studies, it has been identified as the second most frequent cause of diarrhea in 1- to 7-day-old pigs. Mesocolonic edema is a characteristic feature of the disease seen in almost all affected pigs, but this lesion is not pathognomonic. Diagnosis of the disease depends on detection of toxins as described for the disease in horses. Porcine, equine, bovine, and canine *C difficile* isolates may show an antimicrobial susceptibility profile overlapping that of isolates from human patients, raising the

possibility for interspecies transmission of *C. difficile*. Dormant *C. difficile* spores have been found in meat of pigs and beef cattle. Some of the ribotypes isolated were similar or identical to human pathogenic strains.

***Clostridium difficile* in Dogs**

Clostridium difficile has not been established as a primary pathogen in dogs. However, human toxigenic *C. difficile* strains have been frequently isolated from rectal swabs of dogs visiting human patients in hospitals. Human ELISA for *C. difficile* toxins does not perform well in dogs with diarrhea and has poor sensitivity and specificity. Approximately 10% of asymptomatic dogs shed toxigenic *C. difficile* in feces.

***Clostridium difficile* in Calves**

Clostridium difficile has been identified as a potential cause of diarrhea in young calves. The disease could not be reproduced in colostrum-deprived neonatal calves with spores or vegetative cells. *C. difficile* has been found in high prevalence in veal calves early in the veal production process.

***Clostridium perfringens* in Adult Cattle**

In the past few years, hemorrhagic bowel, bloody gut, or jejunal hemorrhage syndrome has emerged sporadically in individual, high-producing dairy cows in early lactation. Although no specific etiology has been established, it is assumed that *Clostridium perfringens* type A is involved, because large numbers of this clostridia may be recovered in most cases. The clinical course is peracute, with anorexia, colic, drop in milk yield, hemorrhage into the intestine, and sudden death despite aggressive supportive and surgical treatment. Gross postmortem findings include severe hemorrhage and necrosis in the intestines. Prevention consists of optimizing nutritional management and avoiding sudden feed changes. Autogenous vaccines in affected dairy herds have been tried with anecdotal success.

ENTEROTOXEMIAS

(*Clostridium perfringens* infections)

Enterotoxemia Caused by *Clostridium perfringens* Type A

Type A strains of *C. perfringens* are commonly found as part of the normal intestinal microflora of animals and lack some of the powerful toxins produced by

strains of other types. *C. perfringens* enterotoxin (CPE) is the principal toxin involved in *C. perfringens* foodborne illness and is associated with nonfoodborne diarrheal disease in different animals. *C. perfringens* also produces a necrotizing toxin associated with necrotic enteritis in poultry (see p 2802) and dogs, colitis in horses, and diarrhea in pigs. *C. perfringens* type A is implicated in a rarely occurring hemorrhagic diarrhea in dogs and has been associated with nosocomial and acquired acute and chronic diarrhea in dogs. The acute form is characterized by a necrotic enteritis in which there is massive destruction of the villi and coagulation necrosis of the small intestine. Many large, gram-positive rods are visible in fecal smears, and large numbers of *C. perfringens* type A are recovered on anaerobic culture of feces of dogs with acute diarrhea. Fecal tests are not useful in determining the cause of diarrhea, however, because of a high number of false-positive results. A commercial ELISA for CPE in dogs is quite specific. PCR for CPE gene expression in dogs is being evaluated. Type A strains from pigs with diarrhea have produced enterotoxin in vitro, and anti-enterotoxin antibodies in sows indicate that enterotoxin is produced in vivo. Enterotoxin has also been demonstrated in the feces of pigs with diarrhea but not in feces of healthy animals. *C. perfringens* isolated from pigs with diarrhea are typically nonenterotoxigenic but produce the cytotoxic β_2 toxin, which possibly plays a role in disease. Experimental disease has been produced in pigs challenged orally with *C. perfringens* type A.

Enterotoxemia Caused by *Clostridium perfringens* Types B and C

Infection with *C. perfringens* types B and C causes severe enteritis, dysentery, toxemia, and high mortality in young lambs, calves, pigs, and foals (see TABLE 1). Types B and C both produce the highly necrotizing and lethal beta toxin responsible for severe intestinal damage. This toxin is sensitive to proteolytic enzymes, and disease is associated with inhibition of proteolysis in the intestine. Sow colostrum, which contains a trypsin inhibitor, has been suggested as a factor increasing the susceptibility of young piglets. Type C also causes enterotoxemia in adult cattle, sheep, and goats.

Clinical Findings: Lamb dysentery is an acute disease of lambs <3 wk old. Many may die before clinical signs are seen, but some newborn lambs stop nursing, become

TABLE 1

ENTEROTOXEMIA CAUSED BY *CLOSTRIDIUM PERFRINGENS* TYPES B AND C

Disease	<i>C perfringens</i> Type	Host
Lamb dysentery	Type B	Lambs ≤ 3 wk old
Calf enterotoxemia	Types B and C	Well-fed calves ≤ 1 mo old
Pig enterotoxemia	Type C	Piglets in first few days of life
Foal enterotoxemia	Type B	Foals in first week of life
Struck	Type C	Adult sheep
Goat enterotoxemia	Type C	Adult goats

listless, and remain recumbent. A fetid, blood-tinged diarrhea is common, and death usually occurs within a few days. In calves, there is acute diarrhea, dysentery, abdominal pain, convulsions, and opisthotonos. Death may occur in a few hours, but less severe cases survive for a few days, and recovery is possible. Pigs become acutely ill within a few days of birth and there is diarrhea, dysentery, reddening of the anus, and a high fatality rate; most affected piglets die within 12 hr. In foals, there is acute dysentery, toxemia, and rapid death. Struck in adult sheep is characterized by death without premonitory signs.

Lesions: Hemorrhagic enteritis with ulceration of the mucosa is the major lesion in all species. Grossly, the affected portion of the intestine is deep blue-purple and appears at first glance to be an infarction associated with mesenteric torsion. Smears of intestinal contents can be examined for large numbers of gram-positive, rod-shaped bacteria, and filtrates can be made for detection of toxin and subsequent identification by neutralization with specific antisera.

Treatment and Control: Treatment is usually ineffective because of the severity of the disease but, if attempted, includes specific hyperimmune sera and oral antibiotics. The disease is best controlled by vaccination of the pregnant dam during the last third of pregnancy, initially with two vaccinations 1 mo apart and annually thereafter. When outbreaks occur in newborn animals from unvaccinated dams, antiserum should be administered immediately after birth.

Type D Enterotoxemia

(Pulpy kidney disease, Overeating disease)

This classic enterotoxemia of sheep is seen less frequently in goats and rarely in cattle. It has a worldwide distribution and affects

animals of any age. It is most common in lambs either < 2 wk old or weaned in feedlots and on a high-carbohydrate diet or, less often, on lush green pastures. The disease has been suspected in well-nourished beef calves nursing high-producing cows grazing lush pasture and in sudden death syndrome in feedlot cattle; however, supportive laboratory evidence in the latter is lacking.

Etiology: The causative agent is *C perfringens* type D. Predisposing factors are essential, the most common being the ingestion of excessive amounts of feed or milk in the very young and of grain in feedlot lambs. In young lambs, the disease usually is restricted to ewes with single lambs, because ewes with twins seldom give enough milk to allow enterotoxemia to develop. In the feedlot, the disease usually is seen in lambs switched rapidly to high-grain diets. As starch intake increases, it provides a suitable medium for overgrowth of *C perfringens*, producing epsilon toxin. The toxin causes vascular damage, particularly in capillaries of the brain. Many adult sheep carry strains of *C perfringens* type D as part of their normal intestinal microflora, which is the source of organisms that infect the newborn. Most such carriers have nonvaccinal antitoxin serum titers.

Clinical Findings: Usually, sudden deaths in the best-conditioned lambs are the first indication of enterotoxemia. In some cases, excitement, incoordination, and convulsions occur before death. Opisthotonos, circling, and pushing the head against fixed objects are common neurologic signs; frequently, hyperglycemia or glycosuria is present. Diarrhea may or may not develop. Occasionally, adult sheep are affected too, showing weakness, incoordination, convulsions, and death within 24 hr. In

goats, the course of disease ranges from peracute to chronic, with signs that vary from watery diarrhea with or without blood to sudden death. Affected calves not found dead show mania, convulsions, blindness, and death within a few hours. Subacutely affected calves are stuporous for a few days and may recover. In goats, diarrhea and nervous signs are seen, and death may occur over several weeks. Type D enterotoxemia occasionally is seen in young horses that have overeaten.

Lesions: Necropsy may reveal only a few hyperemic areas on the intestine and a fluid-filled pericardial sac. This is particularly the case in young lambs. In older animals, hemorrhagic areas on the myocardium may be found as well as petechiae and ecchymoses of the abdominal muscles and serosa of the intestine. Bilateral pulmonary edema and congestion frequently occur but usually not in young lambs. The rumen and abomasum contain an abundance of feed, and undigested feed often is found in the ileum. Edema and malacia can be detected microscopically in the basal ganglia and cerebellum of lambs. Rapid postmortem autolysis of the kidneys has led to the popular name of pulpy kidney disease; however, pulpy kidneys are by no means always found in affected young lambs and are seldom found in affected goats or cattle. Hemorrhagic or necrotic enterocolitis may be seen in goats.

Diagnosis: A presumptive diagnosis of enterotoxemia is based on sudden, convulsive deaths in lambs on carbohydrate-rich feed. Smears of intestinal contents reveal many short, thick, gram-positive rods. Confirmation requires demonstration of epsilon toxin in the small-intestinal fluid. Fluid, not ingesta, should be collected in a sterile vial within a few hours after death and sent under refrigeration to a laboratory for toxin identification. Chloroform, added at 1 drop for each 10 mL of intestinal fluid, will stabilize any toxin present. Although immunologic tests have been developed to replace the traditional mouse assay for detection of toxin, they are less sensitive. A PCR for detection of epsilon toxin gene is available for identification of the isolates as either type B or D.

Control: The method of control depends on the age of the lambs, the frequency with which the disease appears on a particular property, and the method of husbandry. If the disease is seen consistently in young

lambs, ewe immunization probably is the most satisfactory method of control. Breeding ewes should be given two injections of type D toxoid in their first year, a booster injection 4–6 wk before lambing, and each year thereafter.

Enterotoxemia in feedlot lambs can be controlled by reducing the amount of concentrate in the diet. However, this may not be economical, and immunization of all lambs with toxoid on entering the feedlot likely will reduce losses to an acceptable level. Two injections, 2 wk apart, will protect lambs through the feeding period. When aluminum-precipitated toxoids or bacterins are used, the injection should be given at such a site that the local cold abscesses, which commonly develop, can be removed easily during normal dressing and will not blemish the carcass.

TETANUS

(Lockjaw)

Tetanus toxemia is caused by a specific neurotoxin produced by *Clostridium tetani* in necrotic tissue. Almost all mammals are susceptible, although dogs and cats are relatively more resistant than any other domestic or laboratory mammal. Birds are quite resistant; the lethal dose for pigeons and chickens is 10,000–300,000 times greater (on a body wt basis) than that for horses. Horses and lambs seem to be the most sensitive of all species, with the possible exception of people. Although tetanus is worldwide in distribution, there are some areas, such as the northern Rocky Mountain section of the USA, where the organism is rarely found in the soil and where tetanus is almost unknown. In general, the occurrence of *C. tetani* in the soil, especially in cultivated soil, and the incidence of tetanus in people, horses, and lambs is higher in the warmer parts of the various continents.

Etiology and Pathogenesis: *C. tetani*, an anaerobe with terminal, spherical spores, is found in soil, especially cultivated soil, and intestinal tracts. In most cases, it is introduced into the tissues through wounds, particularly deep puncture wounds, that provide a suitable anaerobic environment. In lambs, however, and sometimes in other species, tetanus often follows docking or castration. Sometimes, the point of entry cannot be found because the wound itself may be minor or healed.

The spores of *C. tetani* are unable to grow in normal tissue or even in wounds if the

tissue remains at the normal oxidation-reduction potential of the circulating blood. Suitable conditions for multiplication occur when a small amount of soil or a foreign object causes tissue necrosis. The bacteria remain localized in the necrotic tissue at the original site of infection and multiply. As bacterial cells undergo autolysis, the potent neurotoxin is released. The neurotoxin is a zinc-binding protease that cleaves synaptobrevin, a vesicle-associated membrane protein. Usually, toxin is absorbed by the motor nerves in the area and travels retrograde up the nerve tract to the spinal cord, where it causes ascending tetanus.

The toxin causes spasmodic, tonic contractions of the voluntary muscles by interfering with the release of inhibitory neurotransmitters from presynaptic nerve endings. If more toxin is released at the site of the infection than the surrounding nerves can take up, the excess is carried off by the lymph to the bloodstream and thus to the CNS, where it causes descending tetanus. Even minor stimulation of the affected animal may trigger the characteristic tetanic muscular spasms. The spasms may be severe enough to cause bone fractures. Spasms affecting the larynx, diaphragm, and intercostal muscles lead to respiratory failure. Involvement of the autonomic nervous system results in cardiac arrhythmias, tachycardia, and hypertension.

Clinical Findings: The incubation period varies from one to several weeks but usually averages 10–14 days. Localized stiffness, often involving the masseter muscles and muscles of the neck, the hindlimbs, and the region of the infected wound, is seen first; general stiffness becomes pronounced ~1 day later, and tonic spasms and hyperesthesia become evident. Because of their high resistance to tetanus toxin, dogs and cats often have a long incubation period and frequently develop localized tetanus; however, generalized tetanus does develop in these species.

The reflexes increase in intensity, and the animal is easily excited into more violent, general spasms by sudden movement or noise. Spasms of head muscles cause difficulty in prehension and mastication of food, hence the common name, **lockjaw**. In horses, the ears are erect, the tail stiff and extended, the anterior nares dilated, and the third eyelid prolapsed. Walking, turning, and backing are difficult. Spasms of the neck and back muscles cause extension of the head and neck, while stiffness of the leg muscles causes the animal to assume a “sawhorse” stance. Sweating is common. General

spasms disturb circulation and respiration, which results in increased heart rate, rapid breathing, and congestion of mucous membranes. Sheep, goats, and pigs often fall to the ground and exhibit opisthotonos when startled. Consciousness is not affected. In dogs and cats, localized tetanus often presents as stiffness and rigidity in a limb with a wound. The stiffness progresses to involve the opposing limb and may advance anteriorly. The appearance in generalized tetanus is similar to that described for horses except that the partially open mouth with the lips drawn back (as seen in people) is usually evident. Young, large-breed dogs seem to be most commonly affected.

Usually, the temperature remains slightly above normal, but it may rise to 108°–110°F (42°–43°C) toward the end of a fatal attack. In mild attacks, the pulse and temperature remain nearly normal. Mortality averages ~80% (~50% in dogs in one study). In animals that recover, there is a convalescent period of 2–6 wk; protective immunity usually does not develop after recovery.

Diagnosis: The clinical signs and history of recent trauma are usually adequate for a clinical diagnosis of tetanus. It may be possible to confirm the diagnosis by demonstrating the presence of tetanus toxin in serum from the affected animal. In cases in which the wound is apparent, demonstration of the bacterium in gram-stained smears and by anaerobic culture may be attempted.

Treatment and Control: When administered in the early stages of the disease, curariform agents, tranquilizers, or barbiturate sedatives, in conjunction with 300,000 IU of tetanus antitoxin IV, bid, have been effective in the treatment of horses. Good results have been obtained in horses by injecting 50,000 IU of tetanus antitoxin directly into the subarachnoid space through the cisterna magna. Such therapy should be supported by draining and cleaning the wounds and administering penicillin or broad-spectrum antibiotics. Good nursing is invaluable during the acute period of spasms. The horse should be placed in a quiet, darkened box stall with feeding and watering devices high enough to allow use without lowering the head. Slings may be useful for horses having difficulty standing or rising.

The same approach as described for horses is used in treatment of dogs and cats, except that caution must be exercised in the IV administration of antitoxin, because the equine antitoxin may induce anaphylaxis. In

one study, antitoxin was given to dogs with tetanus only after an intradermal test to detect hypersensitivity reactions. In addition, all dogs received IV penicillin and some also received metronidazole orally. A combination of chlorpromazine and phenobarbital or diazepam may be used to reduce hyperesthetic reactions and convulsions.

Active immunization can be accomplished with tetanus toxoid. If a dangerous wound occurs after immunization, another injection of toxoid to increase the circulating antibody should be given. If the animal has not been immunized previously, it should be treated with 1,500–3,000 IU or more of tetanus antitoxin, which usually provides passive protection for as long as 2 wk. Toxoid should be given simultaneously with the antitoxin and repeated in 30 days. Even though it is not scientifically based, yearly booster injections of toxoid in animals are advised; in people the toxoid is given every 10 yr. The toxoid vaccination interval is currently debated among vaccine recommendations for sport horses. Mares should be vaccinated during the last 6 wk of pregnancy and foals vaccinated at 5–8 wk of age. In high-risk areas, foals may be given tetanus antitoxin immediately after birth and every 2–3 wk until they are 3 mo old, at which time they can be given toxoid. The decision to vaccinate lambs or calves depends on the prevalence of the disease in the area. All animals that have recovered from tetanus should be regularly vaccinated. Animals surviving tetanus do not build a good immunity and should be vaccinated with tetanus toxoid.

All surgical procedures should be conducted with the best possible aseptic techniques. After surgery, animals should be turned out on clean ground, preferably grass pastures. Only oxidizing disinfectants such as iodine or chlorine dependably kill the spores.

CLOSTRIDIAL VACCINES

Vaccination is frequently practiced for protection of animals against clostridial diseases. A wide variety of vaccines is available, singly or in combinations that consist of bacterins, toxoids, or mixtures of bacterins and toxoids. Single vaccination with most clostridial vaccines does not provide adequate levels of protection and must be followed by a booster dose within 3–6 wk. Vaccination of young animals does not yield adequate protective immunity until they are at least 1–2 mo old. Therefore, most vaccination strategies target the pregnant dam so that maximal immunity is transferred to the neonate in colostrum. Most commercial vaccines are inactivated and usually contain 2-, 4-, 7-, or 8-way combinations of clostridial organisms/toxoids. These should be optimally timed for provision of maximal protection at the most likely age of susceptibility.

Tetanus toxoid is commonly used as a single vaccine in horses but is often used in combination in sheep, goats, and cattle. In sheep and goats, a common combination is tetanus toxoid plus *Clostridium perfringens* types C and D. In cattle, a combination frequently used in feedlots is a 4-way vaccine that consists of killed cultures of *C chauvoei*, *C septicum*, *C novyi*, and *C sordellii* to protect against blackleg and malignant edema. A more complex clostridial vaccine that contains *C perfringens* types C and D in addition to the components of the 4-way vaccine may be used to protect cattle against enterotoxemia as well. The addition of *Chaemolyticum* extends the protection to include infectious necrotic hepatitis. The clostridial vaccines often cause tissue reactions and swelling and should therefore be administered to cattle in the neck and by the SC rather than the IM route.

CONGENITAL AND INHERITED ANOMALIES

Embryonic and fetal development are the result of a complex series of well orchestrated events. When properly accomplished, the outcome is a healthy neonate. Errors in the sequential steps of development may be followed by embryonic loss, fetal death, fetal mummification, abortion, stillbirth, birth of nonviable neonates, or birth of viable offspring with defects. When a

developmental disruption results in a deviation from normal that is present or apparent at birth, the defect is said to be congenital. Other developmental defects may not become apparent until later in life, and although the disruptive event occurred before birth, the defect is not strictly classified as congenital. Although the event or agent resulting in disrupted development

remains undefined for many recognizable congenital conditions, technologic advances in the field of teratology have identified an increasing number of specific genetic, environmental, and infectious agents as etiologic determinants of certain cases of defective fetal development.

Teratogens are agents or factors that cause development of physical defects in the embryo or fetus. The timing of teratogenic exposure influences the eventual outcome. Although zygotes, the cells resulting from the union of gametes, are relatively resistant to the effects of most teratogens, they may be affected by chromosomal alterations or aberrations that occur during the process of gametogenesis or fertilization, as well as by genetic mutations that may be passed from one or both parents. As the zygote develops into the embryo and organogenesis progresses, susceptibility to environmental teratogens and teratogenic infectious agents increases. As the conceptus ages further, the fetus becomes increasingly resistant to environmental teratogens. Late-differentiating structures such as the palate, cerebellum, and urogenital system remain at risk well into the fetal period.

Similar, and perhaps indistinguishable, defects may be induced by more than one agent. Exposure to toxic or infectious agents at critical phases of embryonic or fetal development may induce congenital anomalies that closely resemble heritable conditions. With increased awareness of the importance of inherited anomalies by breeders and breed associations, practitioners and diagnosticians must be thorough in investigating cases, to avoid failing to recognize conditions that may be heritable and to avert improperly implicating breeding lines as a cause.

Structural and functional congenital defects have been described in all domestic species. Although congenital defects are often classified or described by the body system or part primarily involved, such classification systems are complicated by frequent simultaneous involvement of multiple body systems. Even so, descriptive classifications provide a basis for comparison and allow for estimation of the time of the disruptive event relative to fetal development, and sometimes etiology (see TABLE 2).

Etiology

Identification of molecular signals that guide sequential development of organs and organ systems, coupled with molecular

diagnostic tools and genomic testing, allow a more detailed understanding of many observed congenital anomalies. It is likely that as these technologies improve, the etiology of other conditions will be clarified.

Chromosomal abnormalities occurring during gametogenesis or fertilization may result in embryo lethal anomalies or occasionally in abnormal but viable offspring. Errors in oogenesis can be associated with increased maternal age in several species and may result in failure of fertilization, reduced embryo viability, or in deficiencies expressed during fetal development. Chromosomal errors such as trisomy, in which there are three instances of a particular chromosome instead of the normal two, have been reported in veterinary medicine, and increasing availability of karyotyping and ancillary chromosomal analysis have increased recognition of these defects. Aging of gametes after suboptimal timing of insemination represents another source of chromosomal abnormality leading to errors in embryonic and fetal development. All cells of the defective embryo may be aneuploid (the presence of an abnormal number of chromosomes in a cell) or various degrees of mosaicism (the presence of two or more populations of cells with different genotypes in one individual who has developed from a single fertilized egg) may exist.

Chromosomal and epigenetic abnormalities may occur during assisted reproductive techniques that involve oocyte collection, culture, and fertilization. Bovine pregnancies resulting from somatic cell nuclear transfer or, to a lesser extent, from in vitro fertilization, are at increased risk of development of abnormal offspring syndrome due to failures in physiologic mechanisms necessary for proper fetal and placental development. These errors in development and placentation can result in fetal death, abortion, abnormally large or small birth weights, or birth of defective neonates, and are often associated with dystocia.

Inherited Defects

Inherited defects resulting from mutant genes present in breeding lines or families have been seen in all breeds. They may be expressed in typical patterns of inheritance such as the common simple autosomal recessive pattern typified by the recently described arthrogryposis multiplex anomaly of Angus cattle. Dominant defect traits are inherited as well and are sometimes selected for.

TABLE 2 SOME COMMON CONGENITAL DEFECTS OF DOMESTICATED ANIMALS

Amelia	Absence of a limb or limbs
Arthrogryposis	Persistent flexure or contracture of a joint or joints
Atresia	Absence or closure of a normal body opening or passage
Brachygnathia	Abnormally short lower jaw
Campylognathia	Curved jaw
Cheiloschisis	Abnormal division of the lip (harelip)
Cryptorchidism	Failure of the testis to descend into the scrotum
Hemimelia	Absence of all or part of the distal half of a limb
Hernia	Abnormal protrusion of an organ or portion of an organ through a defect or natural opening
Hydranencephaly	Virtual absence of cerebral hemispheres and replacement by CSF
Hydrocephalus	Abnormal fluid in the cranial vault accompanied by enlargement of the head
Kyphosis	Abnormally increased convexity of the thoracic spine
Microphthalmia	Abnormally small eye
Palatoschisis	Fissure of the palate (cleft palate)
Perosomus	Developmental anomaly characterized by a greatly deformed body or trunk
Polydactyly	Supernumerary digits
Porencephaly	The presence of cavities in the brain developed during fetal life
Prognathia	Marked projection of the lower jaw
Schistosomia	Developmental anomaly characterized by fissure of the abdominal wall
Scoliosis	Lateral deviation of the spinal axis
Syndactyly	Fusion of the digits
Thoracoschisis	Fissure of the thoracic wall, which may result in herniation of lung tissue

Some polygenetic defects require inclusion of more than one interacting gene. Rat tail syndrome, a congenital form of hypotrichosis in cattle, is controlled by genes at two interacting loci.

Because animals heterozygous for undesirable or lethal recessive traits often cannot be detected by visual examination, and sometimes exhibit a phenotype that is thought to be desirable, inadvertent selection may help spread genetic defects in a particular breed. For example, cattle heterozygous for tibial hemimelia reportedly have rear limb conformation and hair coat characteristics preferred by some breeders, and phenotypic selection of certain sires may have increased the allele

frequency in the population. Similarly, while the **Overo** color pattern is attractive to some horse breeders, animals homozygous for this color pattern are often affected with a lethal congenital anomaly due to failure of intestinal tract innervation secondary to ileocolonic agangliosis. It is recommended to include only one **Overo** parent in a mating. The dominant inheritance of polledness in dairy goats is associated with coinheritance of a recessive allele that results in masculinization of homozygous females (the so-called polled intersex goat). Restrictive breeding programs that ensure at least one member of the breeding pair has horns are recommended to avoid this defect.

Heritable defects in metabolic function may result in embryonic or fetal death, birth of nonviable neonates, or birth of compromised offspring that survive. Such defects may be lethal in utero or early in the postnatal period, or animals may survive in a compromised form. Careful observation and diagnostic evaluation are required to properly identify these conditions and link them to pedigree information.

Deficiency of monophosphate synthase (DUMPS) is a lethal autosomal recessive trait formerly widely dispersed in Holstein cattle. When breeding of two DUMPS carriers results in a homozygous embryo, apparently normal fertilization and embryonic development is followed by death of the fetus in early gestation. Screening of sires destined for use in artificial insemination has successfully reduced the incidence of DUMPS.

Citrullinemia in cattle results in disruption of the urea cycle due to arginosuccinate synthetase deficiency and is lethal in the homozygous state. Affected calves appear healthy at birth but develop increased blood ammonia concentrations and die within a few days.

Defects found on the X chromosome, such as the one responsible for canine X-linked muscular dystrophy in Golden Retrievers, Labrador Retrievers, and other breeds, are expressed in males carrying only a single copy of a defective allele. Both parents are unaffected, with the dam carrying a single copy of the defective gene on an X chromosome.

For a partial list of inherited disorders with a known molecular basis, see TABLE 3.

Use of elite genetic lines in domestic species increased with the rapid and widespread adoption of reproductive technologies, particularly artificial insemination, embryo transfer, and in vitro fertilization. Dissemination of undetected genetic recessives to a large portion of the population domestically and internationally has been an inadvertent and unintended consequence. As the percentage of animals carrying undesirable recessive traits grows, an increased opportunity for breeding genetically related individuals is followed by the expression of the undesirable phenotype. Complex vertebral malformation in Holstein-Friesian dairy cattle was spread internationally primarily due to the influence of a single Holstein sire from the USA and his offspring. Similarly, arthrogryposis multiplex in Angus cattle received international attention due to the influence of a popular bull, his offspring, and descendants. In both cases, genetic testing

developed after description of the condition provided breed associations and breeders opportunities to minimize the effects or eliminate the conditions.

By the time detrimental genetic conditions are recognized in a population or breed, the abnormal allele is often widely distributed. Early recognition and detection are desirable to minimize this possibility. All congenital anomalies should be investigated, and when a condition appears to have an underlying genetic component, appropriate techniques to assess pedigree information and identify the mutated homozygous phenotype should be explored. A structured system of reporting and recording, beginning with accurate clinical and pathologic descriptions, is necessary to centralize data and focus attention on physical and physiologic abnormalities that may be genetic in origin. Pedigree analysis and test mating of closely related animals coupled with recently developed DNA-based testing have the potential to identify specific genetic aberrations, in some cases relatively rapidly after recognition of the defect. Most breed associations have procedures to report congenital anomalies and work with pathologists, geneticists, and molecular biologists to identify emerging genetic defects.

Once known genetic recessive conditions are identified, several options exist to minimize their occurrence. For complex vertebral malformation, testing of all Holstein sires entering artificial insemination programs was chosen. Bulls were identified as being either carriers or free of the defect. The resulting decline in use of semen from carrier bulls led to a decrease in the occurrence of the condition and the allelic frequency within the breed. Other genetic recessive conditions in the same breed, including bovine leukocyte adhesion deficiency and DUMPS were handled similarly, and the recently identified brachyspina syndrome will likely be managed in the same manner. The extensive use of artificial insemination in dairy cattle allows this strategy to have a rapid impact.

In breeds or species with less use of artificial insemination, a more aggressive approach may be required. After recognition of arthrogryposis multiplex, the American Angus Association mandated testing and identification of all sires in active artificial insemination programs. They also required genetic testing to determine carrier status of all animals with suspect pedigrees submitted for registration. No certificate of registration will be issued to carrier animals born after a specified date. Similar requirements for

TABLE 3 CONGENITAL DISORDERS WITH A KNOWN MOLECULAR BASIS

Species	Disorder
Cat	Gangliosidosis (GM1, GM2) Mucopolysaccharidosis (I, VI, VII) Muscular dystrophy (Duchenne, Becker) α -Mannosidosis
Dog	C3 deficiency α -Fucosidosis Glycogen storage disease (I, VII) Hemophilia B Krabbe disease Leukocyte adhesion deficiency Mucopolysaccharidosis (I, VII) Muscular dystrophy (Becker, Duchenne [X-linked]) Myotonia Narcolepsy Nephritis, X-linked Pyruvate kinase deficiency of RBCs Rod-cone dysplasia Severe combined immunodeficiency Tremor, X linked von Willebrand disease III
Cattle	Arthrogryposismultiplex (Angus, Angus-influenced breeds) Brachyspina syndrome (Holstein) Chédiak-Higashi syndrome Complex vertebral malformation (Holstein) Citrullinemia Deficiency of uridine monophosphate synthetase (Holstein) Ehlers-Danlos syndrome (II, V) Glycogen storage disease Goiter, familial (Holstein) Leukocyte adhesion deficiency α -Mannosidosis β -Mannosidosis Maple syrup urine disease Muscular hypertrophy (Shorthorn, Maine-Anjou) Pulmonary hypoplasia with anasarca (Shorthorn) Progressive degenerative myeloencephalopathy (Brown Swiss) Protoporphyrria Spinal muscular atrophy (Brown Swiss) Syndactyly (Holstein, Angus) Tibial hemimelia (Shorthorn, Maine-Anjou)
Sheep	Ceroid lipofuscinosis Chondrodysplasia Glycogen storage disease IV
Goat	Goiter, familial β -Mannosidosis Mucopolysaccharidosis III Reduced casein concentration Polled intersex syndrome
Horse	Hyperkalemic periodic paralysis (Quarter horse, Paint, others) Megacolon Severe combined immunodeficiency (Arabians)
Pig	Hypercholesterolemia Malignant hyperthermia

animals with pedigrees tracing to carriers of neurogenic hydrocephalus have been put in place by this breed association. Extensive testing and identification of carrier individuals is used by the American Quarter Horse Association to minimize the incidence of hyperkalemic periodic paralysis.

As new genetic recessive abnormalities are identified and characterized, genetic tests to determine carrier status can be developed. Breed associations and breeders will adopt testing and identification strategies similar to those mentioned above. However, implementation of testing strategies will be more complicated for nonlethal defects and for conditions in which heterozygotes have a phenotype perceived as desirable.

Environmental Teratogens

Environmental teratogens include plant toxins, viruses, drugs, trace elements, nutritional deficiencies, and physical agents such as irradiation, hyperthermia, uterine positioning, and perhaps pressure during rectal examination for pregnancy. Although the defects produced in the neonate may resemble or mimic heritable defects, they do not follow a familial pattern. Specific causes may be difficult to identify but often follow seasonal patterns associated with growth characteristics of toxic plants or availability of suitable vectors of arthropodborne viruses. Although congenital anomalies may follow maternal disease due to plant intoxication or viral infection, teratogenic effects sometimes occur in the absence of observed clinical signs in the dam.

Biologically active products produced by many plants are known to be teratogens. (See also POISONOUS PLANTS, p.3103.) Ingestion may result in abortion, birth of nonviable neonates, or production of neonates that are abnormal at birth. Production losses can be significant if large numbers of animals gain access to affected plants at critical times in embryonic or fetal development. *Veratrum californicum* (skunk cabbage) has been implicated as a cause of fetal gigantism, prolonged gestation, and craniofacial deformities in sheep grazing rangelands containing the plant. Cyclopamine, a steroidal alkaloid compound produced by the plant, is the teratogenic agent. Experimental dosing with this toxin in ewes on day 13–15 of pregnancy can cause a variety of congenital anomalies. Ingestion on day 14 specifically induces synophthalmia or cyclopean defect. Ewes exposed later in gestation may deliver healthy lambs, illustrating the critical interaction of time of exposure and gestational age.

In cattle, ingestion of several species of lupines (*Lupinus laxiflorus*, *L. caudatus*, *L. sericeus*, or *L. nootkatensis*) has resulted in "crooked calf disease," characterized by joint contractures, torticollis, scoliosis or kyphosis, cleft palate, or combinations of these defects. The quinolizidine alkaloid anagrine is identified as the teratogen, and the critical window for exposure is 40–70 days gestational age. Ingestion of *L. formosus* causes similar skeletal defects and cleft palate in cattle and goats; the teratogen is the alkaloid piperidine. With either toxin, defects are thought to be related to an alkaloidal toxin-induced inhibition of fetal movement during critical gestational periods. Periodic losses due to lupine-induced crooked calf disease occur in the western USA after ingestion by cattle on rangeland.

Conium maculatum (poison hemlock) causes contracture defects and occasionally cleft palate in cattle, goats, sheep, and pigs. Both the plant and seed contain the teratogenic alkaloidal toxin coniine.

Ingestion of *Nicotiana tabacum* (cultivated tobacco) produces skeletal defects in pigs similar to those induced in cattle and pigs by *Lupinus* spp and *C. maculatum*. Congenital amelia and hemimelia in piglets that occurred when pregnant sows were allowed access to tobacco stalks are seldom seen today due to changes in swine management. *Nicotiana glauca* (tree tobacco) also induces contracture defects and cleft palate in cattle, sheep, and goats.

Other plants suspected of causing similar defects in calves include *Senecio* spp, *Cycadales*, *Blighia*, *Papaveraceae*, *Colchicum*, *Vinca* spp, and *Indigofera spicata* and related plants. Sudan grass (*Sorghum vulgare*) has been incriminated as a cause of congenital joint contracture in horses, and *S. sudanense* may cause arthrogryposis in calves.

Pregnant mares consuming fescue pasture or fescue hay infected with the fungal endophyte *Neotyphodium coenophialum* are at risk of abortion, prolonged gestation, hypogalactia, and delivery of weak or dysmature foals (see p.3016). Ergovaline and other ergot alkaloids produced by the endophyte are the cause of fescue toxicosis. Endophyte-free fescue and fescue infected by nontoxic strains of endophyte reportedly can be grazed safely by pregnant mares.

Congenital hypothyroidism in foals has been linked to increases of dietary nitrate concentrations in pregnant mares in western Canada and to dietary exposure of late gestation mares to *N. coenophialum*-infected fescue.

Pesticides, herbicides, pharmaceutical agents, and other chemicals have been incriminated as teratogenic agents. Currently, drugs and chemicals undergoing approval processes in the USA, Canada, and many other countries must be tested for teratogenic potential before commercial licensing. Products may be labeled with instructions to specifically avoid use in animals that are pregnant or may be pregnant. Other products may be labeled as safe for pregnant animals once the fetus exceeds a specified gestational age. When using some herbicides, it may be necessary to withhold animals from pasture for specified periods after application. Extra-label use of pharmaceutical agents in pregnant animals and inadvertent exposure to pesticides and other chemicals carries inherent risks, including adverse effects on the developing fetus. Practitioners and producers should be aware of the potential for pregnancy loss or development of congenital anomalies after administration of therapeutic agents or exposure to pesticides and chemicals and should exercise appropriate caution when using such products.

Infectious Agents

Prenatal viral infections may be teratogenic in cattle, sheep, goats, pigs, dogs, and cats but have rarely been incriminated in congenital defects in horses. The stage of fetal or embryonic development at the time of exposure determines the type and extent of the anomalies observed. Viral infection in late gestation may result in fetal infection and seroconversion without observed clinical signs, while exposure during earlier stages may induce pregnancy loss or induce congenital defects.

Production of neonates with congenital anomalies after in utero infection may follow observable clinical disease in the dam; however, anomalies are also seen without history of disease during pregnancy. On occasion, use of modified-live virus vaccines in pregnant animals has produced congenital defects; such use is discouraged.

Pestivirus infections are teratogenic in many species. Bovine viral diarrhea virus (BVDV) is among the most economically significant infectious agents affecting cattle worldwide, and prenatal infection can cause a variety of congenital defects in survivors, including cerebellar hypoplasia, brachygnathia, alopecia, ocular defects, internal hydrocephalus, and impaired immunocompetence. Immunotolerant, persistently infected animals may result from fetal infection with noncytopathic BVDV before

gestational day 120. These animals serve as a major reservoir of infection.

Pestivirus infections in other species also result in congenital defects. Infection of pregnant ewes with border disease virus (*see p 622*) may manifest as embryonic and fetal death or congenital defects involving the integumentary, nervous, skeletal, endocrine, and immune systems. Defects include tremors, ataxia, abnormal hair coat, low birth weight, facial and ocular abnormalities, depressed immune response, and birth of small, weak lambs with poor growth and viability. Infection of pregnant ewes with BVDV from cattle has produced identical congenital anomalies in sheep.

Classical swine fever (*see p 713*), a pestivirus infection of swine, was once known as hog cholera. The virus has been eradicated in the USA but remains a major cause of swine disease in some areas. Prenatal infection can result in congenital defects similar to those seen in cattle infected with BVDV.

Cache Valley virus infection of pregnant ewes may result in anomalies in their lambs, including arthrogryposis, torticollis, scoliosis, lordosis, hydranencephaly, microcephaly, porencephaly, and cerebellar and muscular hypoplasia. This bunyavirus is spread by mosquitoes and is found in the USA, Canada, and Mexico. Other ruminant species may be affected, and other bunyaviruses have been reported to cause similar congenital defects.

Bluetongue virus, an orbivirus endemic in many areas of North America, South America, Africa, and parts of Asia, has recently expanded its range in Europe. In utero exposure may induce hydranencephaly, porencephaly, and arthrogryposis in sheep, and it can result in abortion, stillbirths, arthrogryposis, campylognathia, prognathia, hydranencephaly, and "dummy calf" syndrome in cattle. Other orbiviruses such as Chuzan virus and perhaps epizootic hemorrhagic disease may cause abortion, congenital defects, and neonatal losses similar to bluetongue virus.

Akabane virus (*see below*), an orbivirus present in many tropical and subtropical areas, is spread by *Culicoides* spp (biting midges). Infection of naive animals can be followed by transplacental infection of the fetus and may produce deformities similar to those seen with viruses such as bluetongue and Cache Valley virus.

Congenital cerebellar hypoplasia in kittens has long been recognized as a result of infection of pregnant queens with feline panleukopenia virus. Infection of pregnant ferrets with feline panleukopenia virus also can result in congenital cerebellar hypoplasia.

Nutritional Factors

Deficiency of one or more nutrients during pregnancy may result in congenital defects in the newborn. Microminerals and vitamins are implicated in a variety of developmental defects. Severe deficiencies may interrupt pregnancy or result in weak or nonviable young.

Iodine deficiency may cause congenital goiter or cretinism in all species. Copper deficiency is a cause of enzootic ataxia in lambs. Manganese deficiency can result in congenital limb deformities in calves. Vitamin D deficiency may cause neonatal rickets, and vitamin A deficiency may cause eye defects or harelip. Experimentally, teratogenic effects have been induced by deficiencies of choline, riboflavin, pantothenic acid, cobalamin, and folic acid, and by hypervitaminosis A.

Physical Agents

Congenital joint contracture after birth of relatively large calves or foals, or associated with cases of twin pregnancy in these normally monotocous species, is a result of restricted motion due to uterine crowding. Many cases are mild and potentially self-correcting after birth.

Torticollis, scoliosis, and limb abnormalities in foals have been associated with intrauterine fetal positioning after transverse or caudal presentation. Pervious urachus in foals is reportedly associated with umbilical cord twisting.

In cattle, aggressive transrectal palpation of the amniotic vesicle before day 42 of gestation (eg, during pregnancy diagnosis) may disrupt vascular supply to the intestinal tract and induce atresia coli. Most cases of this malformation are seen in Holstein cattle, and a genetic predisposition may exist. At least one report suggests an autosomal recessive inheritance pattern for atresia coli.

Gestational Accidents of Unknown Etiology

In many cases of congenital anomalies, the etiology or predisposing factors remain unknown. Some specific anomalies of unknown etiology occur frequently enough to be readily recognized by veterinarians in the field.

Perosomus elumbis is a congenital anomaly that occurs primarily in cattle but also in small ruminants and swine. Affected calves have agenesis of segments of the lumbosacral spinal cord and vertebral column, with secondary hypoplasia, arthrogryposis, and ankylosis of the pelvic limbs. Other anomalies associated with

development of the GI and urogenital systems accompany this condition. The body, limbs, and organs cranial to the developmental defect in the spinal cord appear normal. The condition is fatal, resulting in stillbirth or requiring euthanasia on humane grounds. Dystocia is a frequent complication. Although there are suggestions of inheritance, no definitive cause is recognized. Aberrations in the homeobox gene family, responsible for cranial to caudal patterning, may be involved.

Schistosomus reflexus, a fatal congenital disorder seen in ruminants, is characterized by severe retroflexion of the spinal column, resulting in positioning of the hindlimbs adjacent to the skull, ankylosis of appendicular joints, and failure of closure of the abdominal wall with consequential presence of abdominal viscera outside the body. Other anomalies, including thoracoschisis, may accompany the condition. The presence of an affected fetus results in dystocia, frequently requiring surgical intervention or fetotomy. Some reports utilizing pedigree analysis suggest a genetic etiology, but no specific defect or mode of inheritance has been found. Interestingly, cases involving one affected calf and a healthy co-twin have been reported.

Fetal anasarca is a fatal anomaly seen in several breeds of dogs. The cause remains unknown and may vary from breed to breed. This condition frequently results in dystocia due to the disproportionately large fetus at term. Single or multiple pups within a litter may be affected.

AKABANE VIRUS INFECTION

Akabane is an insect-transmitted virus that causes congenital abnormalities of the CNS in ruminants. Disease due to Akabane virus has been recognized in Australia, Israel, Japan, and Korea; antibodies to it have been found in a number of countries in southeast Asia, the Middle East, and Africa. The disease affects fetuses of cattle, sheep, and goats. Asymptomatic infection has been demonstrated serologically in horses, buffalo, deer, and pigs (but not in people) in endemic areas.

Etiology, Epidemiology, and Transmission: The causal agent, Akabane virus, is an orthobunyavirus and member of the Simbu serogroup of the family Bunyaviridae. It is spread by biting midges (*Culicoides* spp) in Australia, Japan, and Kenya.

Akabane virus is common in many tropical and subtropical areas between ~35°N and 35°S. In these endemic areas,

herbivores are bitten by the vectors, become infected at an early age, and develop a long-lasting immunity by the time of breeding; thus, congenital abnormalities are seldom seen. However, under favorable environmental conditions such as an extended humid summer, the vector (and hence the virus) may spread beyond its usual range into new areas, and outbreaks of congenital infection may be expected. These outbreaks usually occur at the northern or southern limits of the vector distribution or in areas of higher altitude. Similarly, pregnant ruminants from virus- and vector-free areas moved to virus-infected areas are at risk.

The incidence of Akabane virus-induced disease is influenced by the time of gestation at which infection occurs and by the strain of virus. Infections in cattle during the last 3 mo of pregnancy result in a relatively low incidence of disease (5%–10% of calves are affected). The peak incidence is seen after infection in the third and fourth months, when up to 40% of calves may be born with defects. Some strains of Akabane virus produce a very low incidence of abnormalities (<20%) even at the most susceptible stages of gestation, whereas the most severe can cause disease in up to 80% of infected animals.

In sheep and goats, disease is seen but the distinct sequential manifestation of different abnormalities seen in cattle does not occur because of the shorter period of gestation and the shorter period of susceptibility. Most abnormalities develop after infection between days 28–56 of gestation. Few, if any, abnormalities are seen after infection at other times. However, it is not known whether infection in large or small ruminants very early in gestation results in lethal infection, with abortion of the fetus.

Clinical Findings and Lesions: The clinical signs and pathology of Akabane virus infection depend on the species of animal and time of infection. In a herd of cattle with an extended or year-round calving period, the full range of abnormalities may be seen. The most severe defects are seen after susceptible cows have been infected between ~80–150 days of gestation; however, calves can be affected at most times after the first 2 mo of gestation. Calves infected late in pregnancy may be born alive but unable to stand and may have a flaccid paralysis of the limbs, or may be incoordinated and on necropsy show a disseminated encephalomyelitis. Those infected earlier (120–180 days of gestation) have rigid fixation of limbs, usually in flexion

(arthrogryposis), and sometimes also torticollis, kyphosis, and scoliosis with associated neurogenic muscle atrophy due to loss of spinal motor neurons. These abnormalities usually cause dystocia and can result in severe obstetric complications, sometimes resulting in infertility and even death of cows. The first calves born with arthrogryposis are less severely affected than those born during the next 4–6 wk. Initially, only one or two joints may be affected on a single limb, but later cases can have severe fixation of multiple joints on several or all limbs. Calves infected at 80–120 days of gestation are usually born alive and, if able to stand, walk poorly and are depressed and blind. These calves have varying degrees of cavitation of cerebral hemispheres, ranging from porencephaly to severe hydranencephaly. The latter is common, especially among those infected in the earlier stages of pregnancy. Some calves may be affected with both arthrogryposis and hydranencephaly. Calves with severe hydranencephaly may be aborted in midgestation. A useful differential diagnostic feature is the virtual absence of either gross or histologic lesions in the cerebellum, distinguishing Akabane virus infection from other teratogenic viruses such as bovine viral diarrhea virus (BVDV, see p 267). Infrequently, strains of Akabane virus are encountered that cause disease when calves are infected in the first few weeks of life. A range of neurologic signs and pathology consistent with an acute viral encephalitis may be seen. In Japan, strains of Akabane virus that cause disease in adult cattle have also been described.

In small ruminants, the lesions of arthrogryposis and hydranencephaly are often seen concurrently and are common in the same animals. In lambs and kids, a range of other defects may occur, including pulmonary hypoplasia and hypoplasia of the spinal cord. Most Akabane-infected lambs or kids are stillborn or die soon after birth. Abortions are also seen.

Akabane virus-induced congenital abnormalities (especially arthrogryposis and hydranencephaly) have been suspected in horses, but laboratory confirmation has been inconclusive.

Diagnosis: A presumptive diagnosis can be made on the gross CNS lesions, but the disease must be differentiated from other infectious and genetic conditions. Infection can be confirmed by testing sera or body fluids (eg, pericardial or pleural fluid) from unsuckled, affected offspring and their dams for antibodies against Akabane virus. While

the detection of antibody in maternal serum does not confirm Akabane as an etiologic agent, its absence is definitive for exclusion.

Other vectorborne viruses (and also non-vectorborne viruses such as BVDV) can cause congenital defects identical to those of Akabane virus. Aino virus, a relative of Akabane, is found in Australia, Japan, and several other countries where Akabane virus is found and has been an infrequent cause of disease in cattle. In late 2011, Schmollenberg, a newly recognized orthobunyavirus, spread throughout most of western Europe and extended to the UK and also north to Scandinavian countries. This Simbu virus caused disease indistinguishable from Akabane infection in sheep, although the incidence of congenital defects was generally low compared with that caused by Akabane virus. Disease was occasionally seen in cattle but at a very low prevalence. In Japan, Chuzan virus, a reovirus, is transmitted by *Culicoides oxystoma* and causes congenital infection in calves similar to Akabane virus. In the USA, Cache Valley virus, another vectorborne bunyavirus unrelated to Akabane virus, has been associated with congenital defects in sheep and perhaps cattle in some states.

Treatment and Control: There is no specific treatment for animals affected by Akabane virus infection. Measures should be directed at the prevention of infection of susceptible animals with Akabane virus during pregnancy. Introduction of stock from nonendemic to endemic areas should be done well before first breeding. Effective vaccines are available in Japan.

BORDER DISEASE

(Hairy shaker disease)

Border disease (Britain) or hairy shaker disease (Australia and New Zealand) is a congenital disorder of lambs characterized by low birth weight and viability, poor conformation, tremor, and an excessively hairy birth coat in normally smooth-coated breeds. Goat kids may also be affected, and a similar condition occasionally occurs in calves. The disease has been recognized in most sheep-rearing areas of the world, including the western USA. There are currently seven recognized genotypes (BDV-1 to BDV-7) for the border disease virus.

Etiology, Pathogenesis, and Epidemiology: Border disease is caused by infection of the fetus in early pregnancy with a pestivirus (Flaviviridae) closely

related to the viruses of classical swine fever (see p 713) and bovine viral diarrhea/mucosal disease (see p 267). Surviving lambs are persistently viremic, and the virus is present in their excretions and secretions, including semen. Cattle, goats, and pigs are also susceptible to infection with border disease virus. Persistently infected individuals have been demonstrated in all of the aforementioned species from natural in-utero infection. Transmission of border disease virus to cattle can occur from commingled grazing with persistent or acutely infected sheep. Acute infections in immunocompetent animals are usually transient and subclinical and result in immunity to challenge with homologous but not heterologous strains of virus.

Virus acquired in early pregnancy by previously unexposed animals crosses the placenta and invades the fetus. Placentitis occurs 10–30 days after infection and may cause fetal death with expulsion, resorption, or mummification. Abortion may occur at any stage of pregnancy and may pass unnoticed because there is little maternal malaise.

In sustained pregnancies, the virus becomes widely distributed in fetal tissues, but pathologic changes are most obvious in the skin, skeleton, and CNS. Affected lambs may be born 2–3 days early, and many die before or at weaning. In survivors, the clinical signs gradually regress, but such animals remain persistently infected and excrete virus for the remainder of their lives, exposing their progeny and flockmates. Death from a syndrome similar to bovine mucosal disease may occur in these clinically “recovered” hairy-shaker sheep at any time.

In naive flocks exposed to bovine viral diarrhea virus (BVDV), up to 50% or more of lambs born may be affected with border disease. Thereafter, the prevalence declines, although the disease may become endemic when “recovered” lambs are retained for breeding. The virus is most commonly introduced into susceptible flocks by the addition of persistently infected sheep or pregnant ewes carrying an infected fetus. However, sheep can also acquire infection from transiently or persistently infected cattle. For practical purposes, it should be assumed that sheep and cattle are equally susceptible to all strains of border disease virus and BVDV, even though at least four phylogenetic groups of pestiviruses have been identified in domestic ruminants.

Clinical Findings: Affected flocks probably are recognized first at lambing time by an increase in the number of barren ewes and in the birth of undersized lambs with

excessively hairy and sometimes excessively pigmented fleece. Skeletal abnormalities that may be seen in newborn lambs include a decreased crown-rump length, shortened tibia and radius, and a shortened longitudinal axis of the cranium. Some lambs exhibit involuntary muscular tremors, particularly of the trunk and hindlegs. The tremors are reduced at rest and exacerbated by purposeful movement. In others, skeletal defects such as dropped pasterns and mandibular brachygnathia may predominate. Affected lambs have a poor survival rate. In survivors, nervous signs gradually disappear within 3–4 mo. Even in the absence of typical hairy-shaker lambs, outbreaks of low fertility in ewes and poor viability and ill-thrift in lambs may be associated with border disease virus infection.

Lesions: In severe cases, abnormal development of the cerebrum may be seen at necropsy, resulting in hydrocephalus, hydranencephaly, porencephaly, or microcephaly. Cerebellar hypoplasia or cerebellar dysplasia may also occur. Otherwise, the characteristic lesions are microscopic and involve the white matter of the CNS. There is a deficiency of myelin and an increase in interfascicular glial cells, in which myelin-like lipid droplets may accumulate. These changes are most obvious in the newborn and gradually resolve.

Diagnosis: Clinical findings usually allow a diagnosis, although abnormal hairiness of the birth coat may not be apparent in rough-coated breeds of sheep. The diagnosis can be confirmed by histologic demonstration of the pathognomonic lesions in the CNS and with immunocytochemical staining of the virus. In typical hairy-shaker lambs, the virus or viral antigen may be demonstrated readily in blood and tissues by virus isolation, fluorescent antibody tests, immunohisto-

chemistry, or PCR. When testing blood in newborn lambs, precolostral blood is ideal because colostral antibody can mask virus for up to 2 mo. Virus can be isolated from serum or buffy coat cells in cell cultures, but a viral antigen detection ELISA using heparinized or EDTA blood is available. Reverse transcriptase-PCR can also be used to detect viral RNA in clinical specimens and to type ruminant pestiviruses.

Other causes of ovine abortion (eg, bluetongue, *Chlamydia*, listeriosis, *Salmonella*, *Campylobacter*, *Rickettsia* spp, *Toxoplasma gondii*, and Akabane virus) should be considered in the differential diagnosis. In live-born lambs, border disease must be differentiated from swayback (enzootic ataxia), bacterial meningoencephalitis, focal symmetric encephalomalacia, and “daft lamb” disease.

Control: There is no effective treatment for persistently infected lambs. Bulk tank milk samples can be tested for antibodies to BVDV to screen for the presence of virus within dairy sheep flocks. Serology should be performed on the dams of affected lambs. Most should have high levels of antibody and be immune to further challenge with the same strain of virus in subsequent pregnancies. Those that do not have antibody titers should be screened for virus to identify any that are persistently infected. Recovered lambs should not be retained for breeding but can be mixed with replacement stock well before breeding season to maximize opportunities for the latter to become infected and develop immunity before subsequent matings. There is no effective vaccine. BVDV vaccines for cattle cannot be recommended for use in sheep, because border disease viruses most commonly isolated from sheep are antigenically distinct from BVDV most common in cattle.

COXIELLOSIS

Coxiellosis is a zoonotic bacterial infection associated primarily with parturient ruminants, although domestic animals such as cats and a variety of wild animals have been identified as sources of human infection. The zoonotic infection in people

associated with *Coxiella burnetii* is widely known as Q fever. *Coxiella* is considered a potential agent of bioterrorism because of its low infectious dose, stability in the environment, and capability for aerosol dispersion.

Etiology, Epidemiology, and Transmission:

Coxiellosis is caused by the gram-negative coccobacillus *C burnetii*. Although classically considered a rickettsial agent, recent phylogenetic analyses suggest that *C burnetii* is more closely related to *Legionella* and *Francisella* than to the genus *Rickettsia*. It resides and reproduces in the acidified phagolysosomes of host monocytes and macrophages. Two forms exist: the large cell variant is a vegetative form found in infected cells, and the small cell variant is the extracellular infectious form shed in milk, urine, and feces and found in high concentration (10^9 ID₅₀/g) in placental tissue and amniotic fluid. The small cell variant is resistant to heat, drying, and many common disinfectants and remains viable for weeks to years in the environment. Once a domestic ruminant is infected, *C burnetii* can localize in mammary glands, supramammary lymph nodes, placenta, and uterus, from which it may be shed in subsequent parturitions and lactations.

The epidemiology of *C burnetii* is complex because there are two major patterns of transmission. In one, the organism circulates between wild animals and their ectoparasites, mainly ticks; the other occurs in domestic ruminants, independent of the wild animal cycle. Ixodid and argasid ticks can act as reservoirs of the organism. Distribution is worldwide (except New Zealand), and the host range includes various wild and domestic mammals, arthropods, and birds. The disease is enzootic in most areas where cattle, sheep, and goats are kept. In the USA, seroprevalence studies have shown significant variability in prevalence of antibodies to *C burnetii* based on difference in test population, test used, and time of year. Evaluation of bulk tank milk sampling of USA cattle dairies has demonstrated prevalence of the organism at the farm level of 77% to >90%. In a comprehensive seroprevalence study conducted in Canada, 48.6% of sheep operations and 63.2% of goat operations had at least one positive animal. Not surprisingly, seroprevalence in veterinarians and small ruminant farmers is also high.

The greatest risk of transmission occurs at parturition by inhalation, ingestion, or direct contact with birth fluids or placenta. The organism is also shed in milk, urine, and feces. High-temperature pasteurization effectively kills the organism. Ticks may transmit the disease among domestic ruminants but are not thought to play an epidemiologically important role in transmission of disease to people.

Clinical Findings and Diagnosis: Infection in ruminants is usually subclinical but can cause anorexia and late abortion. When infection is subclinical, animals shed much lower bacterial loads of the organism than when abortion occurs. Reports have implicated *C burnetii* as a cause of infertility and sporadic abortion with a necrotizing placentitis in ruminants. New evidence has shown an association of *C burnetii* with subclinical mastitis among dairy cows, although additional work regarding causality is required before this can be considered clinically valid. Experimental infection in cats causes transient fever, dullness, and anorexia lasting several days.

In domestic ruminants, gross lesions are nonspecific, and differential diagnosis should include infectious and noninfectious agents that cause abortion. Immunofluorescence test on paired sera taken ≥ 2 wk apart can be used to detect recent infection; however, shedding of *C burnetii* may occur in the absence of a measurable serum antibody titer in up to 20% of infected animals. Culture, immunohistochemical, and PCR tests may be used to identify *C burnetii* in tissues. Studies conducted in veterinary diagnostic laboratories suggest that *C burnetii* is often found concurrently with other organisms isolated in cases of infectious abortions, so mixed infections may be important. Seasonal variability in shedding of the organism hinders interpretation of a single PCR test. Shedding is highest in the periparturient period and may drop below detectable levels for a significant period during the year despite persistent infection.

Treatment and Control: Q fever in people is a notifiable disease in the USA, primarily because of its status as a possible bioterrorism agent; reporting requirements for animals vary by state. Vaccines for people and animals have been developed but are not commercially available in the USA. Vaccination has prevented infection when administered to uninfected calves and has improved fertility and reduced shedding in previously infected animals.

There is little evidence-based data to suggest that antibiotic treatment in animals provides significant benefit. Human clinical disease is typically treated with tetracyclines, but significant benefit from tetracycline treatment has not been demonstrated in controlled studies in abortion outbreaks of sheep in Europe. Despite the lack of evidence, some practitioners still advocate the use of

parenteral tetracyclines during abortion storms. In known infected herds, the periparturient period represents a significant risk period for transmission because of the large amount of environmental contamination associated with abortion. Standard abortion control measures, including prompt removal of aborted materials (using zoonotic precautions), segregation of animals by pregnancy status, and diagnostic evaluation of abortions, are all warranted.

Zoonotic Risk: Q fever occurs more frequently in persons who have occupational contact with high-risk species. The clinical presentation in people is highly variable clinically, ranging from a self-limiting, influenza-like illness to pneumonia, hepatitis, and endocarditis. *C burnetii* is highly infectious, and a single organism can reportedly cause infection via the aerosol route in people. Individuals who have artificial heart valves are at particular risk, as well as anyone who is significantly immunocompromised. *C burnetii* has been

associated with human abortions, and pregnant women should take precautions to prevent exposure.

The majority of outbreaks in people have been associated with wind dispersion of desiccated reproductive products, contaminated with *C burnetii*, from sites where sheep, goats, or cattle are kept. Farmers and veterinarians are at risk while assisting birthing. Slaughterhouse workers are at risk from contact with infected carcasses, hair, and wool. Transmission may also occur by consumption of unpasteurized milk. Handling of infected tissue poses a threat to laboratory personnel. Q fever has been seen in personnel and human patients in medical institutions where latently infected sheep were used for research. Medical facilities using ruminants in research should attempt to purchase animals from flocks free of coxiellosis or use male animals when possible. In addition, workers should use adequate personal protective equipment to protect against small droplet and aerosol exposure during high-risk medical procedures.

ERYSIPELOTHRIX RHUSIOPATHIAE INFECTION

(Erysipelas, Nonsuppurative polyarthritis, Postdipping lameness)

Erysipelothrix rhusiopathiae is a significant bacterial pathogen of swine, turkeys, and sheep. It is distributed worldwide and has also been isolated from cattle, horses, dogs, cats, mice, rats, fresh and saltwater fish, domestic poultry, and a variety of wild birds and mammals. Erysipeloid, a condition characterized by localized skin infections and cellulitis, may develop in people who work with infected animals, infected carcasses, or infected animal byproducts.

The bacterium can survive in the soil for up to 5 wk; however, soil is not an effective growth medium, and the organism is unable to survive for extended periods of time in the environment. Soil and surface water contamination represent routes of exposure. Asymptomatic carriers are the usual source of infectious organisms, but the bacteria may also be introduced to animal production units by surface water runoff, wild mammals, wild birds, pets, and biting insects. *E. rhusiopathiae* has food safety implications, because it can survive for several months in animal tissues such as

frozen or chilled pork, cured and smoked ham, and feed byproducts such as dried blood.

E. rhusiopathiae is a nonmotile, gram-positive, facultative anaerobic bacillus. It is catalase negative, coagulase positive, oxidase negative, resistant to high salt concentrations, and produces H_2S on triple sugar iron media. Colonies of *E. rhusiopathiae* are either smooth or rough, with rough colonies being slightly larger, with irregular edges. On agar media, colonies are clear, circular, and very small (0.1–1.5 mm in diameter) after 24 hr of incubation, but they increase in size after 48 hr.

The organism is very hardy and can survive and grow in a wide range of pH and environmental temperatures. *E. rhusiopathiae* has demonstrated the ability to resist the action of several classes of disinfectants used in animal production units, including alcohols, aldehydes, oxidizing agents, and phenols. Classes of disinfectants and/or compounds considered to effectively inactivate *E. rhusiopathiae* include hypochlorites (bleach) and caustic

soda (lye; NaOH). The organism is sensitive to the β -lactam (penicillin, ampicillin), cephalosporin (ceftiofur), and tetracycline classes of antibiotics and is resistant to sulfonamides.

SWINE ERYSIPELAS

Infectious disease caused by *Erysipelothrix rhusiopathiae* in pigs is known as erysipelas and is one of the oldest recognized diseases that affect growing and adult swine. Up to 50% of pigs in intensive swine production areas are considered to be colonized with *E. rhusiopathiae*. The organism commonly resides in the tonsillar tissue. These typical healthy carriers can shed the organism in their feces or oronasal secretions and are an important source of infection for other pigs.

Disease outbreaks may be acute or chronic, and clinically inapparent infections also occur. Acute outbreaks are characterized by sudden and unexpected deaths, febrile episodes, painful joints, and skin lesions that vary from generalized cyanosis to the often-described diamond skin (rhomboid urticaria) lesions. Chronic erysipelas tends to follow acute outbreaks and is characterized by enlarged joints and lameness. A second form of chronic erysipelas is vegetative valvular endocarditis. Pigs with valvular lesions may exhibit few clinical signs; however, when exerted physically they may show signs of respiratory distress, lethargy, and cyanosis, and possibly suddenly succumb to the infection.

Etiology: Growth of *E. rhusiopathiae* on nonenriched media produces pinpoint, nonhemolytic colonies after incubation for 24 hr. After 48 hr of incubation, a zone of incomplete hemolysis becomes evident around colonies. The genus of *Erysipelothrix* is subdivided into two major species: *E. rhusiopathiae* and *E. tonsillarum*. In addition, there are other strains that constitute one or more additional species known as *E. species 1*, *E. species 2*, *E. species 3*, and *E. inopinata*. At least 28 different serotypes of *Erysipelothrix* spp are recognized, and pigs are considered to be susceptible to at least 15. Field cases of swine erysipelas are predominately caused by *E. rhusiopathiae* serotypes 1a, 1b, or 2.

On farms where the organism is endemic, pigs are exposed naturally to *E. rhusiopathiae* when they are young. Maternal-derived antibodies provide passive immunity and suppress clinical disease. Older pigs

tend to develop protective active immunity as a result of exposure to the organism, which does not necessarily lead to clinical disease. *E. rhusiopathiae* is excreted by infected pigs in feces and oronasal secretions, effectively contaminating the environment. When ingested, the organism can survive passage through the hostile environment of the stomach and intestines and may remain viable in the feces for several months. Recovered pigs and chronically infected pigs may become carriers of *E. rhusiopathiae*. Healthy swine also may be asymptomatic carriers. Infection is by ingestion of contaminated feed, water, or feces and through skin abrasions.

Clinical Findings: The acute and chronic forms of swine erysipelas may occur in sequence or separately. Pigs that succumb to the acute septicemic form may die suddenly without previous clinical signs. This form occurs most frequently in growing and finishing pigs. Acutely infected pigs are depressed, febrile (104°–108°F [40°–42°C]), and reluctant to stand and move. Affected pigs squeal excessively when handled, require assistance to stand, and prefer to lie down soon after being forced to stand. Affected pigs may also walk stiffly on their toes and shift weight from limb to limb when standing. Anorexia and thirst are common, and febrile pigs will often seek wet, cool areas to lie down. Skin discoloration may vary from widespread erythema and purplish discoloration of the ears, snout, and abdomen, to diamond-shaped skin lesions almost anywhere on the body, but particularly on the lateral and dorsal regions. The lesions may occur as discrete, pink or purple areas of varying size that become raised and firm to the touch within 2–3 days of illness. They may disappear over the course of a week or progress to a more chronic type of lesion, commonly referred to as diamond skin disease. If untreated, necrosis and separation of large areas of skin can occur, and the tips of the ears and tail may become necrotic and slough.

Clinical disease is usually sporadic and affects individuals or small groups, but sometimes larger outbreaks occur. Mortality is variable (0–100%), and death may occur up to 6 days after the first signs of illness. Acutely affected pregnant sows may abort, probably due to the fever, and lactating sows may show agalactia. Untreated pigs may develop the chronic form of the disease, usually characterized by chronic arthritis, vegetative valvular endocarditis, or both. Such lesions may also

be seen in pigs with no previous signs of septicemia. Valvular endocarditis is most common in mature or young adult pigs and is frequently manifest by death, usually from embolism or cardiac insufficiency. Chronic arthritis, the most common form of chronic infection, produces mild to severe lameness. Affected joints may be difficult to detect initially but eventually become hot and painful to the touch and later visibly enlarged. Dark purple, necrotic skin lesions that commonly slough may be seen. Mortality in chronic cases is low, but growth rate is retarded.

Lesions: At necropsy, acutely infected pigs may exhibit skin lesions, enlarged and congested lymph nodes, edematous and congested lungs, splenomegaly, and hepatomegaly. Petechial hemorrhages may be seen on the kidneys and heart.

In chronic erysipelas, valvular endocarditis is seen as proliferative, granular growths on the heart valves, and embolisms and infarctions may develop. Arthritis may involve joints of one or more legs, and the intervertebral articulations may be involved. Affected joints may be enlarged, with proliferative, villous synovitis and increased viscosity of synovial fluid, inflammatory exudates, and thickening of the joint capsule. Proliferation and erosion of articular cartilage may result in fibrosis and ankylosis of the joint.

Diagnosis: Diagnosis of erysipelas is based on clinical signs, gross lesions, response to antimicrobial therapy, and demonstration of the bacterium or DNA in tissues from affected animals. Acute erysipelas can be difficult to diagnose in individual pigs showing only fever, poor appetite, and listlessness. However, in outbreaks involving several animals, the presence of skin lesions and lameness is

likely to be seen in at least some cases and would support a clinical diagnosis. Rhomboid urticaria or diamond skin lesions are almost diagnostic when present; however, similar lesions can also be seen with classical swine fever virus infection (see p 713), *Actinobacillus suis* septicemia, or the porcine dermatitis and nephropathy syndrome. Isolation of *E. rhusiopathiae* from blood of affected pigs, especially after enrichment, is possible in acute cases and helps establish a diagnosis. In addition, molecular methods capable of detecting *E. rhusiopathiae* DNA in affected tissues or blood (ie, PCR assays) can also be used. Recently, immunohistochemical methods to demonstrate the organisms in formalin-fixed paraffin-embedded tissues have become available and are useful in cases when pigs have been treated with antimicrobials before sample submission. A rapid, positive response to penicillin therapy in affected pigs supports a diagnosis of acute erysipelas because of the sensitivity of the organism to penicillin.

Chronic erysipelas can be difficult to definitively diagnose. Arthritis and lameness, coupled with the presence of vegetative valvular endocarditis postmortem, may support a presumptive diagnosis of chronic erysipelas. However, these lesions can be caused by other infectious agents. A positive culture of valvular vegetations or demonstration of *E. rhusiopathiae* DNA in the lesions by PCR is definitive for diagnosing chronic erysipelas.

Serologic tests cannot reliably diagnose erysipelas but can be useful to determine previous exposure or success of vaccination protocols, because antibody titers should increase after vaccination. For this purpose, ELISAs and complement fixation tests are available in selected laboratories.

Differential diagnoses to consider include conditions that can precipitate gross lesions suggestive of acute septicemia. Septicemic salmonellosis due to *Salmonella* Choleraesuis infection, classical swine fever due to pestivirus infection, and septicemia and endocarditis due to *Streptococcus suis* infection should be considered, based on similarity of lesions. Glasser's disease (see p 720) due to *Haemophilus parasuis* infection and *Mycoplasma hyosynoviae* infection can precipitate similar changes in synovial tissues and joints of affected pigs.

Treatment: *E. rhusiopathiae* is sensitive to penicillin. Ideally, affected pigs should be treated at 12-hr intervals for a minimum of 3 days, although longer durations of therapy may be necessary to resolve severe

Acute, severe skin form of swine erysipelas with extensive small, raised, pink/red lesions and some developing dark scabs. Courtesy of Dr. Randal D. A. Cameron.

infections. On an economic basis, penicillin is the best choice for antibiotic therapy, but ampicillin and ceftiofur also yield satisfactory results in acute cases. When injecting large numbers of affected pigs is impractical, tetracyclines delivered in the feed or water may be useful. Fever associated with acute infections can be managed by administration of NSAIDs such as flunixin meglumine or by delivery of aspirin in the water. Erysipelas antiserum is described as an effective adjunct to antibiotic therapy in treating acute outbreaks but is not commonly available. Treatment of chronic infections is usually ineffective and not cost effective.

Prevention: Vaccination against *E rhusiopathiae* is very effective in controlling disease outbreaks on swine farms and should be encouraged. Cessation of vaccination on some farms has been linked to disease outbreaks. Injectable bacterins and attenuated, live vaccines delivered via the water are available and provide extended duration of immunity. Optimal timing of vaccination may vary from farm to farm. When *E rhusiopathiae* is endemic in the production environment, vaccination should precede anticipated outbreaks. Susceptible pigs may be vaccinated before weaning, at weaning, or several weeks after weaning. Male and female swine selected for addition to the breeding herd should be vaccinated with a booster 3–5 wk later. Thereafter, breeding stock should be vaccinated twice yearly. Vaccines should not be administered to animals undergoing antibiotic therapy, because antibiotics can interfere with the subsequent immune response to the vaccine.

Vaccination failures may occur in some herds due to management stresses that compromise the immune system of vaccinated pigs. Antigenic differences between serotypes in vaccines and serotypes circulating on farms can also result in incomplete immunity and disease outbreaks, but this is a rare event because there is good cross-protection among the major *E rhusiopathiae* strains infecting pigs.

In addition to vaccination, attention to sanitation and hygiene and elimination of pigs with clinical signs suggestive of erysipelas infection represent other viable methods that may help control the disease on swine farms.

NONSUPPURATIVE POLYARTHRITIS IN LAMBS

Nonsuppurative polyarthritis is an infectious condition of older, growing lambs

(6–16 wk old) characterized by high morbidity and moderate to severe lameness with enlargement of affected joints.

Etiology: The infectious agent of nonsuppurative polyarthritis, *Erysipelothrix rhusiopathiae*, is thought to infect the animal through wounds created as a result of tail docking and castration procedures. However, outbreaks may also occur after “bloodless” procedures, particularly during extended periods of wet weather, which increases the level of stress and appears to enhance the survivability of the organism in the environment. *E rhusiopathiae* localizes in joints via hematogenous dissemination and infects the synovial membrane. Progression of the synovial infection results in synovitis and damage to articular cartilage and underlying subchondral bone.

Clinical Findings and Lesions: Sudden onset of moderate to severe lameness in a high number of growing lambs is suggestive of nonsuppurative polyarthritis. Lameness typically occurs in two or more limbs, and the joints most often affected are the carpus and hock. Affected lambs are reluctant to move and spend extended periods of time in sternal recumbency. Growth is often severely depressed. Progression of the condition results in proliferation of the synovial membrane, thickening of the joint capsule without significant joint effusion, and eventual erosion of articular cartilage.

Diagnosis: Sudden onset of lameness in a large number of growing-age lambs is suggestive of polyarthritis due to *E rhusiopathiae*. Because joint effusions are minimal, attempts to obtain a sample from affected joints for culture and other diagnostics may be unsuccessful.

Prevention and Treatment: Vaccination should be considered on premises where the disease is a recurring problem. Adopting strict antiseptic techniques and maintaining hygienic conditions for tail docking and castration are recommended but may not prevent the condition. The so-called “bloodless” methods of performing both procedures may reduce the chances of wound contamination, but outbreaks are still possible. Administration of penicillin for 5 days is recommended for effective treatment of the nonsuppurative polyarthritis. Administration of NSAIDs helps improve lameness.

POSTDIPPING LAMENESS IN SHEEP

Postdipping lameness affects lambs and adult sheep. It is characterized by severe lameness that results from infection caused by the penetration of *Erysipelothrix rhusiopathiae* through skin abrasions in the hoof. Postdipping lameness, which normally occurs in outbreaks, has been described in most sheep-raising countries. Because of the reduced usage of sheep dips in recent years, this manifestation is seen less frequently now.

Etiology: With time and repeated use, dipping solutions, which have little or no bacteriostatic activity, become heavily contaminated with various species of bacteria. *E. rhusiopathiae* is a common contaminant, and its presence in the dipping vat, sometimes in enormous numbers, leads to infection of skin wounds during dipping. Small skin abrasions in the region of the hoof and fetlock joint are a common portal of entry. Lesions extending from these wounds to the laminae of the hoof cause

acute postdipping lameness. Outbreaks may also occur when sheep must walk through wet and muddy areas that are heavily contaminated with the organism.

Clinical Findings: Two to 4 days after dipping, a variable number (up to 90%, but usually ~25%) of sheep in the flock may be lame in one or more limbs. Affected limbs appear normal except for the hoof and pastern regions, where the coronary band may be swollen, hot, and painful. Most sheep recover spontaneously in 2–4 wk with nothing more serious than a slight loss of body weight. In some outbreaks, however, administration of penicillin for 5 days may be necessary to salvage affected sheep. Septicemia and polyarthritis are not common with this condition.

Prevention and Treatment: Discarding heavily contaminated dips is the best way to prevent infection with *E. rhusiopathiae* and the lameness associated with this condition. Using an appropriate bacteriostat in dip solutions may reduce the incidence of the condition.

FOOT-AND-MOUTH DISEASE

Foot-and-mouth disease (FMD) is a highly communicable viral disease caused by an *Aphthovirus* of the family Picornaviridae. There are 7 serotypes: A, O, C, Asia 1, and SAT (Southern African Territories) 1, 2, and 3. Further diversity is found in strains within each serotype. It primarily affects cloven-hooved animals of the order Artiodactyla. Livestock hosts include cattle, pigs, sheep, goats, and experimental infections in alpacas and llamas. FMD virus has also been reported in >70 species of wild artiodactyls, including bison, giraffes, Indian elephants, and several species of deer and antelope. The disease is characterized by fever and vesicles in the mouth and on the muzzle, teats, and feet and is spread through direct contact or aerosolized virus via respiratory secretions, milk, semen, and ingestion of feed from infected animals (meat, offal, milk). In a susceptible population, morbidity reaches 100% with rare fatalities except in young animals. FMD was once distributed worldwide but has been eradicated in some regions, including North America and

Western Europe. In endemic countries, FMD places economic constraints on the international livestock trade and can be easily reintroduced into disease-free areas unless strict precautions are in place. Outbreaks can severely disrupt livestock production and require significant resources to control, as in the 2001 UK outbreak.

Epidemiology and Transmission: FMD is endemic in many countries of the Middle East, Africa, Asia, and in parts of South America. Where FMD still occurs, serotypes are not uniformly distributed. Six of the 7 serotypes have occurred in Africa (O, A, C, SAT-1, SAT-2, SAT-3), 4 in Asia (O, A, C, Asia-1), and 3 in South America (O, A, C). North and Central America, Australia, New Zealand, Greenland, Iceland, and Western Europe are free of FMD. In 2001, FMD was introduced into the UK, where it spread to Ireland, the Netherlands, and France. The highly virulent pan-Asiatic serotype O causing the outbreak was the same found throughout Asia.

The virus is transmitted via direct or indirect contact with infected secretions and excretions (including semen and milk), mechanical vectors (people, horses, dogs, cats, birds, vehicles), and air currents over land or water. The virus can enter the body via inhalation, ingestion, or through skin wounds and mucous membranes. Breeding is a possible route of transmission for the SAT viruses in African buffalo populations. An example scenario for introduction into a previously FMD-free area is for a susceptible population, such as pigs, given imported food derived from an infected animal (meat, offal, milk). Virus then spreads from pigs, which can expire up to 3,000 times more virus than cattle, to more susceptible cattle hosts via aerosol. Virus was reported to travel over water >250 km (155 miles) from Brittany, France, to the Isle of Wight, UK, in 1981, but it usually travels no more than 10 km (~6 miles) over land. FMD has high agroterrorism potential because of its infectivity, high transmissibility through wind and inanimate objects, and potential for large economic losses.

People can act as mechanical vectors of FMD by carrying virus on clothing or skin. FMD is not considered a public health problem, but there are reports of people who work in FMD vaccine laboratories who have developed antibodies to the virus. There are few reports of people with laboratory-confirmed cases of clinical illness between 1921 and 1969. The disease in people is usually short-lived and mild, with symptoms including vesicular lesions and influenza-like illness.

Pathogenesis: The primary site of infection and replication of FMD is in the mucosa of the pharynx. The virus may also enter through skin lesions or the GI tract. Once distributed throughout the lymphatic system, the virus replicates in the epithelium of the mouth, muzzle, teats, feet, and areas of damaged skin (eg, knees and hocks of pigs). Vesicles then develop at the organs and rupture within 48 hr. More than 50% of ruminants that recover from illness and those that are vaccinated and have been exposed to virus can carry virus particles in the pharyngeal region—up to 3.5 yr in cattle, 9 mo in sheep, and >5 yr in African buffalo.

FMD virus is environmentally resistant and inactivates outside the pH range 6–9 and desiccation and at temperatures >56°C (132.8°F). It is resistant to lipid solvents such as ether and chloroform, but sodium hydroxide (lye), sodium carbonate (soda ash), citric acid, and acetic acid (vinegar) are effective disinfectants. Iodophores,

quaternary ammonium compounds, hypochlorite, and phenols are less effective disinfectants, especially in the presence of organic matter.

FMD is shed into milk in dairy cows before clinical signs develop, so there is opportunity for virus to spread farm to farm and from cow to calf via raw milk. FMD may survive pasteurization depending on the method (high temperature short time, ultra high temperature, laboratory pasteurization); the lipid component of milk protects virus during heating. FMD virus survives up to 20 wk on hay or straw bedding, in dry fecal matter for up to 14 days in summer, in a fecal slurry for up to 6 mo in winter, in urine for 39 days, and in soil for 3 (summer) to 28 (winter) days.

The incubation period of FMD is variable and depends on the host, environment, route of exposure, and virus strain. After infection with FMD virus, the average incubation period for sheep and goats is 3–8 days, ≥2 days for pigs, and 2–14 days in cattle. The incubation period can be as short as 18 hr for host-adapted strains in pigs, especially under intense direct contact.

Clinical Findings: Clinical signs in cattle include pyrexia of ~104°F, followed by vesicular development on the tongue, hard palate, dental pad, lips, gums, muzzle, coronary band, interdigital cleft, and teats in lactating cows. Acutely affected individuals may salivate profusely, stamp their feet, and prefer to lie down. Ruptured oral vesicles can coalesce and form erosions but heal rapidly, roughly 11 days after vesicle formation. Feet vesicles take longer to heal and are susceptible to bacterial infection leading to chronic lameness. Secondary bacterial mastitis is common due to infected teat vesicles and resistance to milking. After vesicular disease develops, cattle quickly lose condition and milk yield, which can persist chronically.

Infected pigs show mild lameness and blanching around the coronary band and may develop a fever of up to 107°F. Affected pigs become lethargic, huddle among other pigs, and have little interest in feed. Vesicles develop on the coronary band, heel of the foot including accessory digits, snout, mandible, and tongue. Additional vesicles may form on the hocks and knees of pigs housed on rough surfaces. Depending on the severity of vesicles, the horn of the foot may completely slough off and cause chronic lameness in recovered pigs. Young pigs <14 wk old may die without clinical signs of illness because of viral damage to the developing myocardium.

Lameness is usually the first clinical sign of FMD infection in sheep and goats. This is followed by fever and vesicular development on the interdigital cleft, heel bulbs, coronary band, and mouth. Vesicles may also form on the teats of lactating animals and rarely on the vulva and prepuce. Secondary infections result in reduced milk yield, chronic lameness, and predisposition to other viral infections, including sheep/goat pox (see p 869) and peste des petits ruminants (see p 766). Similarly to young pigs, infection in immature sheep and goats results in death without clinical signs due to heart failure.

Experimentally infected camelids are commonly reported to have mild clinical illness, if at all, but can have severe infections resulting in salivation and mouth lesions and sloughing of the footpad and skin of the tarsal and carpal joints. Water buffalo can have mouth and foot lesions, which heal faster and are less severe than those in cattle. FMD infections in wildlife resemble clinical illness in their domestic counterparts, but more severe lesions such as sloughing of antlers or toe horn are reported.

Diagnosis: In cattle and pigs, the clinical signs of FMD are indistinguishable from those of vesicular stomatitis (see p 694), and in pigs from those of swine vesicular disease (see p 735) and vesicular exanthema (see p 738). Therefore, laboratory confirmation is essential for diagnosis of FMD and should be performed in specialized laboratories that meet OIE requirements for Containment Group 4 pathogens. Countries lacking access to a national or regional laboratory meeting these guidelines should send specimens to an OIE FMD reference laboratory. The tissue of choice for sampling is vesicular epithelium or fluid. At least 1 g of epithelium should be placed in a transport medium of phosphate-buffered saline (PBS) or equal parts glycerol and phosphate buffer with pH 7.2–7.6. Samples should be kept refrigerated or transported on ice. If vesicles are not present, oropharyngeal fluid can be collected via probang cup or pharyngeal swabbing for virus isolation or reverse transcription PCR (RT-PCR). Serum (blood) samples may also be tested by these means (OIE *Terrestrial Manual* 2012). Repeated sampling may be necessary to identify a carrier, because virus presence may be low and fluctuate.

Laboratory diagnosis is usually performed via antigen capture–ELISA or serotyping ELISA. This is the preferred

method for countries with endemic FMD for viral antigen detection and serotyping (OIE *Terrestrial Manual* 2012). Concurrent virus isolation may be performed, preferably in primary bovine thyroid cell culture. Detecting nucleic acids via RT combined with real-time PCR is more sensitive and rapid than conventional methods and may be more useful when samples contain low concentrations of virus. ELISA is preferred over complement fixation tests because of its increased sensitivity and specificity, but complement fixation may be performed if ELISA reagents are not available. Commercially available lateral flow devices have not yet been validated by the OIE.

Serologic tests for FMD are used to certify animals for import/export (ie, trade), confirm suspected cases of FMD, test efficacy of vaccination, and provide evidence for absence of infection. Testing cut-offs may be set at different levels for herd-based surveillance versus certifying freedom of infection for trade purposes. The choice of serologic test depends on the vaccination status of the animals. Serologic tests for antibodies to the viral structural (capsid) proteins cannot be used in vaccinated animals, because FMD vaccines induce antibodies to these proteins. Detection of antibodies to nonstructural proteins, which are expressed only during virus replication, can be used to determine past or present infection with any of the 7 serotypes, whether or not the animal has been vaccinated. However, they are less sensitive and may result in false-negatives in cases with limited virus replication such as vaccinated animals that become infected, because the vaccine suppresses viral replication (OIE *Terrestrial Manual* 2012).

Treatment, Control, and Prevention:

The OIE classifies countries and regions as FMD-free without vaccination, FMD-free with vaccination, suspended FMD-free status with or without vaccination, and unrecognized (World Organization for Animal Health, 2013). The current global status of FMD distribution shows geographic areas of viral “hotspots” where FMD prevalence indices are highest over long periods of time. They are commonly located in poor countries where veterinary services and resources are inadequate to control or eradicate FMD. Combined use of trade and movement restrictions of animals and animal products has not completely prevented introductions of FMD into FMD-free areas. These viral incursions into countries or regions where FMD is not enzootic are usually controlled by slaughter

of all infected and susceptible animals, strict restriction of animal and vehicle movement around infected premises, proper carcass disposal, and environmental disinfection, without the use of vaccines. Inactivated virus vaccines are limited in their use, because they protect for only 4–6 mo against the specific serotype(s) contained in the vaccine and protect animals from clinical illness but not viral persistence in the pharyngeal region; therefore, they can induce a carrier state. Additionally, it is difficult to distinguish infected animals from vaccinated animals unless purified killed vaccines are used. Therefore, vaccination is used more in enzootic countries to protect producing animals, particularly high-yielding dairy cattle, from clinical illness because slaughter of all at-risk individuals may be economically unfeasible and can cause food shortages.

Rapid disease reporting is essential to control an FMD outbreak in nonendemic countries. Veterinarians who encounter any vesicular disease in the USA should immediately inform their state or federal veterinary authorities. After an outbreak, tracing is done through epidemiologic inquiries to help identify the source of disease introduction. In countries where

mass slaughter is not possible, strict quarantining and movement restriction should be enforced. However, quarantine may not be long enough to prevent carrier animal movement after an outbreak. When mass euthanasia is performed, infected carcasses must be disposed of via incineration, burial, or rendering on or close to the infected premises. Scavengers and rodents should be prevented or killed to prevent mechanical dissemination of virus. Buildings should be cleaned with a mild acid or alkali disinfectant and fumigation, and people that have come into contact with virus may be asked to decontaminate their clothing and avoid contact with susceptible animals for a period of time.

In some regions, FMD persistence in wildlife populations, such as the wild African buffalo, can make FMD eradication unrealistic. Control measures, such as fencing of wildlife reserves to prevent contact with domestic livestock, have helped limit the spread of virus in certain areas. A twice-yearly vaccination buffer zone in livestock proximal to endemic wildlife reserves may additionally help decrease outbreak occurrence.

There is no specific treatment for FMD, but supportive care may be allowed in countries where FMD is endemic.

FUNGAL INFECTIONS

(Mycoses)

Systemic mycoses are infections with fungal organisms that exist in the environment, enter the host from a single portal of entry, and disseminate within the host usually to multiple organ systems. The soil reservoir is the primary source of most infections, which can be acquired by inhalation, ingestion, or traumatic introduction of fungal elements. (See also **DERMATOPHILOSIS**, p 858.)

Pathogenic fungi establish infection in apparently normal hosts, and such diseases as histoplasmosis, coccidioidomycosis, blastomycosis, and cryptococcosis are regarded as primary systemic mycoses. Opportunistic fungi usually require a host that is debilitated or immunosuppressed to establish infection. Prolonged administration of antimicrobials or immunosuppressive agents appears to increase the likelihood of infection by the opportunistic fungi that cause diseases such as aspergil-

losis and candidiasis, which may be focal or systemic.

Clinical findings and gross lesions are often suggestive of systemic mycoses, but definitive diagnosis requires microscopic identification, culture of the organism, or PCR. Identification of the fungus and the tissue reaction via microscopic examination of exudates and biopsy material is adequate for diagnosis of histoplasmosis, cryptococcosis, blastomycosis, coccidioidomycosis, and rhinosporidiosis. Other diseases, such as candidiasis, aspergillosis, zygomycosis, phaeohyphomycosis, hyalohyphomycosis, and oomycosis (pythiosis and lagenidiosis), usually require more than microscopic evaluation for a definitive diagnosis. Some of these fungi are also common contaminants of cultures; thus, tissue invasion and reaction must be demonstrated for the culture isolation to be considered signifi-

cant. Serology may be useful for diagnosis (and prognosis) of some mycotic diseases such as coccidioidomycosis, pythiosis, and lagenidiosis. Antigen titers have proved useful for cryptococcosis, histoplasmosis, and blastomycosis.

For treatment, see discussions of specific systemic mycoses (below) and see SYSTEMIC PHARMACOTHERAPEUTICS OF THE INTEGUMENTARY SYSTEM, p 2571.

ASPERGILLOSIS

Aspergillosis is caused by several *Aspergillus* spp, especially *A. fumigatus* and *A. terreus*. *A. niger*, *A. nidulans*, *A. viridinutans*, *A. flavus*, and *A. felis* are being recognized more commonly with increasing use of molecular techniques for identification. *Aspergillus* infection is found worldwide and in almost all domestic animals and birds as well as in many wild species. It is primarily a respiratory infection that may become generalized; however, tissue predilection varies among species. The most common forms are pulmonary infections in poultry and other birds; mycotic abortion in cattle; guttural pouch mycosis in horses; infections of the nasal and paranasal tissues, intervertebral sites, and kidneys of dogs; and sinonasal, sino-orbital, and pulmonary infection in domestic cats.

Clinical Findings and Lesions: In **birds**, aspergillosis (see p 2901) is primarily bronchopulmonary, with dyspnea, gasping, and polypnea accompanied by somnolence, anorexia, and emaciation. Mycotic tracheitis has also been described. Torticollis and disturbances of equilibrium are seen when infection disseminates to the brain. Yellow nodules of varying size and consistency or plaque lesions are found in the respiratory passages, lungs, air sacs, or membranes of body cavities. Fur-like growth of fungus may be found on the thickened walls of air sacs. Other species with bronchopulmonary aspergillosis may have nodular lesions in the lungs or an acute pneumonia accompanied by serosanguineous fluid in the pleural cavity and a fibrinous pleuritis.

In **ruminants**, aspergillosis may be asymptomatic, appear in a bronchopulmonary form, cause mastitis, or cause placentitis and abortion. Mycotic pneumonia may be rapidly fatal. Signs include pyrexia; rapid, shallow, stertorous respiration; nasal discharge; and a moist cough. The lungs are firm, heavy, and mottled and do not collapse. In subacute to chronic mycotic pneumonia, the lungs contain multiple discrete granulomas, and

the disease grossly resembles tuberculosis (see p 687).

In the absence of pneumonia, infected cows generally have no signs except for abortion; a dead fetus is aborted at 6–9 mo gestation, and the fetal membranes are retained. Lesions are found in the uterus, fetal membranes, and often the fetal skin. In the uterus, the intercaruncular areas are grossly thickened, leathery, dark red to tan, and contain elevated or eroded foci covered by a yellow-gray adherent pseudomembrane. Maternal caruncles are dark red to brown, and the adherent fetal cotyledons are markedly thickened. Cutaneous lesions in aborted fetuses consist of soft, red to gray, elevated, discrete foci that resemble ringworm.

In **horses**, epistaxis and dysphagia are common complications of gutturomycosis (see p 1463). The infected guttural pouch is characterized by a necrotizing inflammation and is thickened, hemorrhagic, and covered by a friable pseudomembrane. Mycotic rhinitis characterized by dyspnea and nasal discharge has also been described. Aspergillosis can be a rapidly fatal disease associated with diffuse pulmonary invasion. In these cases, acute enteritis is often a predisposing factor. The colitis is thought to result in a profound neutropenia that decreases the immunocompetence of the host, followed by the invasion of *Aspergillus* from disrupted intestinal mucosa. Locomotor and visual disturbances, including blindness, may occur when the infection spreads to the brain and optic nerve.

In **dogs**, aspergillosis is typically localized to the nasal cavity or paranasal sinuses and is usually caused by infection with *A. fumigatus*. Nasal aspergillosis is seen mainly in dolichocephalic breeds; it begins in the posterior region of the ventral maxilloturbinate with signs of lethargy,

Aspergillus fumigatus from canine nasal infection. Courtesy of Ontario Veterinary College.

nasal pain, ulceration of the nares, sneezing, unilateral or bilateral sanguinopurulent nasal discharge, frontal sinus osteomyelitis, and epistaxis. Gross lesions vary considerably with site of infection, but the mucosa of the nasal and paranasal sinuses may be covered by a layer of necrotic material and white to gray-white fungal growth. The mucosa and the underlying bone may be necrotic with loss of bone definition on radiographs or CT.

Disseminated disease in dogs is seen most often in middle-age, female German Shepherds and usually involves *A. terreus*, *A. deflexus*, and *A. niger*. The clinical signs of disseminated aspergillosis may include lethargy, lameness, anorexia, weight loss, muscle wasting, pyrexia, hematuria, urinary incontinence, generalized lymphadenopathy, and neurologic deficits. Lesions are frequently found in the abdominal and thoracic lymph nodes, kidneys, spleen, and vertebrae. Discospondylitis is common.

In cats, sinonasal and sino-orbital disease is seen most often. Aspergillosis is rare in cats compared with dogs. Sinonasal disease can present similarly to the disease in dogs, but sino-orbital disease can be very aggressive, often causing severe facial swelling. In some cases, a mass in the pterygopalatine fossa or ulceration of the hard palate may be seen. The CNS may be invaded, causing neurologic signs.

Diagnosis: Radiographs in dogs with nasal aspergillosis may show generalized radiolucence of the nasal cavity secondary to turbinate tissue destruction. Frontal sinus osteomyelitis is seen in as many as 80% of dogs. Cross-sectional imaging via CT is more sensitive than plain radiographs in demonstrating consistent changes. Visualization of fungal plaques by rhinoscopy together with serologic and either mycologic or radiographic evidence of disease is often how a diagnosis is made. A diagnosis based on culture results alone is not appropriate, because aspergilli are ubiquitous and can be isolated from the nasal cavities of healthy dogs. Positive culture results should be supported by demonstration of narrow, hyaline, septate, branching hyphae within lesions or by serologic tests. The agar-gel double-diffusion test for serum antibody is generally considered unreliable. Dogs with systemic disease usually have neutrophilia, often with a left shift, and a nonregenerative anemia. Azotemia, hyperglobulinemia, hypoalbuminemia, and hypercalcemia are common. Ultrasound usually reveals abdominal lymphadenopathy and renal

lesions. Systemic disease is usually diagnosed by culture of the organism, often from urine. A blood and urine galactomanan antigen assay for diagnosis of systemic aspergillosis in dogs has been described to have moderate sensitivity and specificity.

Treatment: In dogs, topical treatment is considered the treatment of choice for nasal and paranasal aspergillosis. Several surgical techniques and drug regimens have been used with varying success. Clotrimazole formulated in a polyethylene glycol base is generally considered the first-line treatment. It can be administered through indwelling tubes trephined into the frontal sinuses or via the nares as a single infusion. If infusion is via the nares, Foley catheters are used to instill 0.5 g in each side of the nasal cavity. The infused solution is left in place for 1 hr, during which the dog's position is changed periodically to maximize penetration. There is an ~80% success rate using local infusions in this manner. Enilconazole, 10 mg/kg, instilled bid for 7–14 days, via tubes implanted surgically into the frontal sinuses, has also been used with a similar success rate. Drugs given systemically have included ketoconazole, itraconazole, fluconazole, voriconazole, and posaconazole. Fluconazole (2.5–10 mg/kg, divided bid) and itraconazole (5–10 mg/kg/day) are cost-effective options. Ketoconazole (5–10 mg/kg, bid for 6–8 wk), although cost-effective, is not as effective clinically. Voriconazole (3–6 mg/kg/day) is probably the most effective of the azole antifungals for treating aspergillosis, but the cost is much higher than that of the other choices.

In horses, surgical exposure and curettage have been used to treat gutturo-mycosis. Topical natamycin and oral potassium iodide have been reported effective in cases of *Aspergillus* infection. Itraconazole (3 mg/kg, bid for 84–120 days) has been reported effective in *Aspergillus* rhinitis in horses.

Bovine mastitis has been treated successfully with combined intra-arterial and intramammary injection with miconazole.

BLASTOMYCOSIS

Blastomycosis, caused by the dimorphic fungus *Blastomyces dermatitidis*, is characterized by pyogranulomatous lesions in various tissues. It is most common in people, dogs, and cats but has also been described in such widely divergent species as horses, ferrets, deer, wolves, African

lions, bottlenosed dolphins, and sea lions. It appears not to be a disease of cattle, sheep, or pigs. Blastomycosis is generally limited to North America, and most cases have occurred in the Mississippi, Missouri, Tennessee, and Ohio River basins and along the Great Lakes and the St. Lawrence Seaway. There is an endemic area in the Pacific northwest. Even within these river basins, the organism is found in geographically restricted areas. Beaver dams and other habitats where soil is moist, acidic, and rich in decaying vegetation may serve as the ecologic niche for the organism, but it is often difficult to find in the environment. The organism has also been recovered from pigeon and bat feces. Rain, dew, or fog may play a critical role in liberating the infective conidia, which then are aerosolized and inhaled. When respiratory defenses are overwhelmed or immunosuppressed, disseminated disease occurs via hematogenous spread from the lungs. Cutaneous lesions may result from a primary entry through the skin or, more commonly, by dissemination from a pulmonary focus. Needle-stick injuries to veterinary personnel after aspiration of cutaneous lesions from infected animals have resulted in primary cutaneous infection. Ocular lesions tend to develop first in the posterior segment, resulting in granulomatous chorioretinitis and retinal detachment. Anterior segment involvement often follows, resulting in anterior uveitis and panophthalmitis.

Clinical Findings: The signs vary with organ involvement and are not specific. Weight loss may be accompanied by coughing, anorexia, lymphadenopathy, dyspnea, ocular disease, lameness, skin lesions, and fever. Dry, harsh lung sounds from lung lesions are common in dogs with blastomycosis. Signs of pulmonary involvement are seen in as many as 85% of affected dogs. Severe pulmonary involvement results in hypoxemia, which indicates a poor prognosis. Lymph node involvement is seen in approximately half of affected dogs, which is about the same proportion of dogs that have cutaneous involvement. Skin lesions may include proliferative granulomas and subcutaneous abscesses that ulcerate and drain a serosanguineous discharge. The skin lesions are often very small and multifocal in dogs, but large abscesses are occasionally seen, especially in cats. The planum nasale, face, and nail beds are most often involved. Signs of ocular blastomycosis are seen in 30%–50% of affected dogs and include blindness,

uveitis, glaucoma, and retinal detachment. Lameness associated with fungal osteomyelitis or severe paronychia occurs in approximately one quarter of affected dogs. CNS signs are uncommon, occurring in <5% of dogs, but they may be more common in cats. The pattern of systemic involvement is similar in cats, but cats are affected far less commonly than dogs. Hematuria and dysuria may be seen with urogenital blastomycosis.

Lesions: Gross lesions consist of few to numerous, variable-sized, irregular, firm, gray to yellow areas of pulmonary consolidation and nodules in the lungs and thoracic lymph nodes. Dissemination may result in nodular lesions in various organs but especially the skin, eyes, and bone. Cutaneous lesions are single or multiple papules, or chronic, draining, nodular pyogranulomas.

Diagnosis: Blastomycosis should be considered in dogs with draining cutaneous nodules and signs of respiratory disease. In cats, respiratory tract involvement is seen most frequently, followed by involvement of the CNS, regional lymph nodes, skin, eyes, and GI and urinary tracts. Radiographic findings in the lungs include noncalcified nodules or consolidation, with enlargement of the bronchial and mediastinal lymph nodes. The predominant patterns on thoracic radiographs are those of diffuse nodular interstitial and peribronchial densities. Commonly, the bronchial lymph nodes are greatly enlarged and appear in radiographs as dense masses. Diagnosis can be made from biopsy of tissue or aspirated specimens taken from cutaneous lesions or other involved organs by the presence of thick-walled yeast that often have daughter cells budding from a broad base. These round to ovoid, pale pink (H&E) blastospores measure 8–25 μm and have a refractile, double-contoured wall. They may be empty or contain basophilic nuclear material and have single, broad-based buds. An antibody response, detected by agar gel immunodiffusion, usually occurs, but this response is neither sensitive nor specific when attempting to make a definitive diagnosis. An enzyme immunoassay for antibodies to rBAD-1 repeat has shown improved sensitivity. A recently developed antigen enzyme immunoassay has been used in both serum and urine to detect cell-wall galactomannan that is immunologically indistinguishable in histoplasmosis and blastomycosis. Although the titer is not useful in differentiating between the two

infections, it helps diagnose the presence of one of these two systemic mycoses.

Treatment: Itraconazole (5 mg/kg/day) is the treatment of choice for dogs and cats with blastomycosis. A minimum of 2 mo of treatment is necessary, and the drug should be continued until active disease is not apparent. Clinical cure can be expected in ~70% of dogs, with recurrence months or years after treatment noted in ~20% of treated dogs. Most dogs will respond to retreatment with itraconazole. Other azoles such as fluconazole and ketoconazole are not as effective as itraconazole, but a study evaluating cost-effectiveness of fluconazole showed it to be a less expensive alternative, despite longer treatment times. In fulminating cases of blastomycosis, especially those with evidence of hypoxemia, combination therapy with amphotericin B and itraconazole is recommended. Short courses of anti-inflammatory dosages of glucocorticoids have been advocated during the first few days of treatment by some, but steroid use is controversial and may actually worsen the prognosis. The prognosis is best for dogs with only mild lung disease, is more guarded for dogs with moderate to severe lung disease, and is poorest for dogs with CNS involvement.

CANDIDIASIS

Candidiasis is a localized mucocutaneous disease caused by species of the yeast-like fungus *Candida*, most commonly *C. albicans*. It is distributed worldwide in a variety of animals. *C. albicans* is a normal inhabitant of the nasopharynx, GI tract, and external genitalia of many species of animals and is opportunistic in causing disease. Factors associated with candidal infections are disruption of mucosal integrity; indwelling, intravenous, or urinary catheters; administration of antibiotics; and immunosuppressive drugs or diseases. The organism most frequently infects birds (see p 2791), in which it involves the oral mucosa, esophagus, and crop. Superficial infections limited to the mucous membranes of the intestinal tract have been described in pigs and foals. Systemic candidiasis has also been described in cattle, calves, sheep, and foals secondary to prolonged antibiotic or corticosteroid therapy. In cats, candidiasis is rare but has been associated with oral and upper respiratory disease, pyothorax, ocular lesions, intestinal disease, and urocystitis. Infections are rare in dogs and horses. However, *Candida* spp have been

considered a cause of arthritis in horses and mastitis and abortion in cattle. Fungemia and *Candida* peritonitis have been noted in dogs with perforating intestinal lesions after surgery, and mucosal and cutaneous candidiasis has been noted in immunosuppressed dogs and in dogs with diabetes mellitus.

Clinical Findings and Lesions: Signs are variable and nonspecific and may be associated more with the primary or predisposing conditions than with the candidiasis itself. Calves with forestomach candidiasis have watery diarrhea, anorexia, and dehydration, with gradual progression to prostration and death. Affected chicks are listless and have reduced feed intake and growth rate. Porcine candidiasis affects the oral, esophageal, and gastric mucosa, with diarrhea and emaciation the most consistent signs.

Gross lesions of the skin and mucosae are generally single or multiple, raised, circular, white masses covered with scabs. The organism can penetrate keratinized epithelium and cause marked keratinous thickening of the mucosae of the tongue, esophagus, and rumen. In birds, the crop and esophageal lesions are white, circular ulcers with raised surface scabs that produce thickening of the mucosa; an easily removed pseudomembrane is common.

Diagnosis: Fungal organisms are numerous in proliferating epithelial tissue, and diagnosis can be made by examination of scrapings or biopsy specimens from mucocutaneous lesions. *C. albicans* are ovoid, budding yeast cells (2–4 µm in diameter) with thin walls, or they occur in chains that produce pseudohyphae when the blastospores remain attached after budding division. Filamentous, regular, true hyphae also may be visible. The fungal cells generally are limited to epithelial tissue and rarely extend deeper.

Treatment: Nystatin ointment or topical application of amphotericin B or 1% iodine solution may be useful in the treatment of oral or cutaneous candidiasis. Amphotericin B, 500 g in 1 L of 5% dextrose, was administered IV, every 48 hr for 24 days and then every 72 hr for 15 days, to successfully resolve arthritis induced by *C. fumata* in a horse. Fluconazole (5 mg/kg/day, PO, for 4–6 wk) was also used to successfully treat disseminated candidiasis in foals. Itraconazole and amphotericin B lipid complex are considered the treatments of choice in dogs, but few cases have been treated.

COCCIDIOIDOMYCOSIS

(Valley Fever)

Coccidioidomycosis (Valley Fever) is a dustborne, noncontagious infection caused by the dimorphic fungus *Coccidioides immitis*. Infections are limited to arid and semiarid regions of the southwestern USA and to similar areas of Mexico and Central and South America. Although many species of animals, including people, are susceptible, only dogs are affected significantly. Placental infection leading to abortion and osteomyelitis have been described in horses. Ruminants and pigs may have subclinical infections with lesions restricted to foci in the lungs and to thoracic lymph nodes. Inhalation of fungal spores is the only established mode of infection, and spores may be carried on dust particles. Epidemics may occur when rainy periods are followed by drought, resulting in dust storms. Most bovine infections are contracted in dusty feedlots.

Clinical Findings and Lesions: The disease varies from inapparent (cattle, sheep, pigs, dogs, cats) to progressive, disseminated, and fatal (dogs, nonhuman primates, cats, and people). Coccidioidomycosis is primarily a respiratory disease that ranges from self-limiting to chronic. Dissemination occurs in ~20% of canine infections, with many tissues, especially eyes, joints, and bone, affected. Clinical signs can vary greatly, depending on organ involvement and severity of infection. Dogs with disseminated disease may have chronic cough, anorexia, cachexia, lameness, enlarged joints, fever, and intermittent diarrhea. Dissemination to the skin with draining ulceration may occur, but primary infection through the skin is rare. Cats infected with *C immitis* most often present with dermatologic signs (draining skin lesions, subcutaneous granulomatous masses, abscesses), fever, inappetence, and weight loss. Less common clinical signs in cats include respiratory (dyspnea), musculoskeletal (lameness), neurologic, and ophthalmologic abnormalities. Approximately 50% of infected cats appear to have disseminated disease.

Gross lesions may be limited to the lungs, mediastinum, and thoracic lymph nodes, or may be disseminated to various organs. Lesions are discrete, variable-sized nodules with a firm, gray-white cut surface, and resemble those of tuberculosis (see p 687). The nodules are pyogranulomas composed of epithelioid and giant cells, and the center

of some foci may contain purulent exudate and fungal organisms. Some lesions may have mineralized foci.

Diagnosis: In endemic areas, coccidioidomycosis should be considered in dogs with chronic bronchopulmonary disease and when pulmonary nodules and enlarged lymph nodes are found on thoracic radiographs. The lesions are pyogranulomas that contain *C immitis* free in the exudate and in epithelioid and multinucleate giant cells. The organisms vary in size and appear as relatively large (20–80 μ m, up to 200 μ m) spherules with a double-contoured wall. The mature spherules (sporangia) contain endospores (sporangiospores) 2–5 μ m in diameter. Diagnosis is established by demonstrating the spherules in tissues. Serum can also be tested by agar gel immunodiffusion (AGID) assays for detection of precipitin and complement-fixing antibodies. Currently, most commercial laboratories run AGID assays for IgG and IgM antibodies; results of these assays are specific but relatively insensitive. An enzyme immunoassay for *Coccidioides* galactomannan antigen useful in human infections has proved insensitive in dogs. A presumptive diagnosis can be made when serology is positive in an animal with consistent clinical signs. Attempts to culture the fungus should be restricted to those laboratories equipped to handle such dangerously infective cultures.

Treatment: Disease is often self-limiting, but if chronic respiratory signs or multisystemic disease are present, longterm antifungal therapy is needed; with disseminated infection, treatment of at least 6–12 mo is typical. Fluconazole (2.5–10 mg/kg/day) is the most commonly used drug to treat disseminated or chronic respiratory infections. Ketoconazole (10–30 mg/kg/day) and itraconazole (10 mg/kg/day) are also commonly used to treat dogs with coccidioidomycosis but are more expensive and have a higher incidence of adverse effects. Amphotericin B may be the most effective antifungal drug, but it is highly nephrotoxic. It may be indicated in animals that either do not improve or are unable to tolerate the azole antifungals.

CRYPTOCOCCOSIS

Cryptococcosis is a systemic fungal disease that may affect the respiratory tract (especially the nasal cavity), CNS, eyes, and skin (particularly of the face and neck of cats). The causal fungi, *Cryptococcus*

neoformans and *C. gattii*, exist in the environment and in tissues in a yeast form. Infection occurs worldwide. The fungi are found in soil and fowl manure, especially in pigeon droppings. Transmission is by inhalation of spores or contamination of wounds. In avian droppings, it may occur in a noncapsulated form as small as 1 μm , which can be inhaled into the deeper portions of the lungs. Cryptococcosis is most common in cats but also is seen in dogs, cattle, horses, sheep, goats, birds, and wild animals. In people, many cases are associated with a defective cell-mediated immune response.

Clinical Findings and Lesions: Bovine cryptococcosis has been associated only with cases of mastitis, and many cows in a herd may be infected. Affected cows have anorexia, decreased milk flow, swelling and firmness of affected quarters, and enlarged supramammary lymph nodes. The milk becomes viscid, mucoid, and gray-white, or it may be watery with flakes. The disease in horses almost invariably is a respiratory ailment with obstructive growths in the nasal cavities.

In cats, upper respiratory signs secondary to nasal cavity infection are most common and include sneezing; mucopurulent, serous, or hemorrhagic unilateral or bilateral chronic nasal discharge; polyp-like mass(es) in the nostril; and/or a firm, subcutaneous swelling over the bridge of the nose. Cutaneous lesions are also common and are characterized by papules and nodules that are fluctuant to firm. Larger lesions tend to ulcerate, leaving a raw surface with a serous exudate. Neurologic signs associated with cryptococcosis of the CNS may include depression, changes in temperament, seizures, circling, paresis, and blindness. Ocular abnormalities may also develop, including dilated unresponsive pupils and blindness due to exudative retinal detachment, granulomatous chorioretinitis, panophthalmitis, and optic neuritis.

In contrast to cats, dogs often have disseminated disease with CNS or ocular involvement. Clinical signs are often related to meningoencephalitis, optic neuritis, and granulomatous chorioretinitis. Lesions in the nasal cavity of many dogs have been reported, but they are usually not the primary finding or reason for presentation. Approximately 50% of dogs have lesions in the respiratory tract, usually the lungs, and most have granulomas present in multiple systems. Structures often involved in order of decreasing frequency are kidneys, lymph

nodes, spleen, liver, thyroid, adrenals, pancreas, bone, GI tract, muscle, myocardium, prostate, heart valves, and tonsils.

Lesions associated with cryptococcosis vary from a gelatinous mass, consisting of numerous organisms with minimal inflammation, to granuloma formation. The lesion is usually composed of aggregates of encapsulated organisms within a connective tissue reticulum. The cellular response is primarily macrophages and giant cells with a few plasma cells and lymphocytes. Epithelioid giant cells and areas of caseous necrosis are less common than with the other systemic mycoses.

Diagnosis: The most rapid method of diagnosis is cytologic evaluation of nasal exudate, skin exudate, CSF, or samples obtained by paracentesis of the aqueous or vitreous chambers of the eye or by impression smears of nasal or cutaneous masses. Gram stain is most useful; the organism retains the crystal violet, whereas the capsule stains lightly red with safranin. India ink is also used to visualize the organism, which appears unstained and silhouetted against a black background. It is not as definitive as Gram stain unless budding is seen, because lymphocytes, fat droplets, and aggregated India ink particles may be confused with the organism. Wright stain has been used most often in diagnosing canine and feline cases, but this stain can cause the organism to shrink and the capsule to become distorted. New methylene blue and periodic acid-Schiff (PAS) stains are better than Wright stain for this reason. Because cytologic evaluation is rapid, impression smears or potassium hydroxide preparations should always be made of suspected cryptococcal lesions.

If no organisms are seen, a biopsy of the lesion can be taken; part of the sample can be used for culture and the rest processed for routine histology. The organism can be stained with H&E, but the capsule does not stain. The organism is more easily visualized with PAS and Gomori methenamine silver stains, but the capsule does not stain with these, either. The best stain for *Cryptococcus* is Mayer mucicarmine because of its ability to stain the capsule. Immunofluorescent staining can also be used. The large capsule and thin cell wall of *Cryptococcus* differentiate it from *Blastomyces*. *Cryptococcus*, by its budding and lack of endospores, can be distinguished from *Coccidioides immitis*.

Detection of cryptococcal capsular antigen in serum, urine, or CSF is a useful, rapid method of diagnosis in those

suspected cases in which the organism is not identified. A latex agglutination test is commercially available in kit form. The antigen titer can also be used to help determine response to therapy.

The organism can be cultured from exudate, CSF, urine, joint fluid, and tissue samples if a large enough sample volume is available. Sabouraud agar with antibiotics is used if bacterial contamination is likely.

Treatment: Fluconazole (2.5–10 mg/kg/day) or itraconazole (10 mg/kg/day) are considered the treatments of choice. Amphotericin B can be given SC (0.5–0.8 mg/kg diluted in 0.45% saline containing 2.5% dextrose; 400 mL for cats, 500 mL for dogs <20 kg, 1,000 mL for dogs >20 kg), 2–3 times per wk. Amphotericin B lipid complex (1–2 mg/kg for cats or 2–3 mg/kg for dogs) can also be given 3 times/wk for 12–15 treatments. Flucytosine can be used alone; however, drug resistance may develop, so combination therapy with amphotericin is recommended.

EPIZOOTIC LYMPHANGITIS

Epizootic lymphangitis is a chronic granulomatous disease of the skin, lymph vessels, and lymph nodes of the limbs and neck of Equidae caused by the dimorphic fungus *Histoplasma farciminosum*. The disease is seen in Asian and Mediterranean areas but is unknown in the USA. The fungus forms mycelia in nature and yeast forms in tissues and has a saprophytic phase in soil. Infection probably is acquired by wound infection or transmission by bloodsucking insects.

Clinical Findings and Lesions: The disease is characterized by freely movable cutaneous nodules, which originate from infected superficial lymph vessels and nodes and tend to ulcerate and undergo alternating periods of discharge and closure. Affected lymph nodes are enlarged and hard. The skin covering the nodules may become thick, indurated, and fused to the underlying tissues. Lesions also may be present in the lungs, conjunctiva, cornea, nasal mucosa, and other organs. The nodules are pyogranulomas with a thick, fibrous capsule and contain thick, creamy exudate and the causative organisms.

Diagnosis: The clinical features are highly suggestive. Diagnosis can be confirmed by microscopic examination of exudates and biopsy specimens. The yeast forms of the organisms distend the cytoplasm of

macrophages and appear in H&E sections as globose or oval bodies (3–4 μ m) with a central basophilic body surrounded by an unstained zone. The organism closely resembles *H. capsulatum*. Serologic testing is available with serum agglutination titers of 1:80 or higher reported to be positive. Positive titers may be reflective of past exposure, with specificity for current infection being low.

Treatment: No completely satisfactory treatment is known. Surgical excision of lesions combined with antifungal drugs (amphotericin B) could be used.

HISTOPLASMOSIS

Histoplasmosis is a chronic, noncontagious, disseminated, granulomatous disease of people and other animals caused by the dimorphic fungus *Histoplasma capsulatum*. The organism is commonly found in soil that contains bird and bat manure. It produces mycelial growth in the soil and in culture at room temperature and grows in a yeast form in tissues and in cultures at 37°C.

Histoplasmosis is found worldwide. Endemic areas in the USA include the Mississippi and Ohio River valleys. Infection has been described in many animal species, but disease is uncommon to rare in all but dogs and cats. Infection is commonly via aerosol contamination of the respiratory tract, and the lungs and thoracic lymph nodes are the sites of primary infection, although the GI tract may be a primary site of infection, especially in dogs. The organisms enter the bloodstream from a primary focus and become disseminated throughout the body; they may localize in bone marrow or the eyes, where they produce chorioretinitis or endophthalmitis.

Clinical Findings: The signs vary and are nonspecific, reflecting the various organs involved. Chronic GI signs, especially large intestinal diarrhea, are usually most obvious in dogs, but cats tend to have respiratory and nonspecific clinical signs. Many dogs have a protracted course of weight loss to emaciation, chronic cough, persistent diarrhea, fever, anemia, hepatomegaly, splenomegaly, lymphadenopathy, and nasopharyngeal and GI ulceration. Obstructive respiratory difficulty due to tracheobronchial lymphadenopathy also has been seen in dogs. Dissemination may involve the skin, in which weeping, ulcerated, nodular lesions develop. Polyarthropathy, chorioretinitis, and retinal detachment have also been reported in a dog with disseminated

histoplasmosis. Acute histoplasmosis may be fatal after 2–5 wk. In cats, disseminated infection is common. Clinical signs may be nonspecific but often include respiratory difficulty, fever, depression, anorexia, and weight loss. Lymphadenopathy, hepatomegaly, ocular disease (conjunctivitis, granulomatous chorioretinitis, retinal detachment, optic neuritis), lameness, and cutaneous nodules or ulcers may also be seen.

Lesions: Gross lesions include enlargement of the liver, spleen, and mesenteric lymph nodes; ascites; yellow-white, variable-sized nodules in the lungs; and enlargement of bronchial lymph nodes. The enlarged liver may have multiple, scattered, irregular-shaped, pale yellow foci of granulomatous inflammation. Pale foci may be present in the myocardium, and the small intestine may have thickened, gray walls and ulceration of the mucosa.

Diagnosis: Histoplasmosis should be considered when the clinical signs include weight loss, chronic diarrhea, respiratory distress, enlarged bronchial lymph nodes, and pulmonary nodules. *Histoplasma* organisms are usually numerous in affected tissues, and a definitive diagnosis can often be made by fine-needle aspiration and exfoliative cytology. Cytology of bone marrow may be diagnostic in cats. Tissue biopsy may be required if cytology is not diagnostic. *Histoplasma* organisms are difficult to detect with routine H&E stain but stain well with PAS, Gomori methenamine silver, and Gridley fungal stains. Yeast forms in macrophages and giant cells are round to ovoid (1–4 μm) structures with a thin cell wall and a thin, clear zone between the cell wall and cellular cytoplasm. *H. capsulatum* can also be cultured from tissue specimens, fine-needle aspirates, and body fluids. Antigen testing using a quantitative antigen ELISA can be performed on urine, serum, and CSF. Cross-reactivity occurs with blastomycosis.

Treatment: Itraconazole (10 mg/kg/day) is the treatment of choice for disseminated histoplasmosis in dogs and cats, although fluconazole is probably also effective. Ketoconazole, 10–15 mg/kg, bid for 4–6 mo, may be effective in early or mild cases of histoplasmosis in dogs. For severe cases, concurrent treatment with amphotericin B or amphotericin B lipid complex is suggested.

HYALOPHYPHOMYCOSIS

Hyalohyphomycosis is infection caused by nonpigmented fungi (other than the genera

Aspergillus or *Penicillium* or the class Zygomycetes) that in tissue form hyphal elements with hyaline or clear walls. Examples of genera causing hyalohyphomycosis in people and other animals include *Acremonium*, *Fusarium*, *Geotrichum*, *Paecilomyces*, *Pseudallescheria*, *Sagenomella*, *Phialosimplex*, *Geosmithia*, *Geomyces*, and *Scedosporium*. Hyalohyphomycosis is far less common than phaeohyphomycosis.

Clinical Findings: Lesions range from local cutaneous, subcutaneous, corneal, or nasal mucosal disease to disseminated disease involving the lungs and multiple other organ systems. Disseminated and corneal forms have been reported most commonly. Animals presenting with cutaneous lesions should be evaluated for systemic disease. Animals being treated with immunosuppressive drugs for immune-mediated disease may develop cutaneous hyalohyphomycosis and not have lesions at other sites, whereas immunocompetent animals that develop hyalohyphomycosis most often do have disseminated disease, or at least disease that is not confined to the skin.

Diagnosis: The several causative fungi cannot be identified by their histologic features in tissues; culture isolation and/or PCR are required.

Treatment: Surgical removal with or without azole antifungal therapy is the treatment of choice for local disease. Disseminated disease typically carries a grave prognosis. Treatment with newer azole antifungals and/or amphotericin B lipid complex may be attempted and is most likely to be effective if immunosuppressive drugs can be tapered.

MYCETOMAS

Mycetomas are granulomatous nodules of the subcutaneous tissues that contain tissue grains or granules. Within the grains are dense colonies of the organism. When such lesions are caused by fungi, they are known as eumycotic mycetomas. The causal agents of eumycotic mycetomas include a variety of saprophytic geophilic fungi. Eumycotic mycetomas caused by pigmented fungi such as *Curvularia* spp and *Madurella* spp are called black- or dark-grain mycetomas. White-grained mycetomas are caused by unpigmented fungi such as *Acremonium* spp and *Scedosporium apiospermum* (the asexual state of *Pseudallescheria boydii*).

Clinical Findings and Lesions: Most eumycotic mycetomas are confined to the subcutaneous tissue, but white-grain mycetomas may be extensions of abdominal cavity disease. Peritonitis or abdominal masses are typically seen in white-grain mycetomas. Black-grain mycetomas are usually characterized by relatively poorly circumscribed cutaneous nodules on the extremities or face. The lesions may ulcerate or form fistulas. When the feet or limbs are involved, the infection may extend to the underlying bone.

The fungal mycelia proliferate in the lesions and organize into aggregates known as granules or grains. In these granules, the mycelium is compact and frequently bizarre and distorted in form. Chlamydospores are frequent, especially at the periphery, and the mycelium may or may not be embedded in an amorphous, cement-like substance. Histologically, the granules are frequently surrounded by eosinophilic deposits. Granules may be of various colors and sizes, depending on the species of fungus involved.

Diagnosis: A presumptive diagnosis can be made if there are grains within the exudate of draining tracts. For cytology, the grains should be examined for the presence of fungal elements. If no tissue grains are found in the exudate, a biopsy of the lesion should be taken for histopathologic examination. Cultures should be performed to confirm cytologic findings and to identify the causative agent. Either tissue grains or biopsy specimens should be cultured.

Treatment: The prognosis for abdominal mycetomas is guarded, because tissue involvement is usually extensive. Cutaneous mycetomas, while not life-threatening, are often difficult to resolve. Radical surgical excision, including limb amputation, may be effective for some cases of cutaneous mycetomas. Effectiveness of antifungal chemotherapy has been reported in only a few cases. In one report, fluconazole, 50 mg/day for 6 wk, was used to successfully treat a dog with intra-abdominal maduromycosis. In another report, longterm treatment with itraconazole, 5–10 mg/kg/day, failed to resolve a disseminated *Acremonium* infection in a dog.

OOMYCOSIS

(Pythiosis, Lagenidiosis)

Oomycosis is caused by pathogens in the class Oomycetes. These organisms are not

true fungi but are aquatic pathogens in the kingdom Stramenopila. They are more closely related to algae than fungi but cause disease that closely resembles zygomycosis (see p 645). Organisms of significance in veterinary medicine include various species of *Saprolegnia* and *Achyla* (eg, *S. dictyna*), which are the common agents of cutaneous disease in fishes; *Pythium insidiosum*, the cause of a cutaneous and subcutaneous mycosis in horses (bursatti, swamp cancer, leeches), a cutaneous, subcutaneous, and GI disease in dogs, and a cutaneous and paranasal disease of cats; and *Lagenidium* spp, the cause of cutaneous and systemic lesions and large-vessel aneurysms in dogs. Pythiosis is a common disease of domestic animals in some tropical and subtropical areas of the world. In dogs, pythiosis is most often encountered in southeast Asia, eastern coastal Australia, South America, and in the USA, especially along the Gulf coast. In the USA, the disease most often is seen in fall and winter months.

Clinical Findings and Lesions: In horses, lesions are large, roughly circular, granulomatous, ulcerated, fistulated nodules, or subcutaneous swellings with yellow-gray necrotic masses or cores. The lesions are most common on the legs (especially the lower limbs), abdomen, chest, and genitalia. Distribution of lesions is attributable to the aquatic nature of the

Prominent granulation tissue and inflammation due to *Pythium insidiosum* in a horse. Courtesy of Dr. Corrie Brown.

organism. The lesions are pruritic, discharge a mucosanguineous exudate, and often are self-traumatized. The granulomas contain firm, yellowish, coralliform masses of necrotic tissue known as "kunkers," which may be removed intact. Kunkers are foci of coagulative necrosis in vessels that have become sequestered from the surrounding tissue; they contain broad, branching aseptate hyphae and are 1–10 μm in diameter. Bone involvement may be a feature of chronic pythiosis. Enteric pythiosis in horses is characterized by fibrosing and stenotic GI lesions containing intralesional foci of caseous material and fungal hyphae.

Specimens removed at surgery or necropsy consist of fibrous tissue with irregularly spaced, firm, focal areas of necrosis that vary in size and color. Microscopically, alterations vary from foci of acute exudative inflammation with numerous eosinophils to a granulomatous reaction with sequestered areas of necrosis and a framework of hyphae that are thick-walled, branching, and slightly irregular in width.

GI and cutaneous forms of pythiosis are seen and are characterized by severe granulomatous and eosinophilic inflammation. *P. insidiosum* infection is seen most often in the GI tract of young adult dogs, especially Labrador Retrievers. The stomach, proximal small intestine, and ileocolic junction are affected most commonly, but any part of the intestine, esophagus, and colon can be diseased. Clinical signs include vomiting, weight loss, and anorexia. The weight loss can be severe, but affected dogs usually do not appear systemically ill until late in the disease. The lesions are typically characterized by severe transmural thickening of the gastric or intestinal wall, with mesenteric lymphadenopathy in which the lymph nodes are embedded in a large, firm granulomatous mass involving the surrounding mesentery. Bowel ischemia, infarction, or acute hemoabdomen may develop due to extension of disease into mesenteric vessels. Enteric pyogranulomas typically consist of necrotic foci infiltrated and surrounded by neutrophils, eosinophils, epithelioid macrophages, plasma cells, and multinucleated giant cells. Etiologic agents may not be apparent on sections stained with H&E. Sections stained with Gomori methenamine silver show branching, rarely septate hyphae.

Cutaneous pythiosis is typified by nonhealing wounds, invasive masses, and ulcerated nodules with draining tracts. The

extremities, tail head, ventral neck, or perineum are affected most commonly. Pythiosis in cats is rare and typified by either cutaneous or nasopharyngeal lesions.

Lagenidiosis is an oomycotic infection of dogs characterized by progressive, multifocal cutaneous and subcutaneous lesions, most often affecting the extremities, mammary region, perineum, or trunk. Regional lymphadenopathy is common. At least two species of *Lagenidium* have been shown to affect dogs. One of the *Lagenidium* spp causes more aggressive cutaneous infection with systemic involvement, whereas a less aggressive *Lagenidium* spp tends to cause more slowly progressive cutaneous disease. Cutaneous lesions are characterized as firm dermal or subcutaneous nodules, or as ulcerated, thickened, edematous areas of deep cellulitis with regions of necrosis and numerous draining tracts. In contrast to the clinical course of cutaneous pythiosis, in dogs with aggressive *Lagenidium* spp, involvement at distant sites is often seen. Thoracic and abdominal lymph nodes, lungs, and especially great vessels may be affected. Animals with great vessel or sublumbar lymph node involvement typically have cutaneous or subcutaneous lesions on the hindlimbs and often develop hindlimb edema. Great vessel aneurysms may acutely rupture, resulting in hemoabdomen and sudden death.

Diagnosis: In horses, lesions of pythiosis are similar to those of zygomycosis (see p 645) and may be confused with cutaneous habronemiasis (see p 904), excessive granulation tissue, and certain equine neoplasms. In pythiosis, the necrotic cores are distinct from the surrounding tissue, and a seropurulent discharge from the sinus tracts is prominent. The lesions contain irregular, branching (at right angles), rarely septate hyphae, 4–8 μm in diameter.

In dogs, diagnosis can be made by isolation of *P. insidiosum* from infected tissues. Culture identification or PCR has been used. Immunoblot serology for detection of anti-*P. insidiosum* antibodies is available and appears to be both sensitive and specific. Immunoblot serology for detection of anti-*Lagenidium* antibodies in canine serum can provide a presumptive diagnosis of lagenidiosis but must be interpreted in conjunction with results of serologic testing for *P. insidiosum* infection because of the potential for cross-reactivity in serum from dogs with pythiosis. The histologic features of lagenidiosis are

similar to those of pythiosis and zygomycosis. However, *Lagenidium* hyphae are usually much larger and visible on H&E-stained tissues. Definitive diagnosis of lagenidiosis and pythiosis is best made by culture and PCR identification.

Treatment: The prognosis for pythiosis or lagenidiosis is poor if surgical excision cannot be done. Complete surgical excision is the treatment of choice, but the disease is often too extensive at the time of diagnosis to allow complete resection. In animals with lesions limited to a single distal extremity, amputation is recommended. Medical therapy for pythiosis should include itraconazole (10 mg/kg/day) and terbinafine (5–10 mg/kg/day). Steroids may decrease inflammation and improve clinical signs in the short term. Treatment with amphotericin B lipid complex can also be attempted. Approximately 20% of dogs with pythiosis respond to long-term antifungal therapy. Lagenidiosis appears to be poorly responsive to medical therapy. In horses, the prognosis is guarded, and timely recognition and treatment are essential for successful management. Factors that influence prognosis include size and site of lesion and duration of infection. Small lesions of short duration that have not invaded critical structures usually respond best to treatment. Surgical excision, immunotherapy, or a combination of both may be effective. Immunotherapy consists of a series of intradermal or SC injections of killed, sonicated, whole-cell hyphal antigens or precipitated soluble antigens of the causative fungus. Subcutaneous abscesses at the sites of injection, osteitis, or deep-seated laminitis may be a complication of such therapy. Surgical removal plus systemic or local administration of amphotericin B may be a satisfactory treatment if the disease is localized.

PENICILLIOSIS

Infections with *Penicillium* spp are rare in domestic animals. In dogs, infections of the nasal cavity, lungs, lymph nodes, and bones have been reported. Nasal disease is most common and behaves similar to nasal aspergillosis. In cats, the fungus has been isolated from the nasal cavity, orbital cellulitis and sinusitis, and lungs. It has also been reported to cause systemic disease in captive toucanets (*P griseofulvum*) and bamboo rats (*P marneffei*) in southeast Asia. *Penicillium* spp are widely distributed in nature and are found in soils, grains, and various foods and feeds.

Clinical Findings and Lesions: Dogs with nasal penicilliosis have chronic sneezing and an acute to chronic nasal discharge that varies from intermittent hemorrhagic to intermittent or continuous mucoid or mucopurulent. Radiographic findings include areas of turbinate destruction with increased radiolucency. Grossly, the nasal mucosa has foci of necrosis and ulceration; microscopically, fungal hyphae may form a thick mat over an intact mucosa adjacent to these foci. Systemic disease often affects long bones, resulting in lameness.

Diagnosis: Diagnosis is based on fungal culture, character of the lesions, presence of fungal hyphae, and a positive agar-gel double-diffusion test. Cultural isolation of a *Penicillium* sp must be accompanied by demonstration of tissue invasion by the fungus for confirmation. In tissues, *P marneffei* closely resemble the yeast phase of *Histoplasma capsulatum*.

Treatment: Very little has been reported concerning treatment of penicilliosis. Surgical turbinectomy with curettage has been combined with flushing of the nasal cavity with 1% tincture of iodine or povidone-iodine (10:1) and oral thiabendazole. Fluconazole, 2.5–5 mg/kg/day for 2 mo, has been used to successfully treat some dogs with nasal penicilliosis.

PHAEOHYPHOMYCOSIS

Phaeohyphomycosis refers to chronic cutaneous, subcutaneous, mucosal, cerebral, or systemic infection caused by one of several genera and species of pigmented fungi of the family Dematiaceae. Several fungal genera have been reported to affect people and other animals, including *Alternaria*, *Bipolaris*, *Cladophialophora* (*Xylohypha*, *Cladosporium*), *Curvularia*, *Exophiala*, *Fonsecaea*, *Moniliella*, *Phialophora*, *Ramichloridium*, and *Scolecobasidium*. Fungi in this category are saprophytic, widely distributed organisms found in soil, water, and decaying vegetable matter. Infection may result from fungal implantation into tissue at the site of an injury.

Clinical Findings and Lesions: Phaeohyphomycosis has been described in cows, cats, horses, and dogs. The most common clinical presentations include ulcerated cutaneous nodules of the digits, pinnae, nasal planum, and nasal/paranasal tissues in cats. The nodules may ulcerate and have

draining fistulous tracts. These pyogranulomas contain pigmented, septate hyphae with irregular enlargements and thin-walled, budding, yeast-like forms. Granulomatous meningoencephalitis caused by pigmented fungi has been reported in dogs and cats. Dogs treated with multiple immunosuppressive agents, especially cyclosporine, appear to be predisposed to developing multifocal cutaneous lesions. Systemic dissemination is most likely in animals treated with immunosuppressive drugs.

Diagnosis: Phaeohyphomycosis can be diagnosed by microscopic examination of exudate and biopsy specimens, which reveals pigmented, dark-walled, irregularly septate filamentous hyphae (2–6 μm in diameter) or yeast-like cells. Infected tissues may be grossly pigmented, giving an appearance of melanoma. The several causative fungi cannot be identified by their histologic features in tissues; cultural isolation and/or PCR are required. The differential diagnosis should include neoplasia, other granulomas, and epidermoid cysts.

Treatment: Phaeohyphomycosis is generally poorly responsive to treatment. Wide excision of cutaneous or subcutaneous lesions is recommended, followed by 6–12 mo of treatment with itraconazole (10 mg/kg/day). Nonresectable disease should be treated with itraconazole. Voriconazole or posaconazole may be more effective, but voriconazole is not recommended in cats. In dogs being treated with immunosuppressive therapy, the prognosis may be better if the immunosuppressive drugs (especially cyclosporine) can be discontinued.

RHINOSPORIDIOSIS

Rhinosporeidiosis is a chronic, nonfatal, pyogranulomatous infection, primarily of the nasal mucosa and occasionally of the skin of horses, cattle, dogs, cats, and aquatic birds, caused by the fungus *Rhinosporidium seeberi*. Uncommon in North America, it is seen most often in India, Africa, and South America. The organism has not been cultured, and its natural habitat is unknown. Trauma may predispose to infection, which is not considered transmissible.

Clinical Findings and Lesions: Infection of the nasal mucosa is characterized by polypoid growths that may be soft, pink, friable, lobulated with roughened surfaces, and large enough to occlude the nasal

passages. The cutaneous lesions may be single or multiple, sessile or pedunculated. The nasal polyps and cutaneous lesions have a granulomatous, fibromyxoid inflammatory component and contain the fungal organism.

Diagnosis: Rhinosporeidiosis may be confused with other granulomatous lesions of the nasal mucosa and skin, including aspergillosis, entomophthoromycosis, “nasal granuloma,” and cryptococcosis. Microscopic demonstration of spherules (sporangia) of *R. seeberi* in biopsy specimens confirms the diagnosis. The spherules may be numerous, vary in size (up to 300 μm), have thick walls that stain periodic acid-Schiff positive, and contain endospores 4–19 μm in diameter. Developing stages of varying size without spores are distributed throughout the lesion.

Treatment: Surgical excision of the lesions is considered standard, but recurrence is common. Amphotericin B and itraconazole have been described for medical treatment but are generally not as effective as surgery.

SPOROTRICHOSIS

Sporotrichosis is a sporadic, chronic, granulomatous disease of people and various domestic and laboratory animals caused by *Sporothrix schenckii*. The organism is dimorphic and forms mycelia on vegetation and in Sabouraud dextrose agar at 25°–30°C (77°–86°F) but is yeast-like in tissue and media at 37°C (98.6°F). It is ubiquitous in soil, vegetation, and timber; is distributed worldwide; and in the USA is most commonly found in coastal regions and river valleys. Infection usually results from direct inoculation of the organism into skin wounds via contact with plants or soil or penetrating foreign bodies. Disseminated disease caused by inhalation of spores is rare.

Sporotrichosis has been reported in dogs, cats, horses, cows, camels, dolphins, goats, mules, birds, pigs, rats, armadillos, and people. Zoonotic infections can occur. The cat may be the species with the greatest zoonotic potential, and transmission from cats to people has been reported without evidence of trauma. In contrast, transmission from other infected species appears to require inoculation of previously traumatized skin. The large number of organisms shed from the wound and in the feces of infected cats is believed to be responsible for the increased zoonotic potential of feline

sporotrichosis. Epidemics of sporotrichosis have been reported in Brazil. Data from these studies support the importance of cats in the zoonotic transmission of the organism. Caretakers of infected cats were four times more likely to become infected than others living in the same household.

Clinical Findings and Lesions: Sporotrichosis may be grouped into three forms: lymphocutaneous, cutaneous, and disseminated. The lymphocutaneous form is the most common. Small, firm dermal to subcutaneous nodules, 1–3 cm in diameter, develop at the site of inoculation. As infection ascends along the lymphatic vessels, cording and new nodules develop. Lesions ulcerate and discharge a serohemorrhagic exudate. In cats, lesions are most often seen on the head, especially on the bridge of the nose and pinnae. Although systemic illness is not seen initially, chronic illness may result in fever, listlessness, and depression. Respiratory signs may be apparent. The cutaneous form tends to remain localized to the site of inoculation, although lesions may be multicentric. Disseminated sporotrichosis is rare but potentially fatal and may develop with neglect of cutaneous and lymphocutaneous forms or if the animal is inappropriately treated with corticosteroids. Infection develops via hematogenous or tissue spread from the initial site of inoculation to the bone, lungs, liver, spleen, testes, GI tract, or CNS.

Diagnosis: Diagnosis can be made by culture (samples obtained from unopened lesions) or microscopic examination of the exudate or biopsy specimens. In tissues and exudate, the organism is present as few to numerous, cigar-shaped, single cells within macrophages. The fungal cells are pleomorphic and small ($2\text{--}10 \times 1\text{--}3 \mu\text{m}$); buds may be present and give the appearance of a pingpong paddle. A fluorescent antibody technique has been used to identify the yeast-like cells in tissues. In species other than cats, *Sporothrix* organisms are often sparse in exudate and infected tissue, so that diagnosis usually requires culture. In cultures, a true mycelium is produced, with fine, branching, septate hyphae bearing pear-shaped conidia on slender conidiophores.

Treatment: Itraconazole (10 mg/kg/day) is considered the treatment of choice for sporotrichosis. Treatment should be continued 3–4 wk beyond apparent clinical cure. Terbinafine has also been used

successfully. Alternatively, a supersaturated solution of potassium iodide, administered PO, has been used with some success; therapy is continued 30 days beyond apparent clinical cure. During treatment, the animal should be monitored for signs of iodide toxicity: anorexia, vomiting, depression, muscle twitching, hypothermia, cardiomyopathy, cardiovascular collapse, and death. Cats are especially sensitive to iodides and the development of iodism.

Zoonotic Risk: Sporotrichosis is an important zoonosis, with animal-to-human transmission well documented. Strict hygiene must be observed when handling animals (especially cats) with suspected or diagnosed sporotrichosis. People in contact with infected animals should be informed of the contagious nature of the disease when therapeutic options are discussed.

ZYGOMYCOSIS

(Basidiobolomycosis, Conidiobolomycosis, Entomophthoromycosis)

Zygomycosis is used to describe infection with fungi in the class Zygomycetes and two genera in the order Entomophthorales, *Basidiobolus* and *Conidiobolus*. True zygomycete infections are rare, but conidiobolomycosis and basidiobolomycosis are more common and cause pyogranulomatous lesions grossly and histologically similar to those caused by pythiosis and lagenidiosis. This is primarily an infection of the nasopharyngeal mucosa and subcutaneous tissue of horses and rarely other animals (llamas, sheep) by *C. coronatus*, *C. incongruus*, *C. lamprauges*, or *B. ranarum*. These ubiquitous fungi are present in soil and decaying vegetation and, in the case of basidioboli, the GI tracts of amphibians, reptiles, and macropods. *C. coronatus* affects almost exclusively the mucosa of the nose and mouth. *Basidiobolus* infects the lateral aspects of the head, neck, and body. *C. coronatus* is also an important insect pathogen.

Clinical Findings: Ulcerative pyogranulomas of the mucous membrane of the nasopharyngeal tissue, mouth, or nodular growths of the nasal mucosa and the lips may be seen with conidiobolomycosis, resulting in mechanical obstruction of the nasal cavity, dyspnea, and nasal discharge. Local dissemination into the retropharyngeal, retrobulbar, or other tissues of the face may be noted. Lesions in basidiobolomycosis are usually single, circular, ulcerative,

pruritic nodules of the skin of the upper body. Fistulous tracts discharge a serosanguineous fluid from the lesions, which frequently are traumatized. Extension to regional lymph nodes results in swelling of the nodes and development of yellow necrotic foci. Lesions may contain a creamy, yellow central core of necrotic tissue. Disseminated basidiobolomycosis is rare but has been described in dogs and a mandrill.

Lesions: In excised tissues or necropsy specimens, a thickened fibrotic dermis has scattered, red or creamy white areas. The lesions, which contain hyphal forms, a heavy infiltrate of eosinophils, and sequestered areas of necrosis, have histologic features of infectious granulomas.

Diagnosis: Clinically, zygomycosis may be confused with cutaneous habronemia-

sis (see p 904) and oomycosis (see p 641) but can be differentiated by microscopic examination of tissues. In H&E sections, the fungus appears as holes and elongated channels, and many hyphae have a wide eosinophilic cuff; in sections stained for fungi, the organism consists of large, branching, sometimes septate, 2.5–25 μm hyphae. Cultural examination is required to identify the causative fungus.

Treatment: Long-term itraconazole administration is recommended for treatment of nasopharyngeal infection. Although lesions often regress, recurrence is common after treatment is discontinued. Cutaneous zygomycete infections should be treated with wide surgical resection followed by long-term itraconazole.

LEPTOSPIROSIS

Leptospirosis is a zoonotic disease with a worldwide distribution caused by infection with any of several pathogenic serovars of *Leptospira*. The disease affects virtually all mammals and has a broad range of clinical effects, from mild, subclinical infection to multiple-organ failure and death.

Etiology: *Leptospira* are aerobic, gram-negative spirochetes that are fastidious, slow growing, and have characteristic corkscrew-like motility. The taxonomy of *Leptospira* is complex and can be confusing. Traditionally, *Leptospira* were divided into two groups; the pathogenic *Leptospira* were all classified as members of *L. interrogans*, and the saprophytic *Leptospira* were classified as *L. biflexa*. Within each of these species, leptospiral serovars were recognized, with >250 different serovars of pathogenic *Leptospira* identified (based on surface antigens) throughout the world. The serovars are often grouped into antigenically related serogroups. With the increased use of genomic information for the classification of bacteria, the genus *Leptospira* was reorganized. There are currently 21 recognized genomospecies of leptospires, including both pathogenic, intermediate, and nonpathogenic organisms. Pathogenic leptospires are now

identified in 9 species of *Leptospira*, with 6 species being regarded as intermediate in pathogenicity, and 6 being nonpathogenic. Some of the common leptospiral pathogens of domestic animals now have different species names. For example, *L. interrogans* serovar Grippotyphosa is now *L. kirschneri* serovar Grippotyphosa. The two types of serovar Hardjo have been formally split into two species: serovar Hardjo type hardjovovis (found in the USA and much of the world) is now *L. borgpetersenii* serovar Hardjo and the less common serovar Hardjo type hardjo-prajitno (found primarily in the UK) is now *L. interrogans* serovar Hardjo. The revised nomenclature is now reflected in the scientific literature but not on labels for vaccines and pharmaceutical products. Fortunately for clinicians, the serovar and serogroup names remain in common use and are useful when discussing the epidemiology, serology, clinical features, treatment, and prevention of leptospirosis.

Host Susceptibility, Epidemiology, and Transmission: Essentially all mammals are susceptible to infection with pathogenic *Leptospira*, although some species are more resistant to disease. Among common companion animals and livestock, leptospirosis is most frequently recognized in cattle, swine, dogs, and

horses. Cats have historically been considered to be resistant to disease but have been shown to seroconvert on exposure to leptospires. Recent evidence suggests that the role of leptospires in the pathogenesis of feline renal disease should be reexamined. Leptospirosis in wildlife is common, although the disease is most often noticed only when the wildlife serve as a source of infection for domestic animals or people.

Leptospirosis is found throughout the world. The infection (and disease) is more prevalent in warm, moist climates and is endemic in much of the tropics. In temperate climates, the disease is more seasonal, with the highest incidence after periods of rainfall.

Although >250 serovars of pathogenic *Leptospira* are recognized, a subset of leptospiral serovars are prevalent within a particular region or ecosystem and are associated with one or more maintenance hosts, which serve as reservoirs of infection (see TABLE 4). Maintenance hosts are often wildlife species and, sometimes, domestic animals and livestock. Each serovar behaves differently within its maintenance host species than it does in other, incidental host species. In maintenance hosts, leptospirosis is generally characterized by a high prevalence of infection, relatively mild acute clinical signs, and persistent infection in the kidneys and sometimes the genital tract.

Diagnosis of maintenance host infections is difficult because of relatively low antibody responses and the presence of few organisms in the tissues of infected animals. Examples of this type of infection are serovar Bratislava infection in swine and serovar Hardjo infection in cattle. In incidental hosts, leptospirosis is characterized by a low prevalence of infection, severe

clinical signs, and a short renal phase of infection. Diagnosis of incidental host infections is less problematic because of a marked antibody response to infection and the presence of large numbers of organisms in tissues of infected animals. Examples of this type of infection are serovar Grippotyphosa infection in dogs or serovar Icterohaemorrhagiae infection in cattle and swine.

Characterization of a host/serovar interaction as a maintenance or incidental host infection is not absolute. For example, swine and cattle infected with serovar Pomona behave as a host intermediate between the two forms, with the organism persisting in the kidneys but the host showing a marked antibody response to infection.

Transmission among maintenance hosts is often direct and involves contact with infected urine, placental fluids, or milk. In addition, the infection can be transmitted venereally or transplacentally with some host/serovar combinations. Infection of incidental hosts is more commonly indirect, by contact with areas contaminated with urine of asymptomatic maintenance hosts that shed leptospires in their urine. Environmental conditions are critical in determining the frequency of indirect transmission. Survival of leptospires is favored by moisture and moderately warm temperatures; survival is brief in dry soil or at temperatures <10°C or >34°C. The organisms are killed by freezing, dehydration, or direct sunlight.

Pathogenesis: Despite the many serovars of *Leptospira* and host species, the key steps in pathogenesis of the disease are similar in all host/serovar combinations. Leptospires invade the body after penetrating exposed mucous membranes or

TABLE 4 COMMON MAINTENANCE HOSTS OF THE PATHOGENIC LEPTOSPIRES ASSOCIATED WITH DISEASE IN DOMESTIC ANIMALS IN THE USA AND CANADA

Leptospiral Serovar	Maintenance Hosts
Canicola	Dogs
Pomona	Pigs, cattle, opossums, skunks
Grippotyphosa	Raccoons, muskrats, skunks, voles
Hardjo	Cattle
Icterohaemorrhagiae	Rats
Bratislava	Pigs, mice (?), horses (?)

damaged skin. After a variable incubation period (4–20 days), leptospires circulate in the blood and replicate in many tissues including the liver, kidneys, lungs, genital tract, and CNS for 7–10 days. During the period of bacteremia and tissue colonization, the clinical signs of acute leptospirosis, which vary by serovar and host, occur. Agglutinating antibodies can be detected in serum soon after leptospiremia occurs and coincide with clearance of the leptospires from blood and most organs. As the organisms are cleared, the clinical signs of acute leptospirosis begin to resolve, although damaged organs may take some time to return to normal function. In some cases, severely damaged organs may not recover, leading to chronic disease or death.

At this point, the disease in incidental and maintenance hosts diverges. Leptospires remain in the tubules of the kidneys of incidental hosts for a short period of time and are shed in the urine for a few days to several weeks. In maintenance hosts, however, leptospires often remain in the renal tubules, genital tract, and less commonly, the eyes, despite the presence of high levels of serum antibody. Leptospires are shed in the urine and genital secretions of persistently infected animals for months to years after initial infection, and these animals become an important reservoir of infection, with the potential to transmit infection to other reservoir hosts or to incidental hosts at risk of developing clinical disease.

Clinical Findings: The clinical signs of leptospirosis depend on the host species, the pathogenicity of the strain and serovar of *Leptospira*, and the age and physiologic state of the animal. Subclinical infections are common, particularly in the maintenance host. In incidental hosts, leptospirosis is an acute, systemic, often febrile illness characterized by renal and/or hepatic damage. In addition, there may be effects on other body systems resulting in clinical problems such as uveitis, pancreatitis, bleeding, hemolytic anemia, muscle pain, or respiratory disease.

In both incidental and maintenance hosts that are pregnant at the time of infection, localization and persistence of the organism in the uterus may result in fetal infection, with subsequent abortion, stillbirth, birth of weak neonates, or birth of healthy but infected offspring. In general, incidental hosts abort acutely, whereas in maintenance hosts, abortions or other reproductive sequelae may be delayed by several weeks or months.

Diagnosis: Diagnosis of leptospirosis depends on a good clinical and vaccination history and laboratory testing. Diagnostic tests for leptospirosis include those designed to detect antibodies against the organism and those designed to detect the organism in tissues or body fluids. Serologic testing is recommended in each case, combined with one or more techniques to identify the organism in tissue or body fluids.

Serologic assays are the most commonly used technique to diagnose leptospirosis in animals. The microscopic agglutination test (MAT) is most frequently used. It involves mixing appropriate dilutions of serum with live leptospires of serovars prevalent within the region. The presence of antibodies is indicated by the agglutination of the leptospires, with the reported titer being the highest dilution of serum that results in 50% agglutination. The MAT is a complex test to perform and interpret, and it requires the maintenance of live leptospiral cultures. An ELISA test to diagnose canine leptospirosis is offered by a commercial laboratory in the USA. This test detects antibodies to LipL32, a membrane protein found on pathogenic leptospires. The currently available assay provides a qualitative negative or positive result and will also detect antibodies induced by vaccination. A comparison of this test to the MAT has not been reported, and it is likely that the numerical titers provided by the MAT will provide more diagnostically useful information than a qualitative ELISA.

Interpretation of serologic results from the MAT is complicated by a number of factors, including cross-reactivity of antibodies, antibody titers induced by vaccination, and lack of consensus about the level of antibody titer that indicates infection. Antibodies produced in an animal in response to infection with a given serovar of *Leptospira* often cross-react with other serovars. In some cases, these patterns of cross-reactivity are predictable based on the antigenic relatedness of the various serovars of *Leptospira*, but the patterns of cross-reactive antibodies vary between host species. Paradoxical reactions may occur with the MAT early in the course of an acute infection, with a marked agglutinating antibody response to a serovar other than the infecting serovar. In addition, there is evidence of lack of consistency between diagnostic laboratories. For these reasons, the infecting serovar in an individual animal cannot be reliably identified as the serovar to which the animal develops the highest titer. The real value of the MAT is in

providing a numerical titer to allow comparison of acute and convalescent values.

Widespread vaccination of dogs and livestock with leptospiral vaccines also complicates interpretation of leptospiral serology. In general, vaccinated animals develop relatively low agglutinating antibody titers (1:100 to 1:400) in response to vaccination, and these titers persist for 1–4 mo after vaccination. However, some animals develop high titers after vaccination which persist for ≥ 6 mo.

Consensus is lacking as to what constitutes a diagnostic titer for leptospiral infection. A low antibody titer does not necessarily exclude a diagnosis of leptospirosis, because titers are often low in acute disease and in maintenance host infections. In cases of acute leptospirosis, a 4-fold rise in antibody titer is often observed in paired serum samples collected 7–10 days apart. Diagnosis of leptospirosis based on a single serum sample should be made with caution and with full consideration of the clinical picture and vaccination history of the animal. In general, with a compatible clinical history and vaccination >3 mo ago, a titer of 1:800 to 1:1,600 is good presumptive evidence of leptospiral infection. The use of paired acute and convalescent titers is strongly recommended whenever possible. Antibody titers can persist for several months after infection and recovery, although there is usually a gradual decline with time.

Immunofluorescence can be used to identify leptospires in tissues, blood, or urine sediment. The test is rapid and has reasonable sensitivity, but interpretation requires a skilled laboratory technician. Immunohistochemistry is useful to identify leptospires in formalin-fixed tissue but, because there may be small numbers of organisms present in some tissues, the sensitivity of this technique is variable. A number of PCR procedures are available, and each laboratory may select a slightly different procedure. Unfortunately, few publications have confirmed the validity of all the commercially available PCRs, which likely vary considerably in their performance. PCR techniques allow detection of pathogenic leptospires in blood, urine, or tissue samples but do not determine the infecting serovar. Culture of blood, urine, or tissue specimens is the only method to definitively identify the infecting serovar. Blood may be cultured early in the clinical course; urine is more likely to be positive 7–10 days after clinical signs appear. Culture is rarely positive after antibiotic therapy has

begun. Culture of leptospires requires specialized culture medium, the organisms are fastidious and slow-growing, and diagnostic laboratories rarely culture specimens for the presence of leptospires. Thus, culture is of little value to clinicians.

Prevention: Avoidance of exposure to free-ranging wildlife and domestic animals that may be maintenance hosts for *Leptospira* is difficult because rodents, raccoons, opossums, and skunks are frequently found in rural and urban environments. The cornerstone of leptospirosis prevention is vaccination with polyvalent inactivated vaccines. Immunity to leptospirosis is believed to be serovar specific and, therefore, vaccines are formulated for various species to include the relevant serovars. There are currently no leptospiral vaccines for horses. Leptospiral vaccines are generally designed and evaluated for the ability to prevent clinical signs of disease, although some vaccines have also been shown to significantly reduce renal colonization and urine shedding.

Zoonotic Risk: People are susceptible to infection with most of the pathogenic serovars of *Leptospira* but are incidental hosts and, therefore, not important reservoirs of infection. Occupational exposure is a risk factor, and veterinarians, veterinary staff, livestock producers, and dairy workers are at increased risk. In addition, recreational exposure to waters contaminated with urine of domestic animals or wildlife presents a risk. Animal owners have contracted leptospirosis via contact with infected companion animals and livestock.

The principal route of infection is contact with infectious body fluids (blood in acute cases or urine) via mucous membranes. In people, the disease varies from subclinical to severe and can be fatal when renal or hepatic failure occurs. The most common signs are fever, headaches, rash, ocular pain, myalgia, and malaise. Transplacental infection, abortion, and infection of infants via breast feeding have been described, making exposure of pregnant women of particular concern. Laboratory techniques are necessary for a definitive diagnosis. Because diagnosis of leptospirosis in animals is difficult based on clinical signs, veterinarians may wish to implement an infection control program in which animal body fluids are handled only with gloved hands and hand washing is routine. It is also essential for staff to take precautions when

handling or nursing animals suspected or confirmed to have leptospirosis. Appropriate precautions include wearing gowns, shoe covers, and gloves to avoid contaminating exposed skin or spreading organisms. Face shields should be worn when handling wet bedding or cleaning cages, stalls, or runs to avoid contact of aerosolized organisms with mucous membranes.

LEPTOSPIROSIS IN DOGS

Dogs are the maintenance host for *Leptospira interrogans* serovar Canicola, and before widespread vaccination programs, serovars Canicola and Icterohaemorrhagiae were the most common serovars in dogs in the USA. The prevalence of canine serovars has shifted significantly in the last 20 years; currently the most prevalent serovars are believed to be Grippotyphosa, Pomona, and Bratislava; however, this belief is largely based on serologic results that are now known to be inaccurate in predicting the infecting serovar in dogs with leptospirosis. The serovars that cause disease in dogs are likely to vary with geographic region and the presence of reservoir hosts. Unfortunately, current understanding of the serovars that cause natural disease in dogs is limited by the fact that isolation of leptospires is rarely performed; thus, studies to date have relied on serologic data. As noted above, it is now accepted that the results of the MAT do not reliably predict the infecting serovar in dogs (or people) with leptospirosis; thus, the true infecting serovar is unknown in most cases. However, it is likely that the serovars that cause disease in dogs are those circulating in local wildlife. Experimental infections and isolation of organisms from a small number of sick dogs have shown that serovars Icterohaemorrhagiae, Canicola, Autumnalis, Pomona, Bratislava, Sejroe, and Ballum are capable of causing disease in dogs. Knowledge of the infecting serovar in dogs is essential for epidemiologic studies and vaccine development; it is less important for clinicians managing individual cases. It is currently not known whether specific serovars are associated with specific clinical signs in dogs, and there is no published evidence to guide therapy based on serovar identification. It is, however, extremely important for veterinarians to maintain a high index of suspicion for leptospirosis, because this is a zoonotic disease and has a wide range of clinical presentations in dogs. Any age, breed, or

sex of dog is susceptible to leptospirosis, and the diagnosis should not be excluded on the basis of signalment or lifestyle. Canine leptospirosis is not restricted to large-breed dogs, male dogs, or dogs with a predominantly outdoor lifestyle.

Acute kidney injury has been the most common presentation for canine leptospirosis in recent years. Affected dogs may present with lethargy, anorexia, vomiting, abdominal pain, and history of polyuria, oliguria, or anuria. Dogs that survive acute renal failure may return to baseline or progress to chronic kidney disease. Leptospirosis should also be considered in any dog with previously diagnosed chronic kidney disease that develops "acute-on-chronic" kidney injury. Renal tubular damage in leptospirosis may manifest as cylindruria, proteinuria, or glycosuria. In people, acute kidney injury due to leptospirosis is often nonoliguric and can be associated with hyponatremia and hypokalemia. These electrolyte changes have also been noted in canine leptospirosis, along with the expected changes of azotemia, hyperphosphatemia, and acidosis of renal failure. Hyperkalemia is also possible. Polyuria and polydipsia (PU/PD) in the absence of azotemia is a less common manifestation of the renal effects of leptospirosis. PU/PD may be due to a decrease in glomerular filtration rate that is sufficient to cause loss of renal concentrating ability without azotemia. However, PU/PD can also be due to nephrogenic diabetes insipidus.

Acute liver disease may accompany acute renal failure in dogs with leptospirosis, or it may occur alone. Affected dogs may be icteric, and serum biochemistry analysis reveals increased bilirubin and alkaline phosphatase. ALT is typically less markedly increased than alkaline phosphatase. In people and dogs, the jaundice of acute leptospirosis appears to be associated with minimal histopathologic changes in the liver, suggesting that it is due to the "cholestasis of sepsis" rather than to hepatocellular damage.

Muscle pain, stiffness, weakness, trembling, or reluctance to move can be seen in dogs with leptospirosis. These may be the result of vasculitis, myositis, or nephritis. Myalgia is commonly reported in human leptospirosis and is associated with the septicemic phase of the disease.

Less common manifestations of canine leptospirosis include bleeding disorders characterized by petechial hemorrhages, epistaxis, melena, and hematemesis. These findings are most likely due to vasculitis.

Affected dogs may also be thrombocytopenic; however, platelet counts are rarely low enough to be responsible for spontaneous bleeding. The causes and mechanisms of bleeding disorders in leptospirosis are poorly understood, but they have been suggested to be associated with endothelial cell damage. Pulmonary hemorrhage is now one of the most common clinical signs in outbreaks of human leptospirosis. This is a less common finding in canine leptospirosis; however, cough or dyspnea, or radiographic abnormalities have been noted in a number of affected dogs. Uveitis is an uncommon manifestation of leptospirosis in dogs. It appears to be infrequently associated with experimental canine leptospirosis, but rare case reports exist. Additional clinical signs reported in dogs with leptospirosis include vomiting, diarrhea, weight loss, fever, hypothermia, ocular nasal discharge, lymphadenopathy, effusions, and edema.

CBC changes may include neutrophilia, lymphopenia, monocytosis, and mild anemia. These changes are nonspecific; however, mild to moderate thrombocytopenia is seen in >50% of cases and, if detected in combination with azotemia or evidence of cholestasis, should prompt diagnostic testing for leptospirosis. Coagulation abnormalities may include increased fibrin degradation products and prolonged prothrombin time (PT) or activated partial thromboplastin time (APTT). Urinalysis may reveal hyposthenuria, isosthenuria, or hypersthenuria, depending on the degree of renal involvement. Other changes may include proteinuria, glucosuria, cylindruria, hematuria, and pyuria. Leptospirosis could also potentially be associated with renal tubular acidosis.

Reticulonodular pulmonary opacities have been described in the thoracic radiographs of dogs with leptospirosis and attributed to pulmonary hemorrhage. These changes may be diffuse or predominantly involve the caudodorsal lung fields. Abdominal radiographs may be unremarkable or may show renomegaly or hepatomegaly. Changes noted on ultrasonography include renomegaly, pyelectasia, increased cortical echogenicity, perinephric effusion, and a hyperechoic medullary band. However, these changes are not specific for leptospirosis, and absence of these findings does not exclude the diagnosis.

Gross necropsy findings can include jaundice, effusions, and petechial or ecchymotic hemorrhages on any organ, pleural, or peritoneal surface. The kidneys and liver may be enlarged, and lungs may be wet, heavy, and discolored. The liver is often

friable with an accentuated lobular pattern and may have a yellowish brown discoloration. The kidneys may have white foci on the subcapsular surface. Microscopic findings in the liver may include mild random hepatocytic necrosis, nonsuppurative hepatitis, and intrahepatic bile stasis, while swollen tubular epithelial cells, tubular necrosis, and a mixed inflammatory reaction may be seen in the kidneys.

Ideally, a combination of serology and organism detection should be used for diagnosis of canine leptospirosis. Serology is the most frequently used diagnostic test for dogs. Acute and convalescent titers may be necessary to confirm a diagnosis; hence, the use of the MAT is preferred over the ELISA. PCR-based tests are widely available, and collection of both blood and urine samples before administration of antibiotics should be considered for maximal sensitivity. The results of all diagnostic tests should be interpreted in light of the animal's vaccination history, clinical signs, and clinicopathologic findings.

Renal failure and liver disease are treated with fluid therapy and other supportive measures to maintain normal fluid, electrolyte, and acid-base balance. Supportive measures may include antiemetics, GI protectants, phosphate binders, and hepatic support medications. Renal replacement therapy with intermittent hemodialysis or continuous renal replacement therapy should be considered for dogs that are anuric or oliguric despite appropriate supportive therapy. Antibiotic therapy is indicated whenever leptospirosis is suspected and should be instituted before confirmatory test results are available. There are no experimental studies in dogs to guide selection of antibiotic protocols for this species. Current recommendations are to treat with doxycycline (5 mg/kg/day, IV or PO) for 2 wk. For dogs that cannot tolerate doxycycline, initial therapy with a penicillin is appropriate, but this should be followed by a 2-wk course of doxycycline to eliminate the renal carrier phase of infection. Dogs recently exposed to leptospirosis may be treated prophylactically with oral doxycycline for 14 days.

Commercial bacterins for dogs are available for serovars Canicola, Icterohaemorrhagiae, Grippotyphosa, and Pomona. Vaccinated dogs may potentially be susceptible to infection with other serovars, although this has not been tested in an experimental setting. In general, currently available vaccines provide good protection from clinical disease and also

appear to reduce renal colonization and urine shedding. Concerns exist regarding hypersensitivity reactions after leptospiral vaccination in dogs, but these appear to be unjustified based on more recent studies and perhaps associated with the use of more highly purified vaccines. Canine challenge studies have demonstrated duration of immunity of at least 1 yr; thus, prior recommendations for vaccinating every 6 mo are no longer justified.

Because leptospirosis is a zoonotic disease, all veterinary personnel should take appropriate precautions when handling known or suspected infected animals. Such dogs do not need to be placed in isolation but should be nursed with barrier precautions, paying particular attention to avoiding exposure of skin or mucous membranes to urine or blood. Infected dogs should be allowed to urinate in designated areas that can subsequently be cleaned and disinfected. The organisms are killed by all commonly used disinfectants. Owners of dogs recently diagnosed with leptospirosis should be advised of the zoonotic nature of the disease and contact their physicians with any health concerns. Owners should wear gloves when cleaning up urine and should wash their hands after handling the dog, at least until the course of antibiotic therapy is completed.

LEPTOSPIROSIS IN HORSES

In the USA and Canada, *Leptospira interrogans* serovar Pomona type kennewicki and serovar Grippotyphosa are the most common causes of equine leptospirosis. The prevalence of leptospirosis in horses is unknown, but serologic evidence indicates a higher incidence than is apparent clinically. Antibodies to serovar Bratislava are reported frequently in horses in the USA and in Europe; horses are thought to be a maintenance host for this organism, and clinical disease has not been confirmed with Bratislava infections. Acute Pomona infections also commonly cause cross-reacting antibodies for Bratislava and Icterohaemorrhagiae on the MAT, which may explain some of the commonly observed high titers to Bratislava. Clinical leptospirosis in horses is most commonly associated with abortions, acute renal failure, rarely pulmonary or systemic illness in foals, and most importantly recurrent uveitis.

Leptospira interrogans serovar Pomona abortions may account for ~13% of bacterial abortions in mares in endemic regions, although incidence varies considerably

between years. The reason for the yearly variation in incidence of abortions is not clear. Serovar Pomona type kennewicki is responsible for most of the leptospiral abortions in North America, but serovars Grippotyphosa and Hardjo have also been reported. Skunks, raccoons, and red foxes are known to harbor Pomona type kennewicki. Most abortions occur after 9 mo of gestation, and rarely a live foal may be born ill from leptospirosis. Macroscopic lesions are edema, areas of necrosis in the chorion, and placentitis that does not involve the cervical star. Microscopic lesions include necrosis and calcification of the placenta. Placental disease may result in the mare developing hydroallantois. Macroscopically, the fetal liver may have yellow discoloration. Liver disease in the fetus is a multifocal necrosis and giant cell hepatopathy. Tubulonephrosis and interstitial nephritis may be detected in the kidneys of the aborted fetus. Inflammation of the umbilical cord (funisitis) may be recognized by diffuse yellowish discoloration. Aborting mares typically have very high leptospiral antibody titers at the time of abortion and, although quite variable, the time of urine shedding of leptospires after an abortion is often 2–3 mo.

Occasionally, *Leptospira interrogans* serovar Pomona causes fever and acute renal failure in horses. The kidneys become swollen as a result of tubulointerstitial nephritis, and urinalysis may reveal hematuria and pyuria without visible bacteria. On rare occasions, multiple weanling or yearling horses may be affected with fever and acute renal failure after infection.

The most important clinical disease associated with *L. interrogans* serovar Pomona infection in adult horses in North America and *L. kirschneri* serovar Grippotyphosa in Europe is equine recurrent uveitis (ERU). ERU is believed to be an immune-mediated disease sometimes involving antibody against certain *Leptospira* antigens, specifically the LruC outer membrane protein, which cross-reacts with tissues of the lens, cornea, and possibly retina. Live *Leptospira* organisms can be found in the aqueous or vitreous fluid of horses with ERU. High concentration of antibody against *L. interrogans* serovar Pomona in the aqueous humor, compared with serum titers, also suggests persistent local antigenic stimulation. Survival of the organism in the face of high ocular antibody indicates an absence of cells or molecules (eg, complement) involved in bacterial clearance, suggesting an ocular immune

privilege similar to that of the CNS. Recurrent episodes of the disease may be related to a Th17 response of autoreactivity following mimicry and inter- or intramolecular epitope spreading, or both.

Genetic factors are likely involved in the disease process, helping to explain why only some horses infected with *Leptospira* develop uveitis. Appaloosas are thought to be genetically predisposed, and specific MHC markers on ECA1, ELA class I, and an ELA class II microsatellite are strongly associated with the disease. The prevalence of ERU is unknown, but reports suggest that $\geq 1\%$ of horses will develop the disease during their lifetime. It is probable that some cases of ERU are not associated with *Leptospira* infection, and this may vary by geographic region. In some regions, more than 50% of ERU cases are associated with persistent ocular infections with *Leptospira*. *Leptospira*-associated uveitis may cause corneal, anterior chamber, and posterior chamber disease. Therefore, clinical findings may vary from corneal edema, clinically quiet retinal lesions observed on funduscopic examination, and most dramatically recurrent and progressive painful uveitis. The chronic disease of the globe may cause cataracts, retinal degeneration, or even glaucoma.

Diagnosis of *Leptospira* abortion is best accomplished by fluorescent antibody testing (FAT) or immunohistochemical evaluation of the placenta, umbilical cord, fetal liver, or fetal kidney. The sensitivity and specificity of the FAT in these tissues (but not urine) are nearly 100%. Examination of silver-stained kidney samples in horses with renal disease does not yield high accuracy, because there may be false-negative and false-positive findings, likely a result of nonpathogenic serovars. PCR testing is preferred for evaluation of fluids, such as urine, ocular fluids, and blood. Marked increases in serum antibody titers often accompany *Leptospira* abortions or acute renal failure, but serum titers may be low in horses with recurrent uveitis because of the chronic and localized nature of infection. Acute *L. interrogans* serovar Pomona infections often cause marked increases in antibody titers to several serovars (especially Icterohemorrhagiae and Bratislava, but the noninfecting serovar titers usually decline much more quickly over several weeks than the titers to the actual infecting serovar. Collection of a voided urine sample after furosemide administration may improve sensitivity of PCR, darkfield staining, or culture testing. A combination of serology, culture, and PCR

testing of aqueous fluid may be the only way to confirm *Leptospira*-associated uveitis. In ERU, the organism is most commonly found in the vitreous rather than aqueous fluid, which limits the practical application of ocular fluid PCR testing.

In acute disease, systemic antibiotics such as enrofloxacin, penicillin, tetracyclines, or aminoglycosides are useful, but this has not been proved to be the case with recurrent uveitis. There are no leptospiral vaccines approved for horses, although many veterinarians have used vaccines approved for cattle on horse farms that have endemic *Leptospira* abortions or uveitis.

LEPTOSPIROSIS IN RUMINANTS

Leptospiral serovars of major importance in cattle are Hardjo and Pomona in North America, with serovars Grippityphosa, Bratislava, Icterohaemorrhagiae, and Canicola occasionally implicated. The most commonly documented cause of leptospirosis among cattle in the USA and throughout much of the world is serovar Hardjo, for which cattle are the maintenance host. Risk factors for Hardjo infection in cattle have been reported to include open herds, access to contaminated water sources, co-grazing with sheep, and use of natural breeding. Serovar hardjo has the ability to colonize and persist in the genital tract of infected cows and bulls.

Many leptospiral infections in cattle are subclinical, particularly in nonpregnant and nonlactating animals. Acute or subacute leptospirosis is most commonly associated with incidental host infections and occurs during the leptospiremic phase of infection. Clinical signs associated with chronic infections are usually associated with reproductive loss through abortion and stillbirth. Persistent colonization by serovar Hardjo of the uterus and oviducts may be associated with infertility characterized by increased services per conception and prolonged calving intervals.

Uncommonly, severe acute disease occurs in young stock infected with incidental serovars, particularly serovar Pomona and less commonly Icterohaemorrhagiae. Clinical signs include high fever, hemolytic anemia, hemoglobinuria, jaundice, pulmonary congestion, occasionally meningitis, and death. In lactating cows, incidental infections may be associated with agalactia with small quantities of blood-tinged milk. A less severe form of this "milk drop syndrome" may occur in Hardjo-infected lactating cows in the absence of other clinical evidence of infection. In

lactating cows, incidental infections have been reported to cause blood-tinged milk.

The chronic phase of disease is associated with fetal infection in pregnant cows presenting as abortion, stillbirth, or birth of premature and weak infected calves. Infected but healthy calves also may be born. Abortion or stillbirth is commonly the only manifestation of infection but may sometimes be related to an episode of illness up to 6 wk (Pomona) or 12 wk (Hardjo) earlier. Abortions associated with incidental host infection tend to occur late term and in groups or so-called "abortion storms." In contrast, abortions occurring after infection with serovar Hardjo tend to be more sporadic and can occur mid- to late pregnancy and several months after initial infection.

Diagnosis of incidental host infections in cattle is relatively straightforward. In general, infected animals develop high titers to the infecting serovar; an antibody titer >1:800 at the time of abortion is considered evidence of leptospirosis. Leptospire can be demonstrated in placenta and the fetus in some cases by immunofluorescence, PCR, and immunohistochemistry. Diagnosis of serovar Hardjo infection is more difficult and requires a combination of approaches. Serology alone often fails to identify animals infected with serovar Hardjo, because seronegative shedders are common in infected cattle herds. The recommended diagnostic testing strategy includes the primary use of a test (immunofluorescence or PCR) to detect the organism in the urine from a sample of cattle in the herd followed by serologic testing to provide insight into the likely infecting serovar of *Leptospira*.

Cattle with acute leptospirosis can be treated with the label dosage of tetracycline, oxytetracycline, penicillin, ceftiofur, tilmicosin, or tulathromycin. Leptospire also are highly susceptible to erythromycin, tiamulin, and tylosin, although these antibiotics cannot be relied on to remove the renal carrier state. Injectable, long-acting oxytetracycline (20 mg/kg) and sustained-release ceftiofur have been shown to effectively eliminate shedding in cattle infected with serovar Hardjo. Vaccination can be combined with antibiotic treatment in the face of an outbreak of leptospirosis, but vaccination alone will not reduce urinary shedding. All appropriate withdrawal times should be observed.

Bovine leptospirosis vaccines available in the USA and Canada are pentavalent and contain leptospiral serovars Pomona, Grippotyphosa, Canicola, Icterohaemorrhagiae, and Hardjo. These vaccines provide

good protection against disease caused by each of these serovars, with the possible exception of serovar Hardjo. Experimental and field evidence indicates that some traditional five-way leptospirosis vaccines do not provide good protection from serovar Hardjo infection. New vaccines have been introduced to address this issue. If a primary goal of a vaccination program is protection of cattle against Hardjo, care should be taken in selection of a vaccine product. In general, annual vaccination of all cattle in a closed herd or low incidence area, or twice-yearly vaccination in an open herd or high incidence area, is the most effective approach to control.

Relative to cattle and pigs, sheep and goats have been considered resistant to leptospiral infection, with low seroprevalences and only a small number of serogroups being implicated in clinical disease. Sheep can serve as a maintenance host for serovar Hardjo and therefore spread infection to cattle. Incidental infections may cause sporadic outbreaks of acute disease characterized by hematuria, hemoglobinuria, jaundice, and death (usually in lambs), and occasional abortions.

LEPTOSPIROSIS IN SWINE

Leptospira interrogans (serovars Pomona, Icterohaemorrhagiae, Canicola, Hardjo, and Bratislava), *L. borgpetersenii* (serovars Sejroe and Tarassovi), and *L. kirschneri* (serovar Grippotyphosa) are all reported to infect pigs. Serovars Pomona and Bratislava are uniquely adapted to swine; others are maintained in other species but sometimes infect swine. Swine are maintenance hosts for serovar Bratislava, and infected pigs rarely develop signs typical of acute leptospirosis—rather, reproductive failure as evidenced by infertility and sporadic abortion is the most common clinical sign, and venereal transmission may occur. Serovar Pomona, in contrast, is of intermediate pathogenicity for swine, with acute clinical signs seen in young pigs and abortions (often in groups) occurring in pregnant swine. Although Pomona infections are associated with acute, sometimes severe clinical signs suggestive of an incidental host infection, pigs often remain infected and shed serovar Pomona for weeks to a few months after infection. This feature of Pomona infection can be associated with high rates of pig-to-pig transmission among swine reared in

confinement. Incidental infections may occur from strains belonging to the *Grippytyphosa*, *Icterohaemorrhagiae*, and *Canicola* serogroups.

Abortions occurring 2–4 wk before term are the most common manifestation of leptospirosis in pigs. Piglets produced at term may be dead or weak and may die soon after birth. The principal differential diagnosis is porcine reproductive and respiratory syndrome (see p 729), although brucellosis, parvovirus, and SMEDI (stillbirth, mummification, embryonic death, and infertility) share some features with leptospirosis. Acute

leptospirosis, as described in calves, has been described in piglets but is rare. Treatment and control are similar to those described for cattle, using a combination of medication either to prevent infection or to decrease shedding, vaccination, rodent and small mammal control, and feed and water free of *Leptospira* organisms. Immunization through use of bacterins is widely practiced in breeding herds and will reduce the prevalence of infection and abortions. The bacterin must be serovar specific for protection. Bacterins should not be expected to eliminate infection in carriers.

LIGHTNING STROKE AND ELECTROCUTION

Injury or death of an animal due to high-voltage electrical currents may be the result of lightning, fallen transmission wires, faulty electrical circuits, or chewing on an electrical cord. Electrocution due to lightning stroke is seasonal and tends to be geographically restricted. Investigation of possible electrocution should always proceed with caution, because the electrification resulting from broken transmission wires, for example, may still be present. Once the site is clearly safe, the investigation should include the location of the dead animals, examination of all affected animals, and necropsy of those that died.

Certain types of trees, especially hardwoods such as oaks and those that are tall and have spreading root systems just beneath the ground surface, tend to be struck by lightning more often than others. Electrification of such roots charges a wide surface area, particularly when the ground is already damp; passage of charged roots beneath a shallow pool of water causes it to become electrified. A tile drain may spread an electric charge throughout its course. Fallen or sagging transmission wires also may electrify a pool of water, fence, or building, and an animal may also directly contact such wires. Differences exist in conductivity of soil; loam, sand, clay, marble, and chalk are good conductors (in decreasing order), whereas rocky soil is not.

Accidental electrocution of farm animals in a barn or adjacent confinement pen usually occurs as a result of faulty wiring. Electrification of a water or milk line

stanchion or a metal creep or guard rail can result in widespread distribution of an electric current throughout the stable (see **ALSO** STRAY VOLTAGE IN ANIMAL HOUSING, p 2113) that may result in signs of water deprivation or feed refusal.

Death from electric shock usually results from cardiac or respiratory arrest. Passage of current through the heart usually produces ventricular fibrillation, and involvement of the CNS may affect the respiratory or other vital centers.

Clinical Findings: Varying degrees of electric shock may occur. In most instances of electrocution by lightning stroke, death is instantaneous and the animal falls without a struggle. Occasionally, the animal becomes unconscious but may recover in a few minutes to several hours; residual nervous signs (eg, depression, paraplegia, cutaneous hyperesthesia, blindness) may persist for days or weeks or be permanent. Singe marks on or damage to the carcass, damage to the immediate environment, or both, occur in ~90% of cases of lightning stroke but are less likely to be found if the animal is electrocuted by standing on electrified earth. Singe marks tend to be linear and are more commonly found on the medial sides of the legs, although rarely much of the body may be affected. Beneath the singe marks, capillary congestion is common; the arboreal pattern characteristic of lightning stroke can be visualized best from the dermal side of the skin by subcutaneous extravasations of blood. Singe marks are rarely found on recovered animals. Smaller

animals such as pigs that contact electrified water bowls or creeks may be killed instantly or be thrown some distance by the strength of the shock. Electrocuted pigs are often recumbent and may have sustained spinal, pelvic, or limb fractures, resulting from severe muscular contractions.

Diagnosis: The diagnosis is almost always made on circumstantial evidence, ie, location of the carcass(es) and absence of any disease processes when examined by necropsy. The presence of dead animals under a tree, hanging through or near a wire fence, or clustered around a light pole is strong evidence of electrocution by lightning stroke even in the absence of physical evidence like recent burning of tree bark or splitting of poles or boards in a fence.

Rigor mortis develops and passes quickly. Postmortem distention of the rumen occurs rapidly and must be differentiated from antemortem ruminal tympany (see p 227); in both conditions, the blood tends to clot slowly or not at all. The mucosae of the upper respiratory tract, including the turbinates and sinuses, are congested and hemorrhagic; linear tracheal hemorrhages are common, and large blood clots are occasionally found in the trachea, but the lungs are not compressed as in bloat. All other viscera are congested, and petechiae and ecchymoses may be found in many organs. Due to postmortem ruminal distention, the poorly clotted blood is passively moved to the periphery of the body, resulting in postmortem extravasation of blood in muscles and

superficial lymph nodes of the head, neck, and thoracic limbs, and to a lesser extent in the hindquarters. Probably the best indication of instantaneous death is the presence of hay or other feed in the animal's mouth; supportive evidence includes the presence of normal ingesta (especially in the rumen), lack of frothy ingesta (frothy bloat), and presence of normal feces in the lower tract and occasionally on the ground behind the animal. Few conditions affecting livestock cause such peracute death clustered in a small area.

Farm animals often are insured against lightning stroke, and the insurance claims agent or the veterinarian requested to sign an insurance form should closely observe the situation that initiated the claim. The investigator should ascertain that the animal actually died in the high-risk location rather than having been moved after death. This could be done to merely clean up or to deliberately confuse the investigation. Similarly, examination of recent weather information confirming thunderstorms is an important part of the process to substantiate an insurance claim. A well-documented description of where the animal(s) died and the results of a necropsy examination are usually acceptable to support an insurance claim of lightning stroke.

Treatment: Those animals that survive may require supportive and symptomatic therapy. Euthanasia is warranted for those animals recumbent with fractures or severe muscle injuries.

LISTERIOSIS

(Listerellosis, Circling disease)

Listeriosis is a sporadic bacterial infection that affects a wide range of animals, including people and birds. It is seen worldwide, more frequently in temperate and colder climates. There is a high incidence of intestinal carriers. Encephalitis or meningoencephalitis in adult ruminants is the most frequently recognized form.

Etiology and Epidemiology: *Listeria monocytogenes* is a small, motile, gram-positive, nonsporeforming, extremely resistant, diphtheroid coccobacillus that grows under a wide temperature range

4°–44°C (39°–111°F). Its ability to grow at 4°C is an important diagnostic aid (the “cold enrichment” method) for isolation of the organism from brain tissue but not from placental or fetal tissues. Primary isolation is enhanced under microaerophilic conditions. It is a ubiquitous saprophyte that lives in a plant-soil environment and has been isolated from ~42 species of domestic and wild mammals and 22 species of birds, as well as fish, crustaceans, insects, sewage, water, silage and other feedstuffs, milk, cheese, meconium, feces, and soil.

The natural reservoirs of *L. monocytogenes* appear to be soil and mammalian GI tracts, both of which contaminate vegetation. Grazing animals ingest the organism and further contaminate vegetation and soil. Animal-to-animal transmission occurs via the fecal-oral route.

Listeriosis is primarily a winter-spring disease of feedlot or housed ruminants. The less acidic pH of spoiled silage enhances multiplication of *L. monocytogenes*. Outbreaks typically occur ≥ 10 days after feeding poor-quality silage. Removal or change of silage in the ration often stops the spread of listeriosis; feeding the same silage months later may result in new cases.

Pathogenesis: *Listeria* organisms that are ingested or inhaled tend to cause septicemia, abortion, and latent infection. Those that gain entry to tissues have a predilection to localize in the intestinal wall, medulla oblongata, and placenta or to cause encephalitis via minute wounds in buccal mucosa.

The various manifestations of infection occur in all susceptible species and are associated with characteristic clinical syndromes: abortion and perinatal mortality in all species, encephalitis or meningoen- cephalitis in adult ruminants, septicemia in neonatal ruminants and monogastric animals, and septicemia with myocardial or hepatic necrosis (or both) in poultry (see p 2839).

Listeric encephalitis affects sheep, cattle, goats, and occasionally pigs. It is essentially a localized infection of the brain stem that develops when *L. monocytogenes* ascends the trigeminal nerve. Clinical signs vary according to the function of damaged neurons but often are unilateral and include depression (ascending reticular activating system), ipsilateral weakness (long tracts), trigeminal and facial nerve paralysis, and less commonly, circling (vestibulocochlear nucleus). Neurologic signs indicating bilateral cranial nerve deficits are occasionally seen in lambs < 4 mo old.

Septicemic or visceral listeriosis is most common in monogastric animals, including pigs, dogs, cats, domestic and wild rabbits, and many other small mammals. These animals may play a role in transmission of *L. monocytogenes*. This form is also found in young ruminants before the rumen is functional. Although rare, septicemia has been reported in older domestic ruminants and deer. The septicemic form affects organs other than the brain, the principal lesion being focal hepatic necrosis.

The uterus of all domestic animals, especially ruminants, is susceptible to infection with *L. monocytogenes* at all stages of pregnancy, which can result in placentitis, fetal infection and death, abortion, stillbirths, neonatal deaths, metritis, and possibly viable carriers. The metritis has little or no effect on subsequent reproduction; however, *Listeria* may be shed for ≥ 1 mo via the vagina and milk.

Infections acquired via ingestion tend to localize in the intestinal wall and result in prolonged fecal excretion. It has been postulated that contaminated silage results in latent infections, often approaching 100% of the exposed herd or flock, but clinical listeriosis in only a few animals.

Clinical Findings: Encephalitis is the most readily recognized form of listeriosis in ruminants. It affects all ages and both sexes, sometimes as an epidemic in feedlot cattle or sheep. The course in sheep and goats is rapid, and death may occur 24–48 hr after onset of signs; however, the recovery rate can be up to 30% with prompt, aggressive therapy. In cattle, the course is less acute, and the recovery rate approaches 50%. Lesions are localized in the brain stem, and the signs indicate dysfunction of nerve nuclei, including those of the third to seventh cranial nerves.

Initially, affected animals are anorectic, depressed, and disoriented. They may propel themselves into corners, lean against stationary objects, or circle toward the affected side. Facial paralysis with a drooping ear, deviated muzzle, flaccid lip; and lowered eyelid often develops on the affected side, as well as lack of a menace

Right-sided facial and trigeminal nerve paralysis with profuse salivation caused by listeriosis in a goat. Courtesy of Dr. Philip Scott.

response and profuse, almost continuous, salivation; food material often becomes impacted in the cheek due to paralysis of the masticatory muscles. Terminally affected animals fall and, unable to rise, lie on the same side; involuntary running movements are common.

Listeric encephalitis may recur on the same premises in successive years. The number of animals clinically involved in an outbreak usually is <2% but in exceptional circumstances may reach 10%–30% in a flock of sheep.

Listeric abortion usually occurs in the last trimester without premonitory signs. Fetuses usually die in utero, but stillbirths and neonatal deaths occur. The abortion rate varies and may reach 20% in sheep flocks. Fatal septicemia of the dam secondary to metritis is rare. Encephalitis and abortion usually do not occur simultaneously in the same herd or flock. However, the clinical pattern in sheep in the UK has been changing; abortions, encephalitis, and diarrhea are increasing, and outbreaks of abortions and encephalitis occur together in the same flock.

Listeriosis is relatively uncommon in pigs, with septicemia occurring in those <1 mo old and encephalitis in older pigs; it has a rapid, fatal course of 3–4 days.

Lesions: In listeric encephalitis, there are few gross lesions except for some congestion of meninges. Microscopic lesions are confined primarily to the pons, medulla oblongata, and anterior spinal cord.

In septicemic listeriosis, small necrotic foci may be found in any organ, especially the liver. In calves that die when <3 wk old, in addition to focal hepatic necrosis, there is frequently marked hemorrhagic gastroenteritis.

In aborted fetuses, there is slight to marked autolysis, clear to blood-tinged fluid in the serous cavities, and numerous small necrotic foci in the liver, especially in the right half. Necrotic foci may be found in other viscera such as lung and spleen. Shallow erosions, 1–3 mm, may be present in abomasal mucosa. Autolytic changes may mask these lesions. Gram-stained smears of abomasal contents reveal numerous gram-positive, pleomorphic coccobacilli.

Diagnosis: Samples of lumbosacral CSF can be collected under local anesthesia. In cases of listeriosis, the CSF has an increased protein concentration (0.6–2 g/L [normal 0.3 g/L]) and a mild pleocytosis composed of large mononuclear cells.

Listeriosis is confirmed only by isolation and identification of *L. monocytogenes*.

Specimens of choice are brain from animals with CNS involvement and aborted placenta and fetus. If primary isolation attempts fail, ground brain tissue should be held at 4°C (39°F) for several weeks and recultured weekly. Occasionally, *L. monocytogenes* has been isolated from spinal fluid, nasal discharge, urine, feces, and milk of clinically ill ruminants. Serology is not used routinely for diagnosis, because many healthy animals have high *Listeria* titers. Immunofluorescence is effective for rapidly identifying *L. monocytogenes* in smears from animals dead or aborted from listeriosis and from milk, meat, and other sources.

Listeriosis can be differentiated from pregnancy toxemia in ewes (see p 1021) or ketosis in cattle (see p 1024) by careful clinical examination, CSF changes, and 3- β H butyrate concentrations well below 3 mmol/L. Furthermore, facial and ear paralysis are absent in pregnancy toxemia or ketosis. In cattle, the unilateral signs of trigeminal and facial paralysis (often subtle) help differentiate listeriosis from bovine spongiform encephalopathy (see p 1284), thromboembolic meningoencephalitis (see p 754), polioencephalomalacia (see p 1281), sporadic bovine encephalomyelitis (see p 1308), and lead poisoning (see p 3078). Rabies (see p 1302) must always be considered in the differential diagnosis of listeriosis. Animals with brain abscesses and coenurosis (see p 1311) present with circling, contralateral blindness, and proprioceptive deficits, but show no cranial nerve deficits. Vestibular disease is common in growing ruminants; these animals typically show ipsilateral spontaneous nystagmus or strabismus, and remain bright and alert without trigeminal nerve dysfunction.

Treatment and Control: Recovery depends on early, aggressive antibiotic treatment. If signs of encephalitis are severe, death usually occurs despite treatment. *L. monocytogenes* is susceptible to penicillin (the drug of choice), ceftiofur, erythromycin, and trimethoprim/sulfonamide. High doses are required because of the difficulty in achieving minimum bactericidal concentrations in the brain.

Penicillin G should be given at 44,000 U/kg body wt, IM, daily for 1–2 wk; the first injection should be accompanied by the same dose given IV. Supportive therapy, including fluids and electrolytes, is required for animals having difficulty eating and drinking. High-dose dexamethasone (1 mg/kg, IV) at first examination is

considered beneficial by some but is controversial and will cause abortion during the last two trimesters in cattle and after day 135 in sheep.

Results with vaccines have been equivocal, which together with the sporadic nature of the disease, lead to questions about the cost-benefit of vaccination. In an outbreak, affected animals should be segregated. If silage is being fed, use of the particular silage should be discontinued on a trial basis. Spoiled silage should be avoided. Corn ensiled before being too mature and grass silage containing additives are likely to have a more acid pH, which discourages multiplication of *L. monocytogenes*.

Zoonotic Risk: Whether animals serve as a reservoir of infection for people may be questioned, because *Listeria* organisms have been isolated from feces of a significant number of apparently healthy people as well as other animals. However, despite this and the apparently low invasiveness of *L. monocytogenes*, all suspected material should be handled with

caution. Aborted fetuses and necropsy of septicemic animals present the greatest hazard. In cases with encephalitis, *L. monocytogenes* is usually confined to the brain and presents little risk of transmission unless the brain is removed. People have developed fatal meningitis, septicemia, and papular exanthema on the arms after handling aborted material. Pregnant animals (including women) should be protected from infection because of danger to the fetus, with possible abortion, stillbirth, and infection of neonates. Although human listeriosis is rare (upper estimate of 12 cases per million population per yr), mortality can reach 50%. Most cases involve older patients, pregnant women, or immunocompromised people.

L. monocytogenes can be isolated from milk of mastitic, aborting, and apparently healthy cows. Excretion in milk is usually intermittent but may persist for many months. Infected milk is a hazard, because the organism may survive certain forms of pasteurization. *Listeria* also have been isolated from milk of sheep, goats, and women.

LYME BORRELIOSIS

(Lyme disease)

Lyme borreliosis is a bacterial, tick-transmitted disease of animals (dogs, horses, probably cats) and people. Many additional mammalian and avian species become infected but do not develop overt clinical signs. Areas of greatest incidence in the USA are regions in the northeast (particularly the New England states), the upper Midwest, and the Pacific coast. Lyme borreliosis also occurs in moderate climatic regions of Europe and Asia.

Etiology and Transmission: On the basis of DNA analysis, 19 different genospecies fall within the *Borrelia burgdorferi* sensu lato complex. Within this complex, the most important spirochete species are *B. burgdorferi* sensu stricto (North America, Europe), *B. afzelii* (Europe, Asia), *B. bavariensis*, and *B. garinii* (Europe, Asia), all of which are pathogenic for people. Only *B. burgdorferi* sensu stricto has been shown so far to be pathogenic for domestic animals under

experimental conditions. Tick vectors of *B. burgdorferi* sensu lato are hard-shelled *Ixodes* ticks. In the USA, these are primarily *I. scapularis* in the northeast and Midwest and *I. pacificus* on the Pacific coast. *I. ricinus* and *I. persulcatus* are the primary vectors in Europe and Asia. *B. miyamotoi* is another member of the genus *Borrelia*. Although this spirochete is transmitted by ixodid ticks and may cause infections in mammals characterized by clinical signs such as fever, headache, fatigue, and muscle aches, the bacterium is a relapsing, fever-causing organism.

Ixodid ticks hatch from eggs as unfed larvae. Both larvae and nymphs may acquire spirochetes from *Borrelia*-carrying hosts. Small mammals, especially rodents, play a major role as reservoir hosts. Birds and lizards may also harbor certain *Borrelia* species and serve as reservoir hosts. Infection rates of the vectors vary according to region and season and can be as high as 50% in adult ticks. After tick attachment,

>24 hr elapse before the first *B burgdorferi* sensu lato organisms are transmitted into the host's skin. Stable infection of the host occurs at >53 hr into the blood meal. Therefore, early removal of attached ticks reduces the potential for spirochete transmission. *B burgdorferi* sensu lato organisms are not transmitted by insects, body fluids (urine, saliva, semen), or bite wounds. Experimental studies have shown that dams infected before gestation may transmit spirochetes to their pups in utero.

Clinical Findings: Numerous clinical syndromes have been attributed to Lyme borreliosis in domestic animals, including limb and joint disease and renal, neurologic, and cardiac abnormalities. In dogs, intermittent, recurrent lameness; fever; anorexia; lethargy; and lymphadenopathy with or without swollen, painful joints are the most common clinical signs. The second most common syndrome associated with Lyme borreliosis is renal failure, which is generally fatal. It is characterized by uremia, hyperphosphatemia, and severe protein-losing nephropathy, often accompanied by peripheral edema. Bernese Mountain Dogs and Labrador Retrievers in particular often show high *Borrelia*-specific antibody levels; immune complexes in kidney tissues lead to severe inflammation. In human medicine, single case reports have described abnormalities with bradycardia with the cardiac form of Lyme borreliosis, whereas facial paralysis and seizure disorders are thought to be expressions of the neurologic form.

Diagnosis: Diagnosis is based on history, clinical signs, elimination of other diagnoses, laboratory data, epidemiologic considerations, and response to antibiotic therapy. Autoimmune panels, CBC, blood chemistry, radiographs, and other laboratory data are generally normal, except for results pertaining directly to the affected system (eg, soft-tissue swelling in limbs, neutrophil accumulation in synovial fluids of affected joints, uremia in renal disease).

Serologic testing for antibodies specific for *B burgdorferi* sensu lato is an adjunct to clinical diagnosis. Antibodies can be detected with ELISA (including rapid test systems), Western blots, line immunoassays (LIA), and with fluorescent bead-based multiplex assays. Because of their low specificity, indirect immunofluorescent antibody assays are no longer recommended. The standard procedure for antibody detection is a two-tiered approach in which samples are screened with a sensitive ELISA, and only positively

reacting samples are rechecked with specific confirmatory tests. Western blot or LIA testing helps to differentiate the immune response elicited by infection from that induced by vaccination.

Alternatively, blood or serum samples can be tested with peptide-based assays (C6 peptide), which is specific for infection-induced antibodies. However, demonstration of specific antibodies indicates exposure to bacterial antigen only and does not equate to clinical disease. Approximately 5%–10% of dogs in central Europe carry *Borrelia*-specific antibodies with no clinical signs. Additionally, false-negative results can occur with the C6 peptide assays shortly after infection. Long incubation periods, persistence of antibodies for months to years, and the disassociation of the antibody response from the clinical stage of disease make diagnosis by blood testing alone impossible.

Lymphocyte stimulation tests are available that measure the cellular immune response to *Borrelia*. In culture, *Borrelia* antigens are processed by antigen-presenting cells with which specific lymphocytes interact. Released cytokines (eg, interleukin-1 beta) in the culture supernatant are correlates for preceding *Borrelia* infections of the host. Scant information is available in terms of the test's sensitivity and specificity.

Isolation of *B burgdorferi* sensu lato by culture or detection of specific DNA by PCR from joints, skin tissue samples, or other sources may also help in diagnosis. However, direct detection of the organism is difficult, time consuming (up to 6 wk for culture), and in most cases produces negative results. Only a positive result is meaningful. Blood samples are generally negative, because the organism resides in tissue and not in the circulation.

Clinical signs of Lyme borreliosis are nonspecific. In addition to other orthopedic disorders (eg, trauma, osteochondritis dissecans, immune-mediated diseases), other infections should be considered. *Anaplasma phagocytophilum* can also induce intermittent, recurrent lameness. *A phagocytophilum* is transmitted by the same tick genus, and epidemiologic studies have revealed that up to 30% of all dogs in central Europe carry antibodies specific for this agent. Mixed infections should be considered when clinical signs are apparent.

Treatment: Antibiotic therapy is indicated in all cases with clinical signs attributed to Lyme borreliosis. Antimicrobials in the tetracycline (eg, doxycycline 10 mg/kg, PO, bid) and penicillin (eg, amoxicillin 20 mg/kg, PO, tid) groups are effective, and rapid

response is seen in limb and joint disease in most cases, although incomplete or transient resolution of signs occurs in a significant number of affected animals. Doxycycline is preferred over penicillins, because mixed infections with other tickborne pathogens are often found in animals with clinical signs. Clinical and research data indicate that low-level infection in animals, including people, may persist despite antibiotic therapy. In dogs, standard antibiotic doses and treatment for 4 wk have been demonstrated to be effective. If clinical signs recur, the antibiotics mentioned above can be used again, because persistent infection is not the result of acquired antibiotic resistance. Prolonged antibiotic therapy (>4 wk) may be beneficial for animals with continuing disease signs.

Symptomatic therapy directed toward the affected organ system and clinicopathologic abnormalities is also important, especially in renal disease. In limb and joint disease, the use of NSAIDs concurrent with antibiotic therapy may lead to confusion over the source of clinical improvement and make diagnosis based on therapeutic response difficult.

Control and Prevention: Tick avoidance plays an important role in disease control. Although highly effective repellents and acaricides in collars, sprays, and spot-ons are available for use on dogs, lack of owner compliance in application may often be a barrier to effective, long-term tick avoidance.

Killed, whole-cell bacterins to prevent Lyme borreliosis in dogs have been in use since the early 1990s. Vaccines that contain only recombinant outer surface protein A (rOspA) have since been licensed for use in dogs. Vaccines are available in Europe that contain antigens from different species of the *B burgdorferi* sensu lato complex. All current vaccines induce a

strong antibody response predominately to OspA (lysate vaccines) or only against OspA (recombinant vaccines). During the tick's blood meal, antibodies against OspA bind to *Borrelia* organisms residing in the tick. Bound antibodies prevent spirochete migration within the tick and consequently *Borrelia* transmission from ticks to hosts. Later, during the blood meal, *B burgdorferi* sensu lato organisms in the engorging tick stop producing OspA and begin expressing new proteins, OspC and others, before transmission. Development of vaccines that contain multiple *B burgdorferi* antigens that may contribute to enhanced protection is being pursued.

In endemic areas, dogs should be vaccinated before natural exposure to ticks to attain the highest degree of protection. Dogs that have been exposed to ticks should be tested serologically for established infection before vaccination. Postinfection vaccination has little to no therapeutic effect on established infections. Two doses of vaccine should be administered SC to dogs ≥ 9 –12 wk old at 3-wk intervals, or according to label directions. Because antibody levels often drop quickly after the initial two immunizations, additional booster vaccinations should be administered twice within the next year, preferably at 6-mo intervals (suggested schedule: spring, fall, spring) with annual vaccinations thereafter.

Zoonotic Risk: Lyme borreliosis is an important zoonotic disease. Animals and people are infected during the blood meal of hard-shelled ticks (*Ixodes* spp). Companion and farm animals are not the source of infection in people. Pets may bring unattached infected ticks into the household and subsequently the vectors may be passed on to other animals or people during close contact.

MELIOIDOSIS

(Pseudoglanders, Whitmore disease)

Melioidosis is a bacterial infection of animals and people. It is often associated with suppurative or caseous lesions, comprising a mixed purulent and granulomatous response that can occupy any body organ.

Etiology and Epidemiology: The etiologic agent is *Burkholderia pseudomallei*, an oval, motile, gram-negative, facultative anaerobic bacillus with bipolar staining. The organism is ubiquitous throughout southeast Asia, northern

Australia, and the South Pacific. Its distribution is predominantly tropical and subtropical with "hyperendemicity" in the top end of the Northern Territory of Australia and northeast Thailand. The true boundaries of its endemicity are ambiguous because of movement of the organism and its ability to travel to and exist in temperate regions (eg, southwest Australia, France), where it may cause sporadic disease and outbreaks.

B pseudomallei has been introduced to new environments with the export of animals, and shipments of contaminated soil and water could potentially produce the same results. Reports of possible autochthonous melioidosis have also come from India, Pacific islands, Central and South America, the Caribbean, Africa, and the Middle East.

B pseudomallei is a widespread saprophyte and has been isolated from various soil types and surface water of varying depths. Melioidosis outbreaks have coincided with heavy rainfall and flooding associated with high humidity or temperature. Major excavations and disturbances in plumbing resulting in contamination of water supplies have also resulted in outbreaks.

Melioidosis is most commonly seen in sheep, goats, and pigs; other affected species include cattle, buffalo, horses, mules, deer, camels, alpacas, dogs, cats, dolphins, wallabies, koala, primates, birds, tropical fish, reptiles, and people. Laboratory animals affected by melioidosis include hamsters, guinea pigs, rabbits, mice, and rats. Host susceptibility and disease manifestations vary between species. The introduction of naive livestock to endemic regions may predispose them to disease, as seen with sheep, goats, pigs, and camelids. Other species (eg, dogs and cats) may succumb to infection due to immunocompromising conditions.

Transmission: Infection is thought to be opportunistic and primarily a result of transmission from the environment (eg, contaminated soil and surface waters) rather than from animal to animal. The most common routes of infection are via percutaneous inoculation, contamination of wounds, ingestion of soil or contaminated carcasses, or inhalation. Transplacental infection resulting in abortion has been reported in goats. Transmission during breeding and other means of host-to-host transmission may occur. Laboratory-acquired infection and iatrogenic infection via contaminated antiseptics, injections, or

other hospital or surgical equipment have been reported.

Pathogenesis: The virulence of *B pseudomallei* appears to vary among isolates, but these virulence factors are not well understood. Molecular-typed clonal outbreaks have produced a range of different clinical presentations, which indicate that host factors and infecting dose may be just as important in determining the severity of disease. The incubation period ranges from a few days to months or even years. *B pseudomallei* is a facultative intracellular pathogen that can remain dormant for many years before emerging as an active infection.

Clinical Findings: Signs can vary widely within a species, depending on the site of infection, and range from acute to chronic. Fever, anorexia, or swollen glands may be noted. Subclinical infection is common. Infection may be associated with single or multiple suppurative or caseous nodules/abscesses, which can be located in any organ tissue with variable effects. Disease most likely due to percutaneous inoculation often develops at distant sites without evidence of active infection at the inoculation site. The organs most commonly affected include the lungs, spleen, liver, and associated lymph nodes.

Goats often develop mastitis, and aortic aneurysms have been reported. The respiratory system is involved preferentially in sheep; signs can include fever, severe coughing, respiratory distress, and mucopurulent nasal and ocular discharge. CNS disease, with signs that include circling, incoordination, blindness, nystagmus, and spasms, has been seen in cattle, horses, sheep, and goats. Pigs often have asymptomatic lesions on the spleen that are incidental findings at slaughter. Lameness due to septic arthritis and osteomyelitis can occur. Fatalities often occur in association with acute fulminating infections or when vital organs are affected. Various forms of melioidosis have been reported in horses; signs may include weakness, edema and lymphangitis of the limbs, mild colic, diarrhea, coughing, or nasal discharge. Skin infections may resemble fungal eczema initially, progressing to become papular. In dogs, disease may be acute, subacute, or chronic. In acute cases, septicemia with fever, severe diarrhea, and fulminant pneumonia are common. Subacute cases may present as a skin lesion with lymphangitis and lymphadenitis; untreated cases may progress to

septicemia. Chronic disease can occur in any organ with clinical signs that include anorexia, myalgia, edema of the limbs, and skin abscesses.

Lesions: Multiple abscesses that contain thick, caseous greenish yellow to off-white material are noted at necropsy. The organs most commonly involved are the lungs, spleen, lymph nodes, liver, and subcutaneous tissues. Exudative bronchopneumonia, consolidation, and abscesses may be found in the lungs of animals with respiratory disease. Nodules and ulcers may be found on the nasal mucosa and septum and on the turbinates; these may coalesce into irregular plaques. Meningoencephalitis, severe enteritis, suppurative polyarthritis, and other syndromes also have been reported.

Diagnosis: The clinical signs of melioidosis are not diagnostic because of the protean nature of the disease. For a definitive diagnosis, isolation and identification of the organism are required. The organism can be isolated from lesions and discharges. It is possible to culture the organism on routine diagnostic media; however, Ashdown's media is preferred because of a consistently distinctive colony morphology and odor. Gram-stained smears of exudate or pus can sometimes identify bipolar "safety pin"-shaped, gram-negative rods. Serologic tests such as complement fixation and indirect hemagglutination are effective herd surveillance tools. More recently, DNA probes and PCR tests have been developed.

Treatment and Prevention: Treatment with the appropriate antibiotics should be based on culture and sensitivity results.

Treatment may be expensive, prolonged, and possibly unsuccessful, with the risk of recrudescence once treatment is discontinued. The possibility of underlying immunosuppressive conditions should be investigated in less susceptible species. With severe disease, treatment regimens can follow guidelines for human melioidosis with initial intensive therapy using the newer β -lactams (ceftazidime and the carbapenems), possibly in combination with cotrimoxazole for up to 2 mo. This should be followed by subsequent eradication therapy for a minimum of 3 mo with high-dose cotrimoxazole or conventional combination therapy using chloramphenicol, cotrimoxazole, and doxycycline or amoxicillin/clavulanate. Preventive measures are more practical and economical in intensive farming environments and involve raising the animals off the soil, especially avoiding exposing animals to muddy or water-inundated regions and providing clean drinking water via chlorination and filtration. Minimization of environmental contamination by diseased animals is also an important control measure. There is no effective vaccine.

Zoonotic Risk: Melioidosis has zoonotic potential. Infected animals can shed the organism in wound exudates and, depending on the site of infection, from other sources, including nasal secretions, milk, feces, and urine. Mastitis in goats is a common manifestation, and *B pseudomallei* has been isolated from milk, resulting in the requirement for pasteurization of commercial goats' milk in the tropics. Infected animal carcasses are condemned at the abattoir.

NEOSPOROSIS

Neospora caninum is a microscopic protozoan parasite with worldwide distribution. Many domestic (eg, dogs, cattle, sheep, goats, water buffalo, horses, chickens) and wild and captive animals (eg, deer, rhinoceros, rodents, rabbits, coyotes, wolves, foxes) can be infected. Neosporosis is one of the most common causes of bovine abortion, especially in intensively farmed cows. Neosporosis abortion also occurs in sheep, goats,

water buffalo, and camelids, although they may be less susceptible than cattle.

A second *Neospora* species, *N hughesi*, is a cause of myelitis in horses and shares clinical features with equine protozoal myelitis, which in North and South America is usually caused by *Sarcocystis neurona* (see p 1309). The life cycle of *N hughesi* is unknown. Discussion in this chapter deals only with *N caninum* infection.

Epidemiology: Neosporosis in cattle herds manifests in both endemic and epidemic abortion patterns, but it is also possible for a herd to have a high infection prevalence without a noticeable abortion problem. Both endemic and epidemic transmission patterns in cattle are positively associated with the presence and number of dogs in and around farms. Endemic abortion is mainly associated with recrudescence of latent organisms during pregnancy followed by transplacental transmission to the fetus, although occasional transmission from dogs or other canids may compound the problem. Epidemic abortion is a possible consequence of sudden large-scale transmission to pregnant cattle, presumably by ingestion of a mixed ration or water that has been contaminated with infected canine feces. The use of mixed rations in dairy herds probably accounts for the greater prevalence of neosporosis in dairy cattle than in extensively grazed beef cattle.

Transmission: Dogs are definitive hosts of *N. caninum* and are capable of shedding oocysts in feces after eating tissues of infected animals. Gray wolves, coyotes, and dingoes are also definitive hosts, and many other wild canids are suspected. *Neospora* oocysts have an impervious shell that enables survival in soil and water for prolonged periods after canine feces have decomposed. Intermediate hosts such as cattle become infected by ingesting oocysts. Cattle do not produce oocysts and thus do not transmit infections horizontally to other cattle, but latent infection may endure permanently in their tissues and is transmitted to canids by carnivorousism.

In cattle, *N. caninum* can be transmitted transplacentally from an infected cow to the developing fetus, an event that may occur in multiple pregnancies of the same cow. Because most congenital infections are subclinical, congenitally infected heifer calves may be retained and added to the breeding herd and, in turn, may pass infections transplacentally to their own offspring. This endogenous transplacental transmission may enable transgenerational maintenance of the parasite even if the herd does not have frequent transmission from dogs. Exogenous transplacental transmission may occur when a previously uninfected cow ingests *Neospora* oocysts during pregnancy and the fetus becomes infected.

Dogs have been shown to become infected by eating infected cattle (including

placentas) and deer and are presumed to become infected by consuming raw meat diets, barnyard chickens, and a variety of wild animals.

Clinical Findings: Most neosporosis abortions occur in mid to late gestation. Congenitally infected calves may be born weak or with neurologic deficits. However, most congenital infections are subclinical.

In dogs, subclinical infection is the rule, although there are a greater variety of exceptions. Litters or individual puppies may develop progressive hindlimb paresis associated with polyradiculoneuritis, myositis, and muscle atrophy. Adult dogs may have encephalomyelitis, focal cutaneous nodules or ulcers, pneumonia, peritonitis, hepatitis, or myocarditis with use of immunosuppressive drugs.

Diagnosis of Bovine Abortion:

Because neosporosis is only one of many causes of abortion, diagnostic efforts should focus on an array of possible causes. Aborted fetuses should be submitted to a veterinary diagnostic laboratory, together with placenta and a serum sample from the aborting dam. Examination of multiple fetuses increases the odds of accurate diagnosis. If it is impractical to submit an entire fetus, as many of the following specimens as possible should be submitted to exclude other causes of abortion: aseptically collected and chilled lung, liver, spleen, and abomasal fluid; an eyeball for nitrate testing; formalin-fixed specimens of brain (even if soft), lung, thymus, liver, kidney, spleen, adrenal gland, skeletal muscle (eg, tongue and diaphragm), and placental cotyledon; serum from the aborting dam; and thoracoabdominal fluid from the fetus for serology.

A diagnosis of neosporosis abortion can be made with great confidence from the following constellation of findings: 1) lack of other etiologic agents; 2) nonsuppurative inflammation in multiple fetal organs, especially including the brain, heart, and skeletal muscle; 3) immunohistochemical or PCR detection of *Neospora* in fetal tissues; and 4) *Neospora* seropositivity of the dam or fetus. However, such unequivocal findings are not always present. A lesion that is nearly specific for neosporosis abortion in cattle is multifocal cerebral necrosis surrounded by nonsuppurative leukocytic reaction. Confidence in the diagnosis increases with the strength of the *Neospora* antibody level in the aborting dam, with high seropositive

reactions at the time of abortion having greater predictive value than low seropositive reactions. Neosporosis is generally excluded in seronegative dams.

Toxoplasmosis is a more common cause of abortion in sheep and goats and has lesions similar to those of neosporosis, but toxoplasmosis abortion in cattle is rare or nonexistent.

Serologic testing of multiple cows or heifers can be used as an alternative or complementary method to determine whether neosporosis is a major reproductive problem in a herd. This strategy can be helpful when investigating herds with endemic abortion problems. Serum samples should be collected from aborting dams and from an equal number of matched herdmates with normal gestation (generally ≥ 10 per group). Sera should be tested and classified for *Neospora* antibodies. If most cows in the aborting group are seropositive and few are seropositive in the normal group, then neosporosis should be suspected as a cause of abortion in the herd; this may be confirmed by statistical comparison. If most aborting cattle are seronegative, then neosporosis is unlikely to be a major problem.

Diagnosis of Canine Neosporosis:

Clinically affected dogs often have *Neospora* antibody levels much higher than levels seen in subclinically infected individuals. Biopsy of clinically affected tissues demonstrates nonsuppurative inflammation and may reveal the presence of protozoal organisms, but immunohistochemistry or PCR may be required to detect the organisms or to differentiate them from other protozoa.

Dogs with symptomatic neosporosis usually do not shed oocysts in feces. The finding of *Neospora* in routine fecal floats is serendipitous, because dogs typically shed oocysts for only a period of days or weeks after ingesting tissue of an infected animal. The tiny oocysts are round to slightly oval and 10–11 microns in diameter; in comparison, *Giardia* cysts are oblong and approximately 9×13 microns, and coccidia are 2–4 times the diameter of *Neospora*. A smooth outer contour helps to differentiate *Neospora* oocysts from pitted pollen grains of similar size. The oocysts are nearly identical to those of *Hammondia heydorni*, a closely related parasite that has not been associated with systemic disease in dogs or with abortion in ruminants. PCR may be necessary to distinguish between oocysts of *N. caninum* and *H. heydorni*.

Treatment: There is no approved treatment for neosporosis in cattle. Clinical neosporosis in dogs is treated with prolonged administration of clindamycin or potentiated sulfa drugs. The prognosis is negatively associated with the severity of presenting clinical signs and with delayed treatment. The prognosis is poor in puppies if disease has progressed to hindlimb paresis with atrophied, rigid limbs.

Control: Currently, there are no available *Neospora* vaccines for cattle or dogs.

It is common for dairy and beef herds to have at least a small percentage of *Neospora*-infected cattle. Although reducing the risk of *Neospora* transmission is a useful goal, complete eradication from a herd is usually impractical. Contamination of feedstuffs used in mixed rations by canine feces should be avoided. Large dairies can consider erecting dog-proof fences around the area in which feedstuffs are stored outdoors, and automatic gates can be installed to facilitate the daily traffic of heavy machinery. Smaller dairy farms may be able to protect feedstuffs within traditional buildings such as barns, grain bins, and silos.

In addition to protecting feedstuffs, herds with endemic neosporosis abortions may consider not retaining heifer calves born to seropositive cows, thereby reducing the number of congenitally infected replacement heifers that enter the breeding herd. If this technique is used, seropositive dairy cows could be bred using beef semen. For seropositive cows with valuable genetics, the use of embryo transfer to *Neospora*-seronegative surrogates, a technique that blocks endogenous transmission, can be considered.

Dead stock, offal from home slaughter, and placentas should be discarded in a manner that prevents ingestion by dogs to reduce the risk that dogs will become infected and shed *Neospora* oocysts on the farm. Dogs seropositive for *Neospora* have reduced likelihood for future shedding of oocysts than do seronegative dogs; therefore, serologic testing of farm dogs is seldom useful.

Zoonotic Risk: Despite its similarity to *Toxoplasma*, *Neospora* infection has not been clearly associated with any human disease. Laboratory workers should guard against inoculation, which caused fetal lesions in parenterally inoculated primates.

NOCARDIOSIS

Nocardiosis is an opportunistic, noncontagious, pyogranulomatous to suppurative disease of domestic animals, wildlife, and people.

Mastitis, pneumonia, abscesses, and cutaneous/subcutaneous lesions are the major clinical manifestations of nocardiosis in livestock and companion animals.

Nocardia species are aerobic actinomycetes that belong to the order Actinomycetales, which comprises a complex group of pathogens, including the genera *Rhodococcus*, *Mycobacterium*, and *Corynebacterium*, which are related to severe infectious diseases and usually refractory to conventional therapy.

Etiology: *Nocardia* is a pleomorphic, gram-positive, facultative intracellular bacterium, nonmotile and non-spore-forming. In Gram smears, it appears as rods, cocci, or coccobacilli forms with characteristic long or branching filaments and a tendency to fragment into rods and cocci. When cultured, some species of *Nocardia* produce aerial filaments. Components of the cell wall, particularly mycolic acids, render *Nocardia* spp partially acid-fast. Pathogenic *Nocardia* spp are strictly aerobic, growing over a wide temperature range (10°–50°C [50°–122°F]).

In past decades, *Nocardia* species identification has been traditionally based on phenotypic methods, including hydrolysis of different substrates (casein, xanthine, hypoxanthine, and tyrosine), carbohydrate assimilation (glucose, glycerol, galactose, glucosamine, inositol, adonitol, and trehalose), and antimicrobial susceptibility profile. Based on this former classification, the most important pathogenic species for animals and people were represented by the *Nocardia asteroides* complex (*N. asteroides*, *N. nova*, *N. farcinica*), *N. brasiliensis*, *N. pseudobrasiliensis*, *N. otitidiscalearum*, and *N. transvalensis*. However, diagnosis based exclusively on phenotypic assays leads to misidentification or is insufficient to distinguish some species of *Nocardia*. More recently, studies in domestic animals and people have revealed that speciation of *Nocardia* requires confirmation by molecular methods. However, most of the literature about nocardiosis in animals and people was published before this new

molecular speciation. Thus, because of the taxonomic transition of *Nocardia* speciation, for purposes of this chapter, the remaining text will use the former *Nocardia* spp (in reference to the old classification) or molecular species detection of *Nocardia* (in reference to the new taxonomy).

To date, >90 valid species of *Nocardia* are recognized. Of these, >30 have been described as causes of opportunistic human infections, and at least 30 as responsible for animal diseases. Recent use of molecular techniques has led to large taxonomic changes in the *Nocardia* classification, and new species continue to be described.

Epidemiology: *Nocardia* spp are ubiquitous organisms, a component of normal soil microflora; they are commonly found in soil, organic material, freshwater and saltwater, dust, compost vegetation, and other environmental sources.

Nocardiosis is considered an uncommon disease in animals and people. However, reports of animal nocardiosis have increased worldwide.

Infections in livestock and companion animals caused by *Nocardia* spp are acquired by inhalation, traumatic percutaneous introduction of the microorganism, ingestion, or by the intramammary route. The occurrence of disease and infective *Nocardia* spp may vary geographically, influenced by animal management strategies as well as environmental factors, such as dry, dusty, or windy conditions.

Nocardia spp is considered an agent of mastitis of environmental origin in cattle and small ruminants. Nocardial mastitis usually affects herds with a history of inadequate milking management and/or poor hygiene conditions before and after milking. Mammary infections are predominantly caused by soil contamination of teat dips, udders, and milking equipment during washing procedures and by intramammary infusion therapy. Dairy herds affected by nocardial mastitis also have a history of inadequate concentrations of antiseptics in teat dips. Outbreaks of nocardial mastitis have been reported associated with dry-cow therapy (eg, neomycin) or improper intramammary therapy.

In companion animals, disease transmission is related to the inoculation of organisms through puncture wounds

or foreign bodies, or secondary to bites, wounds, or scratches after cat fights. Canine infections have rarely been related to inhalation of the bacterium. The occurrence of nocardiosis in dogs and cats is intimately associated with underlying immunosuppressive disorders, particularly dogs infected by distemper virus and cats affected by leukemia or immunodeficiency virus. Canine nocardiosis occurs at any age group and in both sexes, although it appears to affect mainly males, particularly between 1–2 yr old.

Nocardiosis in horses is recognized as an opportunistic infection and is usually related to immune disorders. In most reported cases of equine clinical nocardiosis, there were underlying immunosuppressive problems, particularly pituitary pars intermedia dysfunction (see p 547) or severe combined immunodeficiency in Arabian foals (see p 818).

Pathogenesis: Pathogenicity of *Nocardia* in domestic animals is attributed to the virulence of the strain, the structure of the bacterial cell wall, host susceptibility, route of transmission, coinfection with immunosuppressive diseases, and development of pyogranulomatous lesions. However, the outcome of *Nocardia* infections is intimately linked to the ability of the strain to resist the initial neutrophil and activated macrophage attack and the cell-mediated immune response.

Immune response against nocardial infections is primarily cell-mediated. These intracellular organisms are able to inhibit phagosome-lysosome fusion in neutrophils and macrophages because of the presence of mycolic acids in their bacterial cell wall. *Nocardia* is also resistant to acids, oxidative enzymes (catalase and superoxide dismutase), and other enzymatic mechanisms of phagocytic cells. In addition, some toxins have been identified in *Nocardia* spp that appear to contribute to the virulence of pathogenic strains.

Nocardia does not induce an effective humoral immune response mediated by the action of B lymphocytes.

Clinical Findings: Mastitis, cutaneous/subcutaneous lesions, abscesses in organs, and pneumonia are the most common clinical signs of nocardiosis in livestock and companion animals.

Mastitis in Ruminants: Former *N asteroides*, *N nova*, *N otitidiscaviarum*, and *N farcinica* are the most common species described in mammary nocardiosis

of domestic ruminants. More recently, based on 16S rRNA sequencing, *N nova* and *N farcinica* were the most frequent species detected in 80 different cases of bovine mastitis in Brazil and, unexpectedly, *N puris*, *N veterana*, *N cyriacigeorgica*, *N arthritidis*, and *N africana* were identified as well.

Nocardial mastitis is generally characterized by a history of chronic evolution and is usually refractory to antimicrobial therapy. Classically, clinical cases of mammary nocardiosis were predominantly seen in one or two animals in the herd, during lactation or the dry period. Clinical examination of the udder shows enlargement, edema, fibrosis, either diffuse or multifocal nodules, and occasionally draining tracts. Strip cup testing reveals serous to purulent milk secretion, showing white to yellow particles ("sulfur granules"). Infected cows have high somatic cell counts. Less frequently, the organism may disseminate from the mammary gland to other organs, causing regional lymphadenitis and pyogranulomatous lesions.

Bovine Farcy: This particular manifestation of bovine nocardiosis is usually limited to the tropics. Bovine farcy is caused by former *N farcinica*. Occasionally, *Mycobacterium farcinogenes* and *M senegalense* are also identified in similar lesions. Bovine farcy is an uncommon cause of chronic lymphangitis, lymphadenitis, and cutaneous nodules. Initially, the lesions consist of cutaneous nodules, particularly in the leg and neck regions. These nodules may slowly enlarge and coalesce to lesions of up to 10 cm in diameter, which rarely ulcerate. The lymphatic vessels appear cord-like.

Horses: Nocardiosis is an uncommon disease in horses. Most nocardial infections in horses were described involving former *N asteroides* and occasionally *N brasiliensis*. More recently, based on molecular assays, *N nova* was described causing recurrent airway obstruction in a horse. Severe pneumonia, pleuritis, disseminated (systemic) abscesses in organs, cutaneous lesions, mycetomas, and rarely, abortion represent the main clinical signs of equine nocardiosis.

Systemic nocardiosis occurs by hematogenous dissemination of bacteria causing abscesses in various organs. Pulmonary nocardiosis is characterized by increased respiratory rate, cough, labored breathing, and nasal secretion. Cutaneous and subcutaneous lesions are generally secondary to traumatic introduction of

Nocardia into the skin, leading to pyodermatitis, cellulitis, and cutaneous nodules located anywhere in the body. The lesions may ulcerate and have an odorless, gray to white discharge. Mycetomas are another type of cutaneous infection and consist of chronic and progressive skin lesions caused after transcutaneous inoculation of *Nocardia* spp. Painless nodules, purulent to necrotic, commonly form, usually limited to the site of injury, and occasionally show purulent discharge through the sinus tract.

Abortion rarely occurs in mares. Two cases were reported in Arabian and Thoroughbred mares at ~6 mo of gestation, both with history of failure to maintain gestation to term. Fetal necropsies showed lesions in lung and liver. *N asteroides* was cultured from the uterus of the Arabian mare.

Companion Animals: In dogs and cats, former *N asteroides*, *N brasiliensis*, *N otitidiscaviarum*, and *N nova* are the most frequent species identified. Recently, based on molecular methods, *N africana*, *N elegans*, and *N tenerifensis* were reported in cats, and *N abscessus* in a dog.

Superficial skin, lymphocutaneous, and thoracic infections, as well as disseminated forms, are the major clinical pictures of nocardiosis in dogs and cats. Cutaneous/subcutaneous abscesses with fistulous tracts, ulcers, mycetomas, and regional lymphadenitis are frequent clinical manifestations of the disease, associated with local skin or lymphocutaneous lesions in cats and resembling human nocardiosis. Skin lesions are seen mainly in the extremities, flank, nose, and neck areas. Canine and feline pulmonary nocardiosis are characterized by mucopurulent oculonasal discharge, anorexia, hyperthermia, weight loss, cough, dyspnea, and hemoptysis. Other systemic or disseminated forms of the disease in companion animals are represented by the presence of abscesses or lesions in two or more sites, including liver, kidneys, spleen, eyes, bones, joints, and abdominal lymph nodes, as well as development of peritonitis, pleuritis, and pyothorax. GI infection can lead to gingivitis, halitosis, and ulceration of the oral cavity. Rarely, the organism affects the urinary tract and heart. Nocardial infection in the CNS is associated with seizures, alertness, and deficits in proprioception.

Miscellaneous: Bovine or equine oral infection secondary to ingestion of fibrous foods can lead to development of pyogranulomatous lesions in the jaw. Abortion may also occur in sows and cows. Submandibu-

lar and mesenteric lymphadenitis was reported in pigs. Nocardiosis in wildlife and fishes generally causes organ abscesses and pneumonia.

Diagnosis: Routine diagnosis is based on epidemiologic findings, clinical signs, and microbiologic examination. Samples of abscesses, skin, tracheobronchial lavage fluid, milk, aspirates, organs, or other tissues should be cultured on sheep blood and/or Sabouraud agar and incubated aerobically for 2–7 days at 37°C and 25°C [98.6°F and 77°F], respectively. However, growth of some *Nocardia* spp in culture media is slow, and incubation should be extended for at least 2 wk. Colonies are circular, convex, smooth or rough, firmly adherent to agar surface, odorless, with various carotenoid-like pigments (cream, white, orange, pink, or red), and present aerial hyphae and typical powdery and dry surface, like fungal organisms. Because *Nocardia* spp are ubiquitous in the environment, microbiologic isolation of a small number of organisms from clinical specimens must be evaluated together with clinical signs and other diagnostic methods.

Microscopically, gram-positive, typically filamentous organisms are seen, with a tendency to fragmentation. Modified Ziehl-Neelsen stain shows partially acid-fast organisms. Fine-needle aspiration has been used in the diagnosis of skin nocardiosis in companion animals. Gram, Giemsa, and panoptic stains show filamentous organisms in aspirated specimens. The leukogram reveals mainly leukocytosis with neutrophilia and monocytosis, whereas the erythrogram shows moderate anemia.

Radiographic images of dogs with pulmonary nocardiosis show diffuse inflammation, nodules, abscesses, and lobar consolidation. Differential diagnoses in domestic animals include infections with *Actinomyces* or *Streptomyces* spp because of the similarities in microbiologic appearance and clinical signs. Face and jaw enlargement in cattle and horses caused by oral nocardiosis should be differentiated from *Actinomyces bovis* (actinomycosis, see p 590), *Actinobacillus lignieresii* (actinobacillosis, see p 589), and *Staphylococcus aureus* (botryomycosis).

Postmortem examination of internal organs and tissues reveals abscesses and/or numerous small to large nodules, discrete to coalescing, of white to gray color. Histologic findings of nocardiosis are characterized by pyogranulomatous to suppurative lesions with areas of necrosis. The lesions or

nodules show a suppurative, necrotic center containing filamentous organisms surrounded by macrophages, lymphocytes, and plasma cells. Occasionally, epithelioid and multinucleated giant cells are found. Histopathology sometimes reveals small, soft granules in discharges of lesions, formed by microcolonies of the organism. Lymph nodes are enlarged.

Different serologic (immunodiffusion, complement fixation, and ELISA) and cutaneous hypersensitivity tests have been proposed to diagnose nocardiosis in animals. However, host animals commonly develop a nonspecific antibody response against *Nocardia*, limiting the use of serologic tests in routine diagnosis.

Currently, phenotypic diagnoses of *Nocardia* spp have been confirmed using molecular methods, including PCR, restriction endonuclease analysis of amplified 65-kDa heat shock protein gene (hsp65), 16S rRNA gene sequence, essential secretory protein A (secA1), gyrase B (gyrB), and DNA-DNA hybridization. These molecular techniques offer a timesaving and reliable means of speciation and have led to a number of taxonomic changes and the identification of new species of *Nocardia*.

Treatment: Animal and human nocardiosis is usually refractory to conventional therapy because of the intracellular location of the bacterium, development of pyogranulomatous lesions, and antimicrobial resistance patterns.

The antimicrobial susceptibility profile varies dramatically between *Nocardia* spp and geographic areas. The National Committee for Clinical Laboratory Standards approved an in vitro standardized susceptibility test for *Nocardia* by broth microdilution. The modified disc diffusion method has been used as well.

Trimethoprim-sulfonamides, aminoglycosides (amikacin, gentamicin), linezolid, amoxicillin-clavulanate, imipenem, and some cephalosporins (cefotaxime, ceftriaxone) are considered drugs of choice for nocardiosis therapy in animals and people. Ampicillin, clarithromycin, doxycycline, erythromycin, and minocycline are described as treatment alternatives for animals. Combined therapy using amikacin with sulfonamides, and amikacin with imipenem or cephalosporins (cefotaxime, ceftriaxone) also have been proposed. Intramammary infusions of trimethoprim-sulfonamides, cephalosporins or aminoglycosides (gentamicin) have been used for 5–7 days to treat clinical mastitis in cattle and goats.

Long-term therapy (1–6 mo in domestic animals and 6–12 mo in people) is required because of clinical relapses after short-term protocols. In companion animals, surgical procedures (debridement, drainage, extirpation of foreign bodies, and washing of lesions with antiseptic solutions) are indicated in cutaneous/subcutaneous lesions and osteomyelitis. However, antimicrobial therapy is successful in only 30%–50% of cases of mastitis in cattle and goats, as well as in pulmonary or extrapulmonary (disseminated or systemic) infections in companion animals and horses. The mortality of animal nocardiosis is attributed mainly to underlying conditions, delayed diagnosis, and improper therapy.

Control and Prevention: There are no specific or effective measures to control animal and human nocardiosis, probably because of the wide distribution of the microorganism in the environment.

In companion animals, immunosuppressive pathogens or debilitating conditions should be investigated as predisposing factors to development of nocardiosis.

Control and prevention of nocardial mastitis is based on measures recommended for environmental agents. Thus, the best measures to control and/or prevent nocardial mastitis remain the early microbiologic diagnosis of mastitis, proper hygiene conditions, cleaning the environment during milking, correct antiseptic concentrations in post- and mainly in pre-dipping solutions, high-quality water to wash the animals and milking equipment, removal of organic material from the milking area, and appropriate intramammary therapy procedures. Because of poor success rates in treatment of mammary infections, segregation of infected animals, chemical drying of affected quarters, or culling of animals are also recommended in control of nocardial mastitis in dairy herds.

Public Health Considerations: Human nocardiosis is an opportunistic disease. In some countries, the clinical impact of nocardiosis is fragmentary, indicating that diagnosis of disease may be neglected or underestimated. Curiously, reports of human nocardiosis have recently increased all over the world. Although the disease typically occurs in immunocompromised patients, nocardiosis has been described in immunocompetent people as well. Former *N asteroides* complex is the main species

described in human nocardiosis. Currently, based on molecular methodologies and rearranged taxonomy, *N. cyriacigeorgica*, *N. brasiliensis*, *N. asteroides*, *N. nova*, *N. farcinica*, *N. transvalensis*, *N. pseudobrasiliensis*, and *N. otitidiscaviarum* have most frequently been detected in human patients.

Pneumonia, cutaneous-subcutaneous lesions, mycetoma, and neurologic manifestations are the most common clinical signs. However, clinical cases of human nocardiosis are intimately associated with immunosuppressive or debilitating disorders, such as AIDS, organ transplants, cirrhosis, diabetes, alcoholism, rheumatic and malignancy diseases (lymphosarcoma, lymphoma), or prolonged use of corticosteroids.

The environment is the natural reservoir of *Nocardia* spp for human and animal infections. Most cases of transmission to people probably occur by inhalation of the organism in dry and warm climate regions (aerosolization). Trauma with skin inoculation is another form of transmission of the bacterium to

people. Cases of cutaneous/subcutaneous nocardiosis have been reported in some patients, secondary to bites or scratches of clinically ill dogs and cats. However, human nocardiosis is apparently not directly transmitted person-to-person or by nosocomial infections. Interestingly, studies have shown great similarity between *Nocardia* spp involved in human and animal infections. Experimental studies regarding temperature resistance using former *N. asteroides* and *N. brasiliensis* isolated from bovine milk and submitted to time/temperature conditions used in usual pasteurization procedures indicated a potential risk of *Nocardia* transmission by milk.

Precautions should be taken among human patients who have immune dysfunctions or debilitating diseases, with special reference to contact with soil or organic material from environments contaminated by domestic animals, contamination of traumatic cutaneous lesions, or close contact with animals suspected of having nocardiosis.

PERITONITIS

Peritonitis is an inflammation of the serous membranes of the peritoneal cavity. It may be a primary disease or secondary to other pathologic conditions. Different infectious and noninfectious agents may cause peritonitis, which may result in a variety of clinical manifestations, disease progression, and outcome. Peritonitis may be acute or chronic, septic or nonseptic, local or diffuse, or adhesive or exudative. The term "tertiary peritonitis," used in human medicine for particular cases of chronic peritonitis with a small number of bacteria or fungi, is not used in veterinary medicine.

Etiology: Primary peritonitis is less common than secondary peritonitis and may be infectious or idiopathic. In infectious primary peritonitis, infectious agents spread via the bloodstream into the peritoneal cavity of animals that are often immunocompromised. Such infectious agents include feline coronavirus (FCoV), which causes feline infectious peritonitis (FIP); *Nocardia* spp; *Mycobacterium* spp; *Haemophilus parasuis*; and other infectious agents. Progression of primary peritonitis tends to be chronic.

Peritonitis occurs secondary to another disease as the result of exposure of the peritoneal cavity to nonspecific infectious or noninfectious agents. It is often acute and frequently results in a progressive, systemic disease. Secondary septic peritonitis is commonly associated with perforation of and leakage from GI organs (eg, traumatic reticuloperitonitis in cattle), with subsequent processes allowing transmural migration of bacteria (eg, neoplasia, intestinal ischemia), or with perforation/rupture of or leakage from other infected viscera (eg, abscesses in liver, spleen, omentum, cystitis, endometritis, pyometra). Furthermore, migration of parasites through the abdominal cavity may also result in leakage of chyme with subsequent septic peritonitis. Perforating wounds of the abdominal wall (eg, dog bites) or dehiscence of abdominal wound closure may result in laceration of viscera and inoculation of foreign material and microorganisms into the peritoneal cavity.

Microorganisms associated with septic peritonitis usually reflect the source of contamination. A mixed bacterial population is seen in GI tract perforation, whereas

perforation of nongastrointestinal viscera (eg, urinary or gall bladder, uterus, prostate) or hematogenous infection of the peritoneal cavity may be more typically associated with aerobic organisms, including *Escherichia coli*, *Streptococcus equi zooepidemicus*, *Staphylococcus*, *Proteus*, *Rhodococcus*, *Klebsiella*, *Salmonella*, *Enterobacter*, *Pseudomonas*, or *Corynebacterium*.

Secondary aseptic peritonitis occurs after contamination of the abdominal cavity with chemical irritants (eg, bile, urine, drugs) or intestinal ischemia. Common conditions are urolithiasis and rupture of the urinary or gall bladder; however, these conditions are not

always aseptic. The originally aseptic peritoneal inflammations may later become septic. In addition, intraperitoneal administration of drugs or fluids may result in temporary inflammatory reactions of the peritoneum. Because New World camelids show severe inflammatory reactions to infections with *Dicrocoelium dentriticum*, peritonitis may develop subsequent to the severe hepatitis. In large animals, peritonitis is most commonly seen in cattle, less often in horses, and rarely diagnosed in pigs, sheep, and goats. It is a serious and often fatal condition in cats (FIP). For common causes of peritonitis in various species, see TABLE 5.

TABLE 5 COMMON CAUSES OF PERITONITIS

Species	Cause
Cattle	Traumatic reticuloperitonitis; rumenitis; abomasal ulcer (perforation); abomasal volvulus; cecal torsion; dystocia (uterine torsion, cesarean section); metritis or pyometra; abdominal surgery; intestinal, rectal, or uterine rupture; liver or abdominal abscess rupture; omphalitis (calves); fat necrosis/pancreatitis; neoplasia (eg, mesothelioma, ileal adenocarcinoma); iatrogenic (eg, rectal perforation, liver biopsy, intraperitoneal injection, rumenocentesis); green algae infection (rare); <i>Setaria</i> infection (rare)
Horses	Parasitic (larval) migration; intestinal injury and ischemia (colic); abdominal abscess rupture (<i>Rhodococcus</i> , <i>Streptococcus</i>); abdominal surgery (colic surgery, castration); gastric, intestinal, or uterine rupture; gastroduodenointeritis, colitis; omphalitis, persistent urachus, or bladder rupture (foals); gastric ulcer (perforation); fat necrosis/pancreatitis; neoplasia (eg, cholangiocellular carcinoma); penetrating trauma to abdominal wall; iatrogenic (rectal perforation, intraperitoneal injection)
Small ruminants	Primary peritonitis (<i>Mycoplasma</i> spp); parasitic (larval) migration (eg, liver fluke, lungworm, <i>Setaria</i> sp); traumatic reticuloperitonitis (less common than in cattle); abdominal abscess rupture; neoplasia (eg, mesothelioma, cholangiocellular carcinoma); iatrogenic (eg, liver biopsy, intraperitoneal injection)
New World camelids	Sequela of parasitic migration/acute hepatitis (dicrocoeliosis of special importance); perforating third-compartment or duodenal ulcers; sequela of urolithiasis/ruptured urinary bladder; traumatic reticuloperitonitis (rare)
Pigs	Glässer's disease (<i>Haemophilus parasuis</i>); intestinal (ileal) perforation; dystocia; sequela of septicemic infections (<i>Salmonella</i> Choleraesuis, <i>Streptococcus suis</i>); polyserositis (<i>Mycoplasma hyorhinis</i>)
Dogs and cats	Feline infectious peritonitis (FCoV); ingested intestinal foreign bodies; gastric, intestinal, rectal, bladder, or uterine rupture; abdominal or intestinal surgery; gastric and duodenal ulcers/perforation; abdominal neoplasia (eg, mesothelioma); hepatitis, gallbladder diseases/rupture; pancreatitis/fat necrosis; gastric dilatation volvulus (dog); penetrating trauma to abdominal wall; <i>Candida albicans</i> (rare); <i>Neospora caninum</i> (rare)

Pathogenesis: Inflammation of the peritoneum is the result of a variety of possible pathogenetic pathways that are species-dependent (eg, peritoneal inflammatory response in cattle is characterized by extensive fibrin formation, horses tend to develop exudative peritonitis) and mainly influenced by etiology (eg, primary or secondary, septic or nonseptic). Because of the release of inflammatory mediators after contact with mechanical, chemical, or infectious agents, serosal capillary permeability is increased and results in leakage of plasma proteins, solutes, and water into the peritoneal cavity. Exudation of protein-rich fluid may result in hypoproteinemia and facilitates bacterial proliferation. The combined effect of large fluid losses into the peritoneal cavity and vasodilatory effects of absorbed toxins may produce profound hypotension and hypovolemia. The inflammation may decrease the animal's antioxidative capacity and result in oxidative stress.

Rupture or perforation of the forestomach, stomach, or intestine with spillage of large volumes of gastric or intestinal contents and rupture or perforation of the contaminated uterus leads to an acute septic peritonitis. Toxins produced by bacteria and tissue breakdown are readily absorbed through the peritoneum and have severe systemic effects leading to hypotension, shock, systemic inflammatory response syndrome (SIRS), and disseminated intravascular coagulation (DIC). Endotoxins and acid-base and electrolyte disturbances directly affect cardiac function, leading to reduced cardiac output and circulatory failure. Paralytic ileus is considered to be a frequent result of acute peritonitis, causing functional obstruction and an increased mortality rate. Large volumes of inflammatory exudates may be secreted into the peritoneal cavity during peritonitis and may lead to impaired respiration by impinging on the diaphragm. Spillage of small amounts of gastric or intestinal content (eg, after transcutaneous rumenocentesis, bar suture techniques for left displaced abomasum surgery) normally result in local peritonitis.

Chronic peritonitis is often characterized by extensive secretion of fibrinogen and subsequent formation of fibrinous/fibrous adhesions. Such adhesions help localize the inflammatory process (eg, traumatic reticuloperitonitis in cattle, type 3 abomasal ulcers in cattle) but may cause mechanical or functional obstruction of the GI tract. Chronic peritonitis in horses often results in recurrent colic episodes.

Clinical Findings: Clinical signs vary depending on the type and etiology of peritonitis. Affected animals may develop toxemia and septicemia, shock, hemorrhage, abdominal pain, paralytic ileus, fluid accumulation, and adhesions in varying degrees. However, there are reports of apparently clinically healthy animals having chronic bacterial peritonitis.

Shock, hypotension, acid-base disturbances, and circulatory collapse after acute septic peritonitis associated with rupture of intestines or uterus often lead to sudden death. These animals normally show only limited clinical signs of peritonitis. In less severe cases, abdominal pain and fever are common. Hypothermia can also be seen as a result of dehydration, hypovolemia, and sepsis. Abdominal pain may be permanent and severe, characterized by guarding the abdomen, stiff gait, or recumbency. In all species, pain responses are most evident in the early stages. Abdominal distention, which may be inapparent, usually is due to accumulation of peritoneal exudates, paralytic ileus, or peritoneal adhesions. Fecal output is often decreased, although frequency of defecation may be increased in the early stages of peritonitis. Animals with secondary peritonitis may also show clinical signs associated with the primary disease.

Rectal palpation is a useful diagnostic technique to evaluate the peritoneum and accessible abdominal organs in large animals; however, local peritonitic processes in the cranial abdomen (eg, traumatic reticuloperitonitis in cattle) do not result in clinical signs that can be diagnosed by rectal examination. Abdominal radiography may be used in small animals. In horses and cattle, radiography can be also used as a diagnostic tool, but high-power x-ray machines are required; therefore, this technique is limited to stationary units in veterinary clinics. Generally, ultrasonography is the most valuable diagnostic tool to examine the abdominal cavity and assess the extent, localization, and character of peritonitis. Additionally, ultrasonography allows a guided abdominocentesis, which can be used (in both large and small animals) to obtain fluid for cytologic and biochemical examination and bacteriologic culture. Diagnostic peritoneal lavage can be used if peritoneal fluid cannot be obtained by abdominocentesis. Diagnostic laparoscopy or laparotomy can be considered to verify the diagnosis. Diagnostic laparotomy is frequently used in cattle because it is inexpensive, can be performed in standing position, and is associated with few or

minor complications; it also makes additional diagnostic procedures unnecessary and can often be combined with therapeutic measures.

Cattle: Clinical signs of peritonitis in cattle are often nonspecific and characterized by reduced feed intake, drop in milk production, and decreased rumination activity. In chronic cases, ruminal contractions may be present but reduced in intensity. Abdominal percussion may reveal ruminal tympany or pneumoperitoneum. Moderate fever is typical during the first 24–36 hr in cattle with acute, local peritonitis. High fever suggests acute, diffuse peritonitis. Cattle with peritonitis often have a shuffling, cautious gait with a rigid arched back, and grunt when walking or passing urine or feces. Deep palpation of the abdominal wall and pain provocation tests result in pain response. Chronic peritonitis is associated with development of fibrous adhesions. Depending on localization, rectal palpation may reveal adhesions between intestinal loops and peritoneum. Cattle may suffer from chronic indigestion (Hoflund syndrome, abomasal impaction) or toxemia, with periods of acute, severe illness caused by partial intestinal obstruction. The majority of cattle develop a localized peritonitis by extensive fibrin formation; however, in a few cases the abdominal cavity contains large volumes of turbid, infected peritoneal fluid.

Small Ruminants, New World Camelids, and Pigs: Generally, the clinical signs in small ruminants, New World camelids, and pigs are similar to those in other animals. However, peritonitis is rarely diagnosed clinically in pigs, sheep, or goats, although it is not an uncommon finding on routine meat inspection after slaughter of pigs. It is more common in llamas and alpacas.

Horses: Clinical signs include colic, distended intestines on rectal examination, gastric reflux, and occasionally diarrhea. Rectal palpation may reveal tacky, dry mucosa and in some cases fibrinous or fibrous adhesions between intestinal loops and other abdominal organs. Intestinal peristaltic sounds are reduced. Tachycardia, weak pulses, poor peripheral perfusion, and fever are common. Weight loss and intermittent abdominal pain (colic) may be seen in horses with chronic peritonitis.

Dogs and Cats: In small animals, anorexia and depression are nonspecific signs of peritonitis, often accompanied by vomiting and decreased defecation. The abdomen may be distended. Abdominal

palpation may be painful, and abdominal masses may be detected. Icterus may be present in generalized biliary peritonitis in small animals. Abdominal radiographs may reveal GI obstruction, bowel dilatation, free abdominal air, ascites, or radiodense foreign material. Loss of serosal details in radiographs indicates abdominal fluid.

Diagnosis: Laboratory analyses are helpful to confirm the clinical diagnosis and determine the severity of peritonitis, and should include a CBC and several biochemical parameters in blood and peritoneal fluid.

Acute, diffuse peritonitis with toxemia is usually accompanied by leukopenia, neutropenia, and a marked increase in immature neutrophils (degenerative left shift). In less severe acute peritonitis, leukocytosis may occur as a result of increased neutrophil production. Acute, localized peritonitis may reveal a normal WBC count with a regenerative left shift. The total WBC count in chronic peritonitis may be normal, with an occasional increase in lymphocytes and monocytes. Anemia may occur due to hemorrhage into the peritoneal cavity but is also commonly associated with chronic inflammatory processes. A number of abnormalities of serum biochemical parameters (eg, total protein, albumin, fibrinogen, bilirubin, LDH, alkaline phosphatase, CK) may accompany peritonitis. Hypoalbuminemia, hyperglobulinemia, and hyperbilirubinemia are frequently present. Generally, the changes in hematologic and biochemical parameters indicate inflammatory processes and tissue damage, but they are not pathognomonic for peritonitis.

The peritoneal fluid is a plasma dialysate with specific physical and chemical properties that depend on membrane permeability, concentrations and electrical charges of ions, and osmotic pressure. The fluid contains cells deriving from the mesothelium and the blood or lymphatic vessels. Under physiologic conditions, peritoneal fluid is a transudate, whereas peritonitis results in a fluid that is typically characterized as an exudate. Analysis of peritoneal fluid is a useful diagnostic method in gastroenterology, because the fluid generally reflects abdominal conditions. The volume of peritoneal fluid is frequently increased in peritonitis. In cases of septic peritonitis, samples of peritoneal fluid should be examined microbiologically to characterize infectious pathogens.

The parameters of the classic transudate-exudate categorization system are shown in TABLE 6. A peritoneal fluid showing properties of both a transudate and an exudate is

commonly called a modified transudate. Use of a scoring system allows further classification as mild, moderate, or severe peritonitis. In practice, however, analysis of peritoneal fluid may be inconsistent, leading to inconclusive results. Therefore, the diagnostic value of this traditional concept is limited. To improve the sensitivity of the distinction between an exudate and transudate of pleural and peritoneal effusions in human medicine, Light's criteria (fluid to serum protein ratio >0.5 , fluid to serum LDH ratio >0.6 , or fluid LDH activity >200 U/L), cutoff values for ratios between peritoneal fluid and plasma or serum of various parameters (eg, lactate, glucose, enzymes), and the serum-ascites albumin gradient (SAAG) have been established. These concepts have been applied to some animal species (ie, horses, cattle, small animals).

Under physiologic conditions, the ratio between lymphocytes and neutrophils is close to 1:1. Acute peritonitis usually results in an increased number of leukocytes, and the percentage of neutrophils can be 60%–90%. However, in cases of peracute septic inflammation, the number of leukocytes may decrease due to necrosis and cell damage. Histologically, a high rate of degenerative leukocytes (cytolysis, karyorrhexis, or karyolysis) can be found. In chronic peritoneal inflammation, the proportion of neutrophils decreases and the proportion of monocytes increases. The presence of intra- or extracellular bacteria confirms septic peritonitis. Gram-staining enables differentiation between gram-positive and gram-negative bacteria and facilitates early antibiotic treatment.

The physiologic total protein concentration in peritoneal fluid is 20–25 g/L. The normal protein ratio between peritoneal

fluid and serum is lower than 1:2. The SAAG is calculated by subtracting the peritoneal fluid albumin concentration from the serum concentration. The cutoff value of 11 g/L for people seems suitable for monogastric animals. However, the reference values for protein ratio and SAAG are not applicable to dairy cattle, mainly because of their higher serum protein and albumin concentrations than those of monogastric animals and people. In addition, in cattle, the protein ratio and SAAG did not show higher diagnostic values than the total protein concentration in peritoneal fluid alone.

In healthy animals, glucose concentration is the same in both serum and peritoneal fluid. Bacterial infection of the peritoneal cavity results in a major decrease of peritoneal glucose concentration. A peritoneal fluid:serum ratio of glucose concentrations <0.5 is highly sensitive and specific for septic peritonitis. Because in animals with septic peritonitis the glucose concentration in peritoneal fluid frequently falls below the detection limit, it is often not even necessary to measure the glucose concentration in serum.

Intestinal ischemia results in an increase of L-lactate concentration in plasma and peritoneal fluid. Although an association exists between L-lactate concentration in peritoneal fluid and plasma, L-lactate in peritoneal fluid is considered to be more closely correlated to the severity of intestinal ischemia. Physiologically, L-lactate concentration in peritoneal fluid is lower than that in plasma (in healthy horses, the ratio is $\sim 1:2$). This ratio is reversed in colicky horses with intestinal ischemia, cows with abomasal volvulus, and dogs with gastric dilatation volvulus. Similar to that in horses, an increased L-lactate concentration in

TABLE 6

CHARACTERISTICS OF TRANSUDATES AND EXUDATES IN CATTLE, HORSES, DOGS, AND CATS

Parameter	Species	Transudate	Exudate
Total protein (g/dL)	All	<2.5	>3
Specific gravity	All	<1.020	>1.025
Cell count ($10^9/L$)	Cattle	0.5–5	>8
	Horses	0.5–5	>8
	Dogs, cats	<3	>5
Color	All	Colorless to yellow	Variable
Turbidity	All	Clear to moderate	Moderate to opaque
Bacteria	All	Absent	May be present

peritoneal fluid has been found in cattle with abomasal volvulus and dogs with gastric dilatation volvulus. In addition, lactate is also a bacterial metabolite (predominately D-lactate); therefore, increased lactate concentration in peritoneal fluid may also indicate septic peritonitis. The accuracy of peritoneal lactate concentration in differentiating septic and nonseptic peritonitis varies between species (eg, 90%–95% in dogs but 65%–70% in cats).

Inflammation can be monitored using acute phase proteins such as C-reactive protein or haptoglobin (in cattle) as markers. Acute phase protein concentrations are increased in peripheral blood and in peritoneal fluid in animals with peritonitis; however, these parameters are general indicators for inflammation and not specific for peritonitis.

Fibrinogen concentration in peritoneal fluid may be increased in animals with peritonitis. However, fibrinogen concentration has limited diagnostic value, because there is only a weak association between peritoneal and blood fibrinogen concentration. An increased concentration of the fibrin degradation product D-dimer indicates intestinal ischemia and inflammation with high sensitivity and specificity. Normal values for human plasma are <0.3 mg/L. Reference values for small animals and horses seem to be similar to those in people. The peritoneal fluid D-dimer concentration in healthy cows is <0.6 mg/L; increased values indicate peritonitis with high sensitivity and specificity.

Inflammation, intestinal ischemia, and reperfusion affect the activities of several enzymes (alkaline phosphatase [ALP], AST, CK, LDH) in peritoneal fluid and peripheral blood. CK activity is primarily increased in serum and peritoneal fluid in cases of intestinal ischemia. The origin of CK is thought to be the muscular layer of the strangulated, ischemic intestines. However, other tissues (eg, striated muscle after colic episodes in horses) may be sources of higher CK activities; therefore, the sensitivity and specificity of CK are low.

LDH activity is a measure of inflammatory response and has been used to differentiate exudate from transudate (peritoneal fluid:serum LDH ratio >0.6; LDH activity of peritoneal fluid >200 U/L). The reference values for monogastric animals, but not those for cattle, are similar to those for people. For cattle, a cut-off value of 960 U/L has been identified.

An increase of ALP during intestinal ischemia and reperfusion has been found in peritoneal fluid of horses with colic and

cows with displaced abomasum. However, the origin of the ALP was not exclusively the damaged stomach or intestine. Other sources of the increased ALP activity in these cases include hepatocytes and granulocytes. Normally, serum ALP activity does not show major changes during intestinal ischemia.

Increased concentrations of protein and globulin in serum and peritoneal fluid are often seen in cats with FIP. However, neither parameter is accurate enough for diagnosis, especially if measured in serum. Calculation of the albumin:globulin ratio may improve the diagnostic value. The traditional Rivalta's test simply differentiates transudates from exudates. Although it produces false-positive results in cats with septic bacterial peritonitis, it still seems useful for FIP diagnosis. The widely used parameter α -1-acid glycoprotein indicates inflammation but is not specific for FIP. Serum anti-feline coronavirus (FCoV) antibody titers must be interpreted critically, because many healthy cats are anti-FCoV-antibody positive. The diagnostic value of anti-FCoV antibody titers in peritoneal fluid is still under discussion. A number of advanced diagnostic methods (eg, immunofluorescent staining of FCoV antigen in peritoneal macrophages, ELISA to detect antigen-antibody complexes in serum, reverse transcriptase-PCR) have been introduced as diagnostic measures to improve accuracy of FIP diagnosis. Generally, the laboratory tests performed on peritoneal fluid are superior to those that use serum. Further immunohistochemistry for intracellular FCoV antigen in macrophages derived from ocular or dermal lesions of FIP cats may aid the diagnosis. (See also FELINE INFECTIOUS PERITONITIS, p 780.)

Prognosis: Although the mesothelium of the peritoneum is able to regenerate rapidly, peritonitis must be considered a severe, life-threatening disease with a guarded prognosis. Prognosis strongly depends on the character and severity of the disease and, therefore, must be determined individually. General survival rates of 50%–70% have been reported, with much lower rates for return of productivity in farm animals. In horses, the prognosis for further use in equestrian sport is guarded. Furthermore, horses that survive peritonitis frequently suffer from recurrent colic episodes. Despite new developments in therapy, the prognosis for cats with FIP remains poor. It is still a lethal disease with no effective long-term treatment.

Treatment: Adequate therapy depends on the diagnosis and the results of physical examination and laboratory analyses. In severe cases of septic peritonitis, the initial treatment must be directed toward saving the life of the animal and stabilizing cardiovascular and other organ functions. In severe cases, euthanasia is a consideration. Therapy should include treatment of hypovolemic/toxic shock, aggressive anti-inflammatory therapy, and treatment of the metabolic and rheologic disturbances (eg, electrolyte and acid-base disorders, disseminated intravascular coagulation). Replacement fluids, electrolytes, plasma, or whole blood may be necessary to maintain cardiac output and improve circulation. It is of major importance to prevent circulatory failure from complications of disseminated intravascular coagulation. Antioxidative treatment using vitamins C and E or short-acting glucocorticoids might be useful. Additional prokinetic drugs might be necessary to increase and coordinate the motility of the GI tract.

Appropriate antimicrobial therapy should be started once septic peritonitis is suspected or confirmed. Peritoneal fluid samples should be obtained for culture and sensitivity testing. Parenteral broad-spectrum antimicrobial therapy must be applied initially. Aminoglycoside or fluoroquinolone antibiotics are effective against gram-negative organisms, and penicillins or cephalosporins are effective against gram-positive bacteria. The antimicrobial drug may be changed later according to the results of cytology and culture and sensitivity testing. Antimicrobial and anti-inflammatory treatment should continue through the healing period.

If possible, therapy should be initiated to eliminate the cause of peritonitis. In animals with suspected leakage of abdominal organs, surgery should be performed immediately to explore the abdomen and repair the defects, followed by peritoneal lavage with an isothermic, isotonic, balanced electrolyte solution before the abdominal cavity is closed. Although frequently performed, there is no proven clinical benefit in adding antimicrobial drugs to the lavage solution. Solutions containing antiseptics (eg, povidone-iodine) also have no proven clinical benefit and may even function as chemical irritants and exacerbate the inflammation. Heparin treatment may be considered in cases of DIC and may prevent extensive fibrin formation within the peritoneal cavity.

The application of abdominal drains and subsequent lavage is possible in small and large animals to treat severe peritonitis,

removing septic and proinflammatory material from the abdominal cavity. Whereas the removal of septic peritoneal fluid is generally accepted as beneficial, the efficacy of repeated peritoneal lavage is under debate. Whereas some reports describe positive effects, others claim that intensive lavage may disturb healing of the epithelium and result in further spread of the inflammation. The composition of the lavage solution is also under debate; there are no or very few advantages to adding antibiotics or antiseptics. The decision to manage peritoneal drainage is based on the severity of the case, experience level, intensive care possibility, and equipment. Maintenance of drain patency can be difficult, especially in cattle, caused by the extensive fibrin formation in the abdominal cavity. In animals treated by peritoneal drainage or lavage, serum protein and electrolyte levels should be monitored periodically, because both are lost with drainage of exudate.

Nutritional support should be anticipated, because many animals with peritonitis will not eat. Enteral nutrition helps to maintain the health of the intestinal mucosa; however, vomiting (dogs and cats) or anorexia may force the consideration of alternatives. In ruminants and New World camelids, transfaunation using rumen fluid obtained from other animals or commercially available products has proved beneficial. In certain animals, total or partial parenteral nutrition may be necessary to provide a portion of the nutritional requirements while enteral nutrition is being initiated. Administration of antioxidants and vitamins should be considered. Vomiting is sometimes a sequela of peritonitis in small animals; antiemetic treatment is indicated in such cases.

Feline coronavirus infection may cause a primary feline infectious peritonitis (FIP). Therapy is palliative (eg, interferon therapy, glucocorticoids, supportive therapy) and directed toward slowing down the inflammation. However, no effective long-term therapy is available. Commercial vaccines for prophylaxis are available in some countries; however, there are conflicting reports on their efficacy and safety. The vaccine is not effective when administered to animals already exposed to FCoV; however, it may offer some protection when administered to seronegative animals.

In chronic adhesive peritonitis, laparoscopy or laparotomy may be considered to cut adhesions that prevent intestinal motility or to remove/drain intestinal abscesses. However, the success of such interventions might be limited.

PLAGUE

Plague, caused by *Yersinia pestis*, is an acute and sometimes fatal bacterial zoonosis transmitted primarily by the fleas of rats and other rodents. Enzootic foci of sylvatic plague exist in the western USA and throughout the world, including Eurasia, Africa, and North and South America. In addition to rodents, other mammalian species that have been naturally infected with *Y. pestis* include lagomorphs, felids, canids, mustelids, and some ungulates. Domestic cats and dogs have been known to develop plague from oral mucous membrane exposure to infected rodent tissues, typically when they are allowed to roam and hunt in enzootic areas. Birds and other nonmammalian vertebrates appear to be resistant to plague. On average, 10 human plague cases are reported each year in the USA; most are from New Mexico, California, Colorado, and Arizona. Most human cases result from the bite of an infected flea, although direct contact with infected wild rabbits, rodents, and occasionally other wildlife and exposure to infected domestic cats are also risk factors.

Etiology: *Y. pestis* is a gram-negative, nonmotile, coccobacillus belonging to the Enterobacteriaceae family. It exhibits a bipolar staining, "safety pin" appearance when stained with Wright, Giemsa, or Wayson stains. *Y. pestis* grows slowly even at optimal temperatures (28°C [82.4°F]) and can require ≥48 hr to produce colonies. Several types of media can be used to grow *Y. pestis*, including blood agar, nutrient broth, and unenriched agar. Colonies are small (1–2 mm), gray, nonmucoid, and have a characteristic "hammered copper" appearance. Different virulence factors are expressed by the organism at different temperatures and environments, allowing the organism to survive in flea vectors and then be transmitted to and multiply in mammalian hosts. The organism does not survive for long at high temperatures or in dry environments.

Epidemiology and Transmission: *Y. pestis* is maintained in the environment in a natural cycle between susceptible rodent species and their associated fleas. Commonly affected rodent species include ground squirrels (*Spermophilus* spp) and wood rats (*Neotoma* spp). Cats and dogs are usually exposed to *Y. pestis* by mucous

membrane contact with secretions or tissues of an infected rodent or rabbit or by the bite of an infected flea. People are usually exposed by an infected flea bite but are sometimes exposed due to contact with infected animals or via respiratory droplet transmission from pneumonic cases. Risk factors for cats acquiring plague include hunting and eating rodents and rabbits, visiting an enzootic plague area, finding dead rodents around the yard or areas that the animal frequents, and exposure to infected fleas. Plague epizootics cause nearly 100% mortality in affected wild rodent and rabbit populations. Once their host has died, *Y. pestis*-infected rodent and rabbit fleas will seek other hosts, including cats and dogs, and potentially be transported into homes. Rodent and rabbit flea species are different from dog and cat fleas (*Ctenocephalides* spp), although most veterinarians and pet owners will not be able to visually distinguish flea species. Dog and cat fleas are rare in most plague-enzootic areas of the western USA; therefore, fleas on pets in these areas may be more likely to be fleas from wildlife, including rodents or rabbits.

Pathogenesis: Fleas become infected with *Y. pestis* when feeding on a bacteremic mammal. It has been thought that most flea transmission of plague occurs when the bacteria multiply and block the flea's digestive tract, preventing it from digesting subsequent blood meals; the flea then regurgitates the plague bacteria and inoculates the host on which it is attempting to feed. Recent experiments have shown that some species of unblocked fleas are better transmitters of plague. These fleas became infectious within a day of feeding and remained infectious for ≥4 days, also inoculating the host on which they are feeding with plague bacteria that have been multiplying within the flea's upper GI tract. In mammalian hosts, plague presents clinically in one of three forms: bubonic, septicemic, or pneumonic. After inoculation into the skin by a flea bite or into mucous membranes by contact with infectious secretions or tissues, the bacteria travel via lymphatic vessels to regional lymph nodes. These infected lymph nodes are called buboes, the typical lesion of bubonic plague.

Secondary septicemic plague can develop when the organism spreads from the affected lymph nodes via the bloodstream but can also occur without prior lymphadenopathy (primary septicemic plague) and affect numerous organs, including the spleen, liver, heart, and lungs. Pneumonic plague can develop from inadequately treated septicemic plague (secondary pneumonic plague) or from infectious respiratory droplets (primary pneumonic plague), typically from a coughing pneumonic plague patient (animal or human).

Clinical Findings and Lesions: The clinical presentation of plague in cats is most commonly bubonic plague. The incubation period ranges from 1–4 days. Cats with bubonic plague typically present with fever, anorexia, lethargy, and an enlarged lymph node that may be abscessed and draining. Oral and lingual ulcers, skin abscesses, ocular discharge, diarrhea, vomiting, and cellulitis have also been documented. A retrospective review of 119 naturally infected cats found that 53% of cats had bubonic plague; of those, 75% had submandibular lymphadenopathy, with bilateral enlargement in ~¼ of cases. Affected lymph nodes show necrosuppurative inflammation, edema, and hemorrhages and contain numerous *Y. pestis* organisms. In experimentally infected cats, fever was as high as 106°F (41°C), peaking ~3 days after exposure; mortality was as high as 60% in untreated cats. Ten of 16 (62.5%) cats exposed orally developed enlarged lymph nodes in the medial retropharyngeal, submandibular, sublingual, and tonsillar regions, palpable 4–6 days after exposure. *Y. pestis* was isolated from the throats of 15 of these cats. In 6 subcutaneously exposed cats (mimicking a flea bite), none had palpably enlarged lymph nodes in the head or neck region, but four had subcutaneous abscesses at the inoculation site.

Cats with primary septicemic plague have no obvious lymphadenopathy but present with fever, lethargy, and anorexia. Septic signs may also include diarrhea, vomiting, tachycardia, weak pulse, prolonged capillary refill time, disseminated intravascular coagulopathy, and respiratory distress. Primary pneumonic plague has not been documented in cats. Cats with secondary pneumonic plague may present with all the signs of septicemic plague along with a cough and other abnormal lung sounds. Characteristic necropsy findings can include livers that are pale with light-colored necrotic nodules, enlarged spleens with necrotic nodules, and lungs with diffuse interstitial pneumonia, focal congestion, hemorrhages, and necrotic foci.

Dogs infected with plague are less likely to develop clinical illness than cats, although cases have been seen in enzootic areas. Symptomatic plague infection has been documented in three naturally infected dogs; clinical signs included fever, lethargy, submandibular lymphadenopathy, a purulent intermandibular lesion, oral cavity lesions, and cough.

Cattle, horses, sheep, and pigs are not known to develop symptomatic illness from plague, whereas clinical illness has been documented in goats, camels, mule deer, pronghorn antelope, nonhuman primates, and a llama. Infected mountain lions and bobcats have shown clinical signs and mortality similar to those of domestic cats.

Diagnosis: Plague must be differentiated from other bacterial infections, including tularemia (see p 692), abscesses due to wounds (cat fight bites), and staphylococcal and streptococcal infections. During acute illness, preferred antemortem samples for culture include whole blood, lymph node aspirates, swabs from draining lesions, and oropharyngeal swabs from cats with oral lesions or pneumonia. Diagnostic samples should be taken before antibiotics are administered. *Y. pestis* cultures can take 48 hr for visible growth to develop. An air-dried glass slide smear of a bubo aspirate can be used for a fluorescent antibody test that detects the F1 antigen on *Y. pestis* cells. This test can be performed in a matter of hours in an experienced laboratory and is both sensitive and specific.

Postmortem specimens should include samples of liver, spleen, and lung (for pneumonic cases) and affected lymph nodes. In areas where tularemia is also present, samples should be collected under a biosafety hood, or the entire animal submitted to a veterinary diagnostic laboratory where aerosol precautions can be implemented. Serologic antibody tests can be confirmatory but require acute and convalescent samples taken 2–3 wk apart, demonstrating a 4-fold rise in antibody titer. Single acute sera are often negative if taken early in the course of illness or can be problematic in an enzootic area where animals may retain antibody titers from previous exposures.

Treatment: Because of the rapid progression of this disease, treatment for suspected plague (and infection control practices) should be started before a definitive diagnosis is obtained. Streptomycin

cin has been considered the drug of choice in human cases but is difficult to obtain and rarely used today. Gentamicin is currently used to treat most human plague cases and should be considered a suitable alternative choice in veterinary medicine for seriously ill animals, although it is not approved for this purpose. Animals with renal failure require adjusted dosages.

Doxycycline is appropriate for treatment of less complicated cases and to complete treatment of seriously ill animals after clinical improvement. Tetracycline and chloramphenicol are also options. Penicillins are not effective in treating plague. In treatment studies with experimentally infected mice, the fluoroquinolones performed as well as streptomycin. Fluoroquinolones have not been studied in any veterinary clinical trials, but there is growing evidence from their use in enzootic areas that they are effective in the treatment of plague in dogs and cats. The recommended duration of treatment is 10–21 days, with clinical improvement (including defervescence) expected within a few days of treatment initiation.

The duration of infectivity in treated cats is not definitively known, but cats are thought to be noninfectious after 72 hr of appropriate antibiotic therapy with indications of clinical improvement. During this infectious period, cats should remain hospitalized, especially if there are signs of pneumonia. Human cases have occurred in cat owners trying to give oral medications at home, exposing them to contact with the oral cavity and associated infectious secretions.

Prevention and Zoonotic Risk: Along with treatment and diagnostic considerations, protection of people and other animals and initiation of public health

interventions are critical when an animal is suspected to have plague. Animals with signs suggestive of plague should be placed in isolation, with infection control measures implemented for the protection of staff and other animal patients without waiting for a definitive diagnosis. The use of gloves, surgical masks, eye protection (if splashes or sprays are anticipated), patient isolation (animal or human), and standard hygiene and disinfection procedures for protection from potentially contaminated respiratory droplets, body fluids, and secretions from the patient (animal or human) are essential. Of the 23 human patients who developed cat-associated plague in the USA between 1977 and 1998, 6 were veterinary staff; the rest were cat owners or others handling a sick cat. After pneumonia has been excluded, or once there is evidence of clinical improvement after 72 hr of appropriate therapy, isolation procedures may be relaxed, but standard disinfection and hygiene procedures should continue.

Local or state public health officials should be notified promptly when plague is suspected to help conduct appropriate diagnostic tests, initiate an environmental investigation, and assess the need for fever watch or prophylactic antibiotics in potentially exposed people. To decrease the risk of pets and people being exposed to plague, pet owners in enzootic areas should keep their pets from roaming and hunting, limit their contact with rodent or rabbit carcasses, and use appropriate flea control. Epidemiologic data, fact sheets, public education brochures, and other information on plague is available on the Web sites of the CDC and the New Mexico Department of Health.

RHODOCOCOSIS

Rhodococcosis is a pyogranulomatous disease of domestic animals, wildlife, and people. It is caused by *Rhodococcus equi* (formerly *Corynebacterium equi*), the pathogenicity of which has been mainly attributed to the presence of virulence-associated antigens and plasmids.

Etiology: *Rhodococcus* spp belong to the aerobic actinomycetes in the order Actinomycetales, which is taxonomically related to the genera *Mycobacterium*,

Corynebacterium, and *Nocardia*. *R. equi* is a facultative intracellular opportunistic pathogen. In Gram smears, the bacteria appear as gram-positive rods, cocci, or rod-shaped (pleomorphic) organisms.

The virulence of *R. equi* is intimately associated with its ability to survive and multiply inside macrophages, mainly the presence of a large plasmid that contains genes encoding a number of proteins associated with virulence (*Vap*). Seven genes have been classically associated with *R. equi*

virulence, the most important being the *VapA* plasmid because of its probable regulatory action over other genes. This gene regulation of *R equi* is a complex mechanism, influenced by various factors, including iron and magnesium availability, as well as environmental conditions such as temperature and pH.

Epidemiology: *R equi* has been isolated from a wide variety of species, including horses, cattle, swine, sheep, goats, dogs, cats, camelids, birds, and wild animals.

R equi is distributed worldwide. It is widespread in surface soil, particularly in feces of foals and other herbivores, and in their environment. *R equi* may survive up to 12 mo in soil and can multiply in a wide temperature range (15°–40°C) and neutral pH (6.5–7.3).

Inhalation of soil dust particles is considered the main route of infection for domestic animals. Contaminated water and food is a less frequent route of infection, except for swine. Infected sputum may be swallowed by foals with pneumonia, causing ulcerative colitis and mesenteric lymphadenitis. Foals showing clinical and subclinical disease may spread *R equi* via aerosols.

Risk factors associated with a higher prevalence of disease in horses include large numbers of foals and mares, transient equine population, high foal density, foals born to mares that shed high numbers of the microorganism in the feces, and inadequate transfer of maternal antibodies. Poor animal management, housing, seasonal effect on foals' birth, and environmental conditions (eg, dry, dusty, windy) have also been reported as predisposing conditions.

VapA plasmid is usually found in foal and bovine rhodococcosis cases, indicating a major risk of infection to companion animals by contact with livestock or their environment.

Pathogenesis: The outcome of exposure to *R equi* is strongly influenced by the virulence, infective dose, and age and immune response of the host. Virtually all foals are exposed to *R equi* shortly after birth, although most do not develop clinical signs. Adult horses are commonly resistant to the clinical disease, because they have developed effective immune responses against *R equi*.

R equi may invade the animal via the respiratory or digestive tracts or the skin. It then spreads through hemolymphatic vessels, reaching different tissues and

organs and developing pyogenic reactions in the liver, spleen, kidneys, bones, brain, and lymph nodes.

The basis of pathogenicity is attributed to the ability of the organism to survive and multiply inside macrophages, subsequently destroying these phagocytic cells. Other factors that contribute to the pathogenesis include the iron acquisition mechanism and the presence of phospholipase C and cholesterol oxidase (so called "equi factors"). In nonequine species, immunosuppressive conditions of the host may enable avirulent or less virulent strains to persist inside phagocytes.

Passive humoral immunity generated by ingestion of mare colostrum contributes to the control of *R equi* infection in foals. However, humoral response by itself does not confer complete protection. Consistent evidence supports the essential role of cellular immune response in control of *R equi* infections.

Clinical Findings: Suppurative bronchopneumonia and ulcerative colitis in foals, lymphadenitis in cattle and swine, and cutaneous or organ abscesses are the major clinical manifestations of rhodococcosis in domestic animals. *R equi* infections are frequently found only in foals and swine, whereas they are rare or uncommon in small ruminants, companion animals, birds, and wildlife.

In horses, *R equi* is a commensal intestinal organism; it can actively multiply in the intestines of foals up to ~3 mo old and can also be isolated from the feces of adult horses. Suppurative bronchopneumonia is the primary clinical sign in foals. Foals are affected between 2 wk and 6 mo of age, although foals 1–3 mo old are most commonly affected, possibly because of the decline in maternal antibodies at ~6 wk of age. On endemic farms, it is estimated that 5%–40% of foals may develop clinical signs, and up to 50% of cases may be fatal. Foals >6 mo old appear to be refractory to development of clinical signs. (See also *RHODOCOCOSIS EQUI PNEUMONIA IN FOALS*, p 1451.)

Initially, foals show nonspecific signs, including fever, lack of appetite, and reluctance to move and suckle. Most foals with lung infections show respiratory distress, with tachycardia, tachypnea, and a strong inspiratory effort manifested by abdominal movement and nostril flaring. On auscultation, inspiratory and expiratory wheezes and crackles are possibly audible, predominantly in the cranioventral region. Decreased airway sounds suggest

consolidation, extensive abscess formation, or occasional pleural effusion. Mucous membranes may be pale or cyanotic. Weight loss, cough, and serous to mucopurulent nasal secretion are not consistent signs. Typically, the disease is insidious in foals because of the ability of horses to compensate for respiratory lesions, making early diagnosis difficult.

Abdominal *R equi* infections in foals are clinically manifest by diarrhea, ulcerative colitis, mesenteric lymphadenitis, abdominal abscesses, typhilitis, and peritonitis. Foals rarely develop intestinal signs without pulmonary signs, but intestinal lesions are found in ~30%–50% of foals with pulmonary rhodococcosis. Colic, diarrhea, and weight loss are the major clinical signs of the intestinal form.

Immune-mediated polysynovitis affects ~20%–30% of foals, caused by immune complex deposition in joints. Any joint may be involved, although the tibiotarsal and stifle joints are most commonly affected. Synovial fluid aspiration reveals nonseptic mononuclear pleocytosis, without isolation of *R equi*. Septic arthritis of foals is another joint lesion caused by *R equi*. Different from immune-mediated polysynovitis, the septic lesion is usually combined with lameness signs.

A variety of other *R equi* infections are sporadically seen in horses, including cellulitis, ulceration, subcutaneous abscesses, lymphangitis, lymphadenitis, renal abscesses, pleuritis, hepatitis, and hepatoencephalopathy. Ocular signs, such as hypopyon and immune-mediated uveitis, may be seen. Osteomyelitis causing ataxia, decubitus, and limb paralysis is uncommon. Rarely, *R equi* is associated with abortion, placentitis, and infertility in mares, and it has been occasionally isolated from equine semen.

Clinical manifestations in adult horses are uncommon. The disease probably affects immunocompromised horses, or animals coinfecting with immunosuppressive agents, infected by plasmid strains expressing *VapA*. The predominant clinical signs in adult horses are similar to those in foals, with suppurative bronchopneumonia, pleuritis, enteritis, lymphadenitis, and osteomyelitis.

In **swine**, *R equi* infections are basically restricted to the lymphatic tract. Usually, pyogranulomatous cervical lymphadenitis is seen, although mesenteric, bronchial, and other lymph nodes may be involved. *R equi* has also been isolated from apparently normal lymph nodes. Occasionally, pneumonia may be seen. Gross lesions in

lymph nodes caused by *R equi* observed in slaughterhouses resemble those caused by *Mycobacterium* spp, a major cause of swine lymphadenitis (see p 690).

Rhodococcosis is rare in **dogs and cats**, although it is more commonly reported in cats than in dogs. The most common routes of infection in dogs and cats are traumatic percutaneous introduction of microorganisms, primary contamination of wounds, or secondary to scratches in cat fights. Most cats present with cutaneous lesions on one extremity, along with localized swelling, ulcers, and fistulas with purulent drainage. The lesions are commonly painful, and usually no systemic signs are seen. Regional lymph nodes may be enlarged. Respiratory and visceral involvement represents the systemic or disseminated form of disease. Pyothorax is usually caused by dissemination of the organism from mediastinal lymph nodes. These animals present with fever, anorexia, dyspnea, and weight loss. In visceral infections, there is abdominal distention with palpable fluid, splenomegaly, hepatomegaly, and mesenteric lymphadenomegaly. Underlying conditions, including immunosuppressive viral infections, should be investigated in cats with rhodococcosis.

In **ruminants**, lymphadenitis (mesenteric, submaxillary, and bronchial), pneumonia, pyometra, ulcerative lymphangitis, and occasionally mastitis have been reported in cattle and buffalo. Pneumonia is the most common clinical picture in goats. Sporadic abortion and organ abscesses have been reported in sheep and goats.

Diagnosis: Periodic clinical examinations, WBC counts, serum fibrinogen levels, serologic tests, and diagnostic imaging have been proposed as measures for early diagnosis, mainly because of the insidious and precocious characteristic of foal rhodococcosis. Weekly physical examination, including thoracic auscultation, is an effective clinical practice for early diagnosis. Monthly or more frequent monitoring of increased WBC counts ($>13,000$ cells/ μ L), serum fibrinogen concentration (>400 mg/dL), and thoracic ultrasonography are also valuable procedures for early diagnosis. Efficacy of periodic immunodiffusion testing in predicting individual cases in affected foals is controversial.

Supportive clinical and epidemiologic findings are important in presumptive diagnosis, but diagnosis by isolation, microbiologic culture, and phenotypic characterization of *R equi* is considered the

"gold standard." Tracheobronchial lavage, skin, synovial and peritoneal fluid, organs, and abscesses are the main clinical specimens used. On staining, the presence of gram-positive pleomorphic organisms supports a presumptive diagnosis, although this preliminary identification of the organism should be carefully evaluated, because few bacteria may be present in some clinical samples. Tracheobronchial lavage is the main clinical specimen for isolation of *R equi* in foals. However, the organism may occasionally be isolated from the trachea of foals without signs of pneumonia. Nasal swabs of foals are not indicated as evidence of rhodococcosis because of contamination with local microflora. Likewise, the presence of *R equi* in the nasal region is not predictive of pulmonary infection.

R equi is naturally isolated from feces of most livestock species, especially foals. Despite the fact that foals often swallow sputum containing *R equi*, <20% of foals confirmed with pulmonary rhodococcosis show positive fecal isolation of bacterium.

R equi can be isolated from feces, soil, or other contaminated samples. Potentially contaminated material, including feces, soil, and sand of parks and yards, should be submitted to selective culture media.

Neutrophilic leukocytosis, hyperfibrinogenemia, and hyperglobulinemia are the most consistent hematologic findings in foals with rhodococcosis. Thrombocytosis and monocytosis are variable findings. Serum amyloid A (SAA), an acute-phase protein, has been proposed as an inflammatory marker of rhodococcosis because of increased SAA levels in foals with *R equi* infections. Abdominal and thoracic effusions are usually exudates and reveal increased protein levels and nucleated cell counts.

Thoracic, abdominal, and joint radiography have also been used in diagnosis. Initial pneumonia is characterized by a mild to moderate, diffuse bronchointerstitial pattern, revealing small nodules and possibly cavitory masses, which can be multiple and large in severe cases. Occasionally, mediastinal lymphadenomegaly is seen. Thoracic ultrasonography is valuable to evaluate mainly peripheral lung lesions.

Serologic assays (eg, agar-gel immunodiffusion, ELISA, synergistic hemolysis inhibition) have been proposed for use in diagnosis, particularly of horses. However, titer results have varied greatly, probably because of differences in antigen preparation, interference of maternal antibodies,

and continuous exposure to *R equi* in the environment. In addition, these tests have failed to differentiate between healthy and sick foals and, therefore, are inappropriate for diagnosis of individual cases.

Detection of *R equi*-specific DNA by PCR is also available for rapid and reliable diagnosis. However, because *R equi* can be found in the trachea of foals without pulmonary signs, PCR may be positive in healthy animals. Thus, epidemiologic aspects, clinical signs, hematologic tests, imaging findings, microbiologic culture, and/or molecular assays must all be considered in making a diagnosis.

Lesions: Suppurative abscesses with necrotic areas and regional lymphadenitis are the major gross lesions seen at necropsy. Typically, pulmonary lesions reveal multiple firm nodules, atelectasis, congestion, and cavitory lesions. Multiple miliary lesions may be seen as well. Multifocal enteritis, typhilitis, mesenteric lymphadenitis, and Peyer's patches reaction are seen in cases of intestinal involvement. Abdominal dissemination is characterized by peritonitis and organ abscesses. Septic arthritis, hypopyon, and vertebral osteomyelitis are signs indicative of hematogenous dissemination. Abortion, placentitis, and fetal infection are uncommon.

Histologically, the tissue and organ lesions are characterized as pyogranulomatous lesions containing foci of necrosis. The lesions reveal numerous gram-positive pleomorphic organisms phagocytized by macrophages, multinucleate giant cells, and fewer neutrophils. Moderate infiltrate of plasma cells and lymphocytes are also found.

The primary pathogens that should be differentiated from *R equi* as causal agents of foal respiratory diseases are *Salmonella* spp, *Streptococcus equi*, influenza virus, herpesvirus, and migrating stages of *Parascaris equorum*. Differential diagnosis of *R equi* causing intestinal manifestations should be performed with *Clostridium* spp, *Salmonella* spp, *Escherichia coli*, *Strongyloides westeri*, rotavirus, and coronavirus. Septic arthritis caused by *R equi* should be differentiated, especially from *Salmonella* spp and *Streptococcus equi*. Swine lymphadenitis caused by *Mycobacterium* spp should be differentiated from *R equi* because of similar appearance of lymph nodes at the slaughterhouse.

Treatment: Treatment involves appropriate antimicrobial therapy, surgical drainage, debridement, and supportive care.

R equi is typically refractory to conventional antimicrobial therapy. Successful therapy varies dramatically between animal species, probably because of the intracellular location of the pathogen, development of pyogranulomatous lesions, and antimicrobial resistance patterns of the isolates. Antimicrobial susceptibility profile of animal and human strains usually shows in vitro sensitivity to rifampin, erythromycin, aminoglycosides (lincomycin, gentamicin), and imipenem. However, lipid-soluble drugs are the antimicrobials of choice because of the need for adequate tissue and cellular penetration, particularly into macrophages.

Since 1980, the standard effective chemotherapy protocol for foals is based on administration of rifampin (5 mg/kg, PO, bid, or 10 mg/kg/day, PO) and erythromycin (25 mg/kg, PO, tid, or 37.5 mg/kg, PO, bid). These drugs have a synergic effect, and their combined use decreases resistance rates. Throughout the past decade, the macrolides clarithromycin (7.5 mg/kg, PO, bid) and azithromycin (10 mg/kg/day, PO) have been investigated as treatment alternatives because of their bioavailability, stability, and higher concentration in the cells than erythromycin. The combination of rifampin and clarithromycin has shown better efficacy than rifampin-erythromycin or azithromycin-rifampin.

The duration of treatment is variable, although 4–8 wk is frequently recommended. Therapy may be extended in complicated cases in foals. However, after a longer course of therapy, some foals may develop antibiotic-associated colitis. Recent resistance of *R equi* isolates to rifampin and erythromycin have been described, especially with use of these drugs as monotherapy.

Azithromycin has been used as an alternative to erythromycin in foals with adverse signs after the use of erythromycin, including respiratory distress and diarrhea. However, there is a paucity of information regarding prolonged use (≥4 wk) and adverse effects of this drug.

In companion animals, combined therapy using rifampin (10 mg/kg/day, PO) and clarithromycin (7.5–12.5 mg/kg, PO, bid) for 2–5 wk may be recommended. Combined treatment using lincomycin (20 mg/kg, PO, bid, for 7–10 days) and gentamicin (5–8 mg/kg/day, SC, IM, or IV, for 5 days) has been effective in some cats, although longterm therapy or a second course of antimicrobials may be necessary. Erythromycin (15 mg/kg, PO, bid, for 14 days) may be combined with rifampin or other drugs in treatment of dogs and cats.

Surgical drainage of abscesses and debridement are indicated in some cutaneous lesions. Hydration and adequate nutrition are recommended as supportive care. NSAIDs may be used to control fever and in animals with arthritis.

Despite appropriate antimicrobial therapy and supportive care, domestic animals with respiratory distress, tachycardia, severe thoracic imaging abnormalities, and osteomyelitis have a poor prognosis.

Control and Prevention: Control procedures are recommended to maximize the resistance of foals to infection and to reduce infection pressure in their environment. Adequate transfer of colostral immunoglobulins to foals is essential. Different measures have been proposed to prevent and control animal rhodococcosis, particularly in foals, including decrease in environmental exposure to *R equi*, passive immunization (hyperimmune plasma), active immunization (vaccination), and early diagnosis of disease.

The exposure of domestic animals, particularly foals, to *R equi* in the environment is theoretically the main risk factor for transmission. A high number of mares and foals on farms, and high density, leading to higher levels of *R equi* in manure, appear to be predominant risk factors for equine rhodococcosis. Thus, decreasing the number of mares and foals and reducing foal density have been recommended on farms with endemic rhodococcosis.

Removal of excess manure from livestock paddocks, stalls, and pastures could theoretically decrease growth of *R equi*, and consequently, the risk of infection. However, high concentrations of pathogenic *R equi* are usually found in the feces of foals, because they commonly swallow sputum containing virulent strains and excrete the pathogen in their feces. Infected foals should be isolated and their manure removed immediately to help control the disease.

Direct involvement of dust as the major risk factor for livestock rhodococcosis is controversial. Nevertheless, irrigation of paddocks and stalls, as well as growing grass in foal environments that are excessively dusty, may decrease aerosolization.

The use of hyperimmune plasma as an alternative prophylactic measure for equine passive immunization against *R equi* is based on the protective action of plasma components (immunoglobulin, interferon, complement factors, cytokines, and fibronectin). Hyperimmune plasma

decreases the severity of clinical signs in foals, although it does not seem to have a curative effect or to shorten the course of disease. Protocols for administration are variable, but hyperimmune plasma is most effective when used before exposure to *R. equi*. Most commonly, 1 L of hyperimmune plasma (or 20 mL/kg of foal), IV, is used for foals 1–60 days old. The initial dose for foals is variable, given at 1–10 days of age, and followed by a second dose at 30–50 days of age. However, because foals are challenged early (in the first days of life), the first dose is probably the most effective for protection.

Different vaccines have been developed to induce active immunity in foals. Most foals challenged with virulent *R. equi* strains develop a protective and prolonged immune response. However, insufficient neonatal response or relative immunologic immaturity, interference with maternal antibodies, and the intracellular location of *R. equi* limit the active immunization of foals in field conditions.

Killed vaccines have shown ineffective or controversial results in inducing a cellular immune response against *R. equi*.

Infection with *R. equi* strains without *VapA* and *VapB* genes does not induce protection of foals, indicating that virulent strains are essential for composition of effective vaccines. Studies in experimental

and field conditions using *VapA* vaccines have shown enhanced clearance of *R. equi*. Administration of oral live *VapA* vaccines has induced high concentrations of *VapA*-specific antibodies, despite being considered impractical for vaccination of a large number of animals. Efforts are ongoing to develop vaccines using modern concepts, such as transposons, and recombinant and DNA vaccines containing *VapA* antigen, which induces humoral and especially cellular immune response.

Zoonotic Risk: Traditionally, contact with soil or manure, or inhalation of aerosols contaminated by livestock, represents the major routes of transmission of *R. equi* to people. Alternatively, human infection may occur by transcutaneous trauma, ingestion, or wound contamination. Recent evidence supports that consumption of pork products or undercooked pork may be a probable route of infection to people because of contamination of the meat with lymph node content or feces.

R. equi has emerged as a pulmonary pathogen among immunocompromised people. Therefore, it is recommended that immunocompromised people avoid contact with livestock and their environment, as well as consumption of undercooked pork products.

SWEATING SICKNESS

Sweating sickness is an acute, febrile, tickborne toxicosis characterized mainly by a profuse, moist eczema and hyperemia of the skin and visible mucous membranes. It is essentially a disease of young calves, although adult cattle are also susceptible. Sheep, pigs, goats, and a dog have been infected experimentally. It occurs in eastern, central, and southern Africa and probably in Sri Lanka and southern India.

Etiology: The cause of sweating sickness is an epitheliotropic toxin produced by females of certain strains of *Hyalomma truncatum*. The toxin develops in the tick, not in the vertebrate host. Four tick salivary gland proteins with molecular mass ranging from 27–33 kDa have been proposed to be associated with sweating sickness immunodominance, whereas a 32 kDa band salivary gland protein was found to be unique to a

sweating sickness–positive strain. The potential to produce toxin is retained by ticks for as long as 20 generations, and possibly longer. Attempted experimental transmissions between affected and healthy animals by contact or inoculations of blood have been unsuccessful.

Graded periods of infestation of a susceptible host by “infected” ticks have different effects on the host. A very short period has no effect; the animal remains susceptible. A period just long enough to produce a reaction may confer immunity, but if the exposure is >5 days, severe clinical signs and death may result. Recovery confers a durable immunity, which may last ≥4 yr. Other closely related forms of *H. truncatum* toxicoses have been described.

Clinical Findings: After an incubation period of 4–11 days, signs appear

suddenly and include hyperthermia, anorexia, listlessness, watering of the eyes and nose, hyperemia of the visible mucous membranes, salivation, necrosis of the oral mucosa, and hyperesthesia. Later, the eyelids stick together. The skin feels hot, and a moist dermatitis soon develops, starting from the base of the ears, the axillae, groin, and perineum and extending over the entire body. The hair becomes matted, and beads of moisture may be seen on it. The skin becomes extremely sensitive and emits a sour odor. Later, the hair and epidermis can be readily pulled off, exposing red, raw wounds. The tips of the ears and the tail may slough. Eventually, the skin becomes hard and cracked and predisposed to secondary infection or screw worm infestation. Affected animals are sensitive to handling, show pain when moving, and seek shade.

Often, the course is rapid, and death may occur within a few days. In less acute cases, the course is more protracted and recovery may occur. Mortality in affected calves is 30%–70% under natural conditions. Morbidity in endemic areas is ~10%. The severity of infection is influenced by the number of ticks as well as by the length of time they remain on the host.

Lesions: Emaciation, dehydration, diphtheroid stomatitis, pharyngitis, laryngitis, esophagitis, vaginitis or posthitis, edema and hyperemia of the lungs, atrophy

of the spleen, and congestion of the liver, kidneys, and meninges are found, in addition to the skin lesions. Experimentally infected adult cattle showed typical lesions of moist eczema, and mucous membrane changes were accompanied by a marked decrease in circulating leukocytes with severe neutropenia.

Diagnosis: For diagnosis, it is essential to determine the presence of the vector. Typically, there is a generalized hyperemia with subsequent desquamation of the superficial layers of the mucous membranes of the upper respiratory, GI, and external genital tracts, and profuse moist dermatitis followed by superficial desquamation of the skin.

Prevention and Treatment: Control of tick infestation is the only effective preventive measure. Adult ticks show a predilection to attach in the tail switch. Removal of ticks, symptomatic treatment, and good nursing care are indicated. Non-nephrotoxic antibiotics and anti-inflammatory agents are useful to combat secondary infection. Immune serum can be an effective specific treatment, although associated with problems of donor availability, possible serum contamination, and IV administration of a relatively large volume. A refined precipitated immunoglobulin suspension proved ineffective as a specific treatment, probably because of low concentrations of effective immunoglobulins.

TOXOPLASMOSIS

Toxoplasma gondii is a protozoan parasite that infects people and other warm-blooded animals, including birds and marine mammals (see p 1865). It has been found worldwide from Alaska to Australia.

Etiology and Pathogenesis: Felids are the only definitive hosts of *T. gondii*; both wild and domestic cats therefore serve as the main reservoir of infection. There are three infectious stages of *T. gondii*: tachyzoites (rapidly multiplying form), bradyzoites (tissue cyst form), and sporozoites (in oocysts).

T. gondii is transmitted by consumption of infectious oocysts in cat feces, consumption of tissue cysts in infected meat, and by

transplacental transfer of tachyzoites from mother to fetus. *T. gondii* initiates enteroepithelial replication in unexposed cats after ingestion of uncooked meat containing tissue cysts. Bradyzoites are released from tissue cysts by digestion in the stomach and small intestine, invade intestinal epithelium, and undergo sexual replication, culminating in the release of oocysts (10 µm diameter) in the feces. Oocysts are first seen in the feces at 3 days after infection and may be released for as long as 20 days. Oocysts sporulate (become infectious) outside the cat within 1–5 days, depending on aeration and temperature, and remain viable in the environment for several months. Cats generally develop

immunity to *T. gondii* after the initial infection and therefore shed oocysts only once in their lifetime.

After being consumed in uncooked meat containing tissue cysts (carnivores) or in feed or drink contaminated with cat feces containing oocysts (all warm-blooded animals), *T. gondii* initiates extraintestinal replication. Bradyzoites and sporozoites, respectively, are released and infect intestinal epithelium. After several rounds of epithelial replication, tachyzoites emerge and disseminate via the bloodstream and lymph. Tachyzoites infect tissues throughout the body and replicate intracellularly until the cells burst, causing tissue necrosis. Tachyzoites measure $4\text{--}6 \times 2\text{--}4\text{ }\mu\text{m}$ in diameter. Young and immunocompromised animals may succumb to generalized toxoplasmosis at this stage. Older animals mount a powerful, cell-mediated immune response to the tachyzoites (mediated by cytokines) and control infection, driving the tachyzoites into the tissue cyst or bradyzoite stage. Tissue cysts are usually seen in neurons but also seen in other tissues. Individual cysts are microscopic, up to $70\text{ }\mu\text{m}$ in diameter, and may enclose hundreds of bradyzoites in a thin, resilient cyst wall. Tissue cysts in the host remain viable for many years, and possibly for the life of the host.

Clinical Findings: The tachyzoite is the stage responsible for tissue damage; therefore, clinical signs depend on the number of tachyzoites released, the ability of the host immune system to limit tachyzoite spread, and the organs damaged by the tachyzoites. Because adult immunocompetent animals control tachyzoite spread efficiently, toxoplasmosis is usually a subclinical illness. However, in young animals, particularly puppies, kittens, and piglets, tachyzoites spread systemically and cause interstitial pneumonia, myocarditis, hepatic necrosis, meningoencephalomyelitis, chorioretinitis, lymphadenopathy, and myositis. The corresponding clinical signs include fever, diarrhea, cough, dyspnea, icterus, seizures, and death. *T. gondii* is also an important cause of abortion and stillbirth in sheep and goats and sometimes in pigs. After infection of a pregnant ewe, tachyzoites spread via the bloodstream to placental cotyledons, causing necrosis. Tachyzoites may also spread to the fetus, causing necrosis in multiple organs. Finally, immunocompromised adult animals (eg, cats infected with feline immunodeficiency virus) are extremely susceptible to developing acute generalized toxoplasmosis.

Diagnosis: Diagnosis is made by biologic, serologic, or histologic methods, or by some combination of these. Clinical signs of toxoplasmosis are nonspecific and are not sufficiently characteristic for a definite diagnosis. Antemortem diagnosis may be accomplished by indirect hemagglutination assay, indirect fluorescent antibody assay, latex agglutination test, or ELISA. IgM antibodies appear sooner after infection than IgG antibodies but generally do not persist past 3 mo after infection. Increased IgM titers ($>1:256$) are consistent with recent infection. In contrast, IgG antibodies appear by the fourth week after infection and may remain increased for years during subclinical infection. To be useful, IgG titers must be measured in paired sera from the acute and convalescent stages (3–4 wk apart) and must show at least a 4-fold increase in titer. Additionally, CSF and aqueous humor may be analyzed for the presence of tachyzoites or anti-*T. gondii* antibodies. Postmortem, tachyzoites may be seen in tissue impression smears. Additionally, microscopic examination of tissue sections may reveal the presence of tachyzoites or bradyzoites. *T. gondii* is morphologically similar to other protozoan parasites and must be differentiated from *Sarcocystis* species and *Neospora caninum*.

Treatment: For animals other than people, treatment is seldom warranted. Sulfadiazine (15–25 mg/kg) and pyrimethamine (0.44 mg/kg) act synergistically and are widely used for treatment of toxoplasmosis. Although these drugs are beneficial if given in the acute stage of the disease when there is active multiplication of the parasite, they will not usually eradicate infection. These drugs are believed to have little effect on the bradyzoite stage. Certain other drugs, including diaminodiphenylsulfone, atovaquone, and spiramycin are also used to treat toxoplasmosis in difficult cases. Clindamycin is the treatment of choice for dogs and cats, at 10–40 mg/kg and 25–50 mg/kg, respectively, for 14–21 days.

Prevention and Zoonotic Risk: *T. gondii* is an important zoonotic agent. In some areas of the world, as much as 60% of the human population has serum IgG titers to *T. gondii* and are likely to be persistently infected. Toxoplasmosis is a major concern for people with immune system dysfunction. In these individuals, toxoplasmosis usually presents as meningoencephalitis and results from the emergence of *T. gondii* from tissue cysts located in the brain as

immunity wanes rather than from primary *T. gondii* infection. Toxoplasmosis is also a concern for pregnant women because tachyzoites can migrate transplacentally and cause birth defects in human fetuses. Infection with *T. gondii* may occur after ingestion of undercooked meat or accidental ingestion of oocysts from cat feces. To prevent infection, the hands of people handling meat should be washed thoroughly with soap and water after contact, as should all cutting boards, sink tops, knives, and other materials. The stages of *T. gondii* in meat are killed by contact with soap and water. *T. gondii* organisms in meat can also be killed by exposure to extreme cold or heat. Tissue cysts in meat are killed by heating the meat throughout

to 67°C (152.6°F) or by cooling to -13°C (8.6°F). *Toxoplasma* in tissue cysts are also killed by exposure to 0.5 kilorads of gamma irradiation. Meat of any animal should be cooked to 67°C (152.6°F) before consumption, and tasting meat while cooking or while seasoning should be avoided. Pregnant women should avoid contact with cat litter, soil, and raw meat. Pet cats should be fed only dry, canned, or cooked food. The cat litter box should be emptied daily, preferably not by a pregnant woman. Gloves should be worn while gardening. Vegetables should be washed thoroughly before eating, because they may have been contaminated with cat feces.

There is currently no vaccine to prevent toxoplasmosis in people.

TUBERCULOSIS AND OTHER MYCOBACTERIAL INFECTIONS

Tuberculosis (TB) is considered a reemerging, infectious granulomatous disease in animals and people caused by acid-fast bacilli of the genus *Mycobacterium*. Although commonly defined as a chronic, debilitating disease, TB occasionally assumes an acute, rapidly progressive course. The disease affects practically all species of vertebrates. The widespread occurrence of multidrug-resistant (MDR) strains and extensively drug-resistant (XDR) strains of *M. tuberculosis* is of concern to clinicians and public health and regulatory officials involved in the control of disease. Bovine TB is still a significant zoonosis in nonindustrialized countries of the world. Signs and lesions are generally similar in the various species.

Etiology: The main types of *M. tuberculosis* complex (mammalian tubercle bacilli) recognized are *M. tuberculosis*, *M. canettii*, *M. bovis*, *M. caprae*, *M. pinnipedii*, *M. microti*, *M. mungi*, and *M. africanum*. The *M. avium* complex includes *M. avium* (avian tubercle bacilli), *M. avium hominissuis* (isolated from people, swine, and other mammals), and *M. intracellulare*. The types differ in cultural characteristics and pathogenicity. Several serovars of *M. avium* are recognized; however, only serovars 1, 2, and 3 are pathogenic for birds. *M. bovis* may survive on pasture for

≥2 mo, and *M. avium* may survive in soil for ≥4 yr.

All types may produce infection in host species other than their own. *M. tuberculosis* is most specific; it rarely produces progressive disease in animals other than people and nonhuman primates, infrequently in dogs and pigs, and has very rarely been isolated from skin lesions in exotic birds. *M. bovis* can cause progressive disease in most warm-blooded vertebrates, including people. *M. caprae*, an organism closely related to *M. bovis*, has been isolated from people, goats, cattle, and several other species in Europe. *M. avium* is the species of most importance in birds, but it has a wide host range and is also pathogenic for pigs, cattle, sheep, deer, mink, dogs, cats, certain exotic hoofed animals, and some cold-blooded animals. *M. avium hominissuis* is the cause of tuberculosis in people, swine, and other animals. *M. genavense* and other pathogenic mycobacteria are infrequently isolated from exotic and free-living wild and domestic birds (see p 692). *M. intracellulare* causes disease in cold-blooded animals and has been isolated from many other species.

Pathogenesis: Inhalation of infected droplets expelled from the lungs is the usual route of TB infection, although ingestion, particularly via contaminated milk or water,

also occurs. Intrauterine and coital methods of infection are recognized less commonly. Inhaled bacilli are phagocytosed by alveolar macrophages that may either clear the infection or allow the mycobacteria to proliferate. In the latter instance, a primary focus may form, mediated by cytokines associated with a hypersensitivity reaction that consists of dead and degenerate macrophages surrounded by epithelioid cells, granulocytes, lymphocytes, and later, multinucleated giant cells. The purulent to caseous, necrotic center may calcify, and the lesion may become surrounded by granulation tissue and a fibrous capsule to form the classic "tubercle." The primary focus plus similar lesions formed in the regional lymph node is known as the "primary complex." In alimentary forms of disease, the primary focus may be found in the pharynx or mesenteric lymph nodes or, less commonly, in the tonsils or intestines. The cellular composition of and presence of acid-fast bacilli in tuberculous lesions differ between and within host species.

The primary complex seldom heals in animals and may progress slowly or rapidly. Dissemination through vascular and lymphatic channels may be generalized and rapidly fatal, as in acute miliary TB. Nodular lesions may form in many organs, including the pleura, peritoneum, liver, kidney, spleen, skeleton, mammary glands, reproductive tract, and CNS. A prolonged, chronic course may also ensue, with lesions usually having a more localized pattern of distribution.

Clinical Findings: The clinical signs of TB reflect the extent and location of lesions. Generalized signs include progressive emaciation, lethargy, weakness, anorexia, and a low-grade, fluctuating fever. The bronchopneumonia of the respiratory form of the disease causes a chronic, intermittent, moist cough with later signs of dyspnea and tachypnea. The destructive lesions of the granulomatous bronchopneumonia may be detected on auscultation and percussion. Superficial lymph node enlargement may be a useful diagnostic sign when present. Affected deeper lymph nodes cannot always be palpated, but they may cause obstruction of the airways, pharynx, and gut, leading to dyspnea and ruminal tympany.

In pigs, lesions caused by *M avium hominissuis* or *M avium avium* are most often seen in lymph nodes associated with the GI tract, although generalized disease involving the liver, lung, and spleen does occur.

Diagnosis: The single most important diagnostic test for TB is the intradermal tuberculin test. Old tuberculin prepared from the culture filtrate of *M tuberculosis* is used to detect disease in nonhuman primates exposed to *M tuberculosis* or *M bovis*. In other animals, purified protein derivatives (PPDs) prepared from the culture filtrate of *M bovis* or *M avium* can be used. Diagnosis based on clinical signs alone is very difficult, even in advanced cases. Radiography is useful in nonhuman primates and small animals. Microscopic examination of sputum and other discharges is sometimes used. Necropsy findings of the classic "tuberculous" granulomas are often very suggestive of the disease. Confirmation of diagnosis is by isolation and identification of the organism, with culture usually taking 4–8 wk, or by PCR, which requires only a few days. Molecular techniques, such as restriction fragment length polymorphism (RFLP) or variable number tandem repeat (VNTR) provide definitive information useful in conducting epidemiologic investigations.

The delayed-type hypersensitivity response of the host, responsible for much of the pathology of TB, is fundamental to the tuberculin skin test widely used for diagnosis in large animals. The single intradermal (SID) test involves inoculation of PPD prepared by precipitation of protein from the culture filtrate of *M bovis*. PPD preparations improve specificity. In a reactor, the antigen stimulates a local infiltrate of inflammatory cells and causes skin swelling that can be detected by palpation and measured by calipers. The reaction is read at 48–72 hr for maximum sensitivity and at 96 hr for maximum specificity. Test sites used vary in sensitivity and between countries/areas and include the neck region, caudal fold at the tail base, and vulval lip. One disadvantage of the *M bovis* SID test is that cross-reactions may occur in animals infected with *M kansasii*, *M avium*, *M tuberculosis*, *M avium paratuberculosis*, or other mycobacteria that share some antigenic determinants with *M bovis*.

In areas with a high incidence of avian TB or other mycobacterial infections such as paratuberculosis, the comparative tuberculin skin test can be used, with biologically balanced *M bovis* and *M avium* PPD tuberculins inoculated simultaneously but at separate sites in the neck. The agent causing sensitization provokes the greater skin reaction. Other diagnostic tests used for TB include the thermal test, which may

detect a pyrexia peak (104°F [$>40^{\circ}\text{C}$]) at 6–8 hr after SC inoculation with tuberculin. The Stormont test uses an intradermal inoculation of PPD followed by a second inoculum at the same site 7 days later. The test is read for swelling 24 hr later.

False-negative results may occur in animals with poor immune response such as those in the early stages of infection, nonresponsive cases in advanced disease, or old animals. Cattle that have recently calved may also have false-negative results. Current research is focused on the identification of antigens such as secretory proteins and genetically engineered proteins of *M. bovis* for use in improved in vitro diagnostic tests. Serologic tests such as ELISA appear to be of limited diagnostic use, consistent with the lesser role of antibody compared with the cellular immune response in TB. In vitro cellular assays have been developed (ie, interferon- γ assay) using WBCs stimulated with *M. bovis* antigen and may be used as a supplemental test to the widely used SID test; however, they have not come into widespread use in many nonindustrialized countries because of cost and the necessity to conduct cellular assays in the laboratory within 24 hr after collection of blood specimens.

Control: The main reservoir of *M. bovis* infection is cattle. However, other animals have been found to be reservoirs in some countries, including badgers and red deer (England, Ireland); red deer, possums, and ferrets (New Zealand); mule deer, white-tailed deer, elk, and American bison (North America); African buffalo (South Africa); and water buffalo (Australia). The prevalence of disease in such reservoirs influences the incidence of disease in other species. Carnivores and scavengers can acquire *M. bovis* by consumption of infected carcasses. These species include lion, coyote, wolf, hyena, cheetah, black bear, bobcat, and leopard. Warthogs, ferrets, raccoon, European wild boar, opossums, and feral pigs have also been found to be infected with *M. bovis*.

The three principal approaches to the control of TB are test and slaughter, test and segregation, and chemotherapy. The test and slaughter policy is the only one assured of eradicating TB and relies on the slaughter of reactors to the tuberculin test. In an affected herd, testing every 2 mo is recommended to rid the herd of individuals that can disseminate infection. Routine hygienic measures aimed at cleaning and disinfecting contaminated food, water troughs, etc, are also useful. Test and

slaughter has been used widely in the UK, USA, Canada, Germany, New Zealand, and Australia. In some European countries, where test and slaughter would have been impractical, varying forms of test and segregation have been used, with test and slaughter used only in the final stages of eradication.

The BCG (bacille Calmette-Guérin) vaccine, sometimes used to control TB in people, has proved to provide little protection against virulent *M. bovis* in most animal species, and inoculation often provokes a severe local granulomatous reaction. Moreover, BCG-vaccinated animals usually respond on the tuberculin skin test.

CATTLE

Most of the general discussion above applies to bovine TB. The introduction of milk pasteurization was a major step in the fight against *Mycobacterium bovis* TB and continues to be an important control procedure in many nonindustrialized countries.

SHEEP AND GOATS

Lesions caused by *Mycobacterium bovis* in the lungs and lymph nodes of sheep and goats are similar to those seen in cattle, and the organism may sometimes disseminate to other organs. Sheep and goats are quite resistant to *M. tuberculosis* infection. The intradermal skin test is commonly used for diagnosis. The comparative tuberculin skin test conducted in the cervical region using biologically balanced purified protein derivative tuberculin of *M. bovis* and *M. avium* can be used to differentiate sensitization to other mycobacteria. The responses should be observed at 48 and 72 hr for induration and swelling.

DEER AND ELK

Tuberculosis due to *Mycobacterium bovis* is an important problem in most species of farmed and wild cervids, including axis deer, fallow deer, roe deer, mule deer, sika deer, as well as red deer/elk/wapiti. Deer appear to be unusually susceptible to *M. bovis* infections. *M. avium* infections may produce similar lesions. *M. tuberculosis* infection is uncommon. Tuberculous lesions may be confined to isolated lymph nodes of the head, or they may be found extensively in lymph nodes and organs after a rapid, fulminating disease course. Abscessation in deer should always raise suspicions of tuberculosis. A presumptive

diagnosis may be made using the tuberculin skin test and/or by in vitro cellular assays (blood lymphocyte immune-stimulation test or γ interferon assay), or a combination of these tests. Infection should be confirmed by an organism-based test.

HORSES

Horses are relatively resistant to tuberculosis caused by *Mycobacterium tuberculosis*; however, they are susceptible to *M bovis*. When tuberculosis does develop, tuberculous, noncalcified lesions are often found in the liver, mesenteric lymph nodes, lungs, and other sites. Tuberculin test results are rather erratic.

ELEPHANTS

Tuberculosis due to *Mycobacterium tuberculosis* has been reported in captive elephants. Lesions most often involve the lung and associated lymph nodes. Nonspecific responses are observed on tuberculin skin tests and on some in vitro immunologic tests; therefore, diagnosis should be made on an organism-based test of trunk washes. Multidrug regimens, including isoniazid and rifampin, have been developed that eliminate shedding of *M tuberculosis* in discharges and minimize development of drug-resistant strains. It is important to emphasize that drug sensitivity tests should be conducted to determine the susceptibility of the organism. Also, blood concentrations should be monitored periodically to confirm they are high enough to kill the bacteria.

PIGS

Pigs are susceptible to *M tuberculosis*, *M bovis*, and *M avium* complex. *M avium avium* and *M avium hominissuis* are most frequently isolated; serologic identification of isolates is useful in epidemiologic investigations. Granulomatous lesions are most often found in the cervical, submandibular, and mesenteric lymph nodes, but in advanced disease lesions may also be found in the liver and spleen. Typically, enlarged nodes contain small, white or yellow, caseous foci, usually without any evidence of mineralization. Pigs with disease due to *M tuberculosis* may have similar regionalized lesions. Pigs are particularly susceptible to *M bovis*, which is usually acquired from shared grazing or ingestion of contaminated dairy products. This can cause a rapidly progressive, disseminated disease with caseation and liquefaction of lesions. The single intradermal test conducted on the dorsal surface of

the ear or in skin of the vulva is often useful for diagnosis. Test responses should be observed at 48 hr after injection of tuberculin.

DOGS

Dogs may be infected with *Mycobacterium tuberculosis*, *M bovis*, and occasionally with *M avium* complex or *M fortuitum*, commonly from a human or bovine source. Tuberculous lesions are usually found in the lungs, liver, kidney, pleura, and peritoneum; they have a gray appearance, usually with a noncalcified, necrotic center. Lesions are often exudative and can produce a large quantity of straw-colored fluid in the thorax. False-negative tuberculin tests are often seen in dogs. Radiographs and a thorough history are useful in diagnosis. Treatment is not often recommended. Affected dogs in close contact with people should be euthanized because of public health concerns.

CATS

Cats are quite resistant to infection with *Mycobacterium tuberculosis* but are susceptible to *M bovis*, *M avium* complex, or *M microti*. *M lepraemurium* has been isolated from granulomatous lesions in the skin. Some unclassified acid-fast bacilli have also been isolated. Contaminated milk causing GI tract lesions, typically in the mesenteric lymph nodes, is the most common circumstance, and historically this was responsible for a very high percentage of tuberculous cats in Europe. Rapid, hematogenous dissemination to other organs, including the lungs and regional lymph nodes, can occur. Infected skin or deeper wounds sometimes give rise to tuberculous sinuses. Lesions have a central area of necrosis, usually without calcification. The tuberculin skin test is considered unreliable in cats. Diagnosis may be assisted by radiography and ELISA. Identification of the organism is necessary to confirm a diagnosis. Efficacious treatment protocols are not available. Therefore, it is recommended that cats infected with *M bovis* be euthanized because of public health concerns.

RABBITS

Naturally occurring, or so-called spontaneous tuberculosis in rabbits is an uncommon finding; most cases are caused by *Mycobacterium bovis* or *M avium*. Rabbits apparently become infected when exposed to other tuberculous animals or by ingesting milk from tuberculous cattle. *M avium* has been reported in rabbits that are housed in

close contact with domestic or exotic birds infected with *M avium*. Rabbits are relatively resistant to *M tuberculosis*; such infections are seldom reported. Rabbits infected with *M avium* complex may develop milary lesions involving the lung and liver. Tuberculin skin tests may be conducted on the skin of the abdomen. Test sites should be observed for induration and swelling at 24 and 48 hr after injection of *M bovis* purified protein derivative.

GUINEA PIGS

Guinea pigs are quite susceptible to infection with either *Mycobacterium tuberculosis* or *M bovis*. Lesions are most often seen in the parenchyma of the lung and adjacent lymph nodes. Also, guinea pigs are susceptible to certain serovars of *M avium* complex with lesions seen in lymph nodes associated with the GI tract. Tuberculin skin tests can be conducted by injection of purified protein derivative of *M bovis* and of *M avium* (1:100 dilution containing 5,000 tuberculin units) at separate sites in the skin of the abdomen. The preferred injection site is 2 cm posterior to the xyphoid cartilage and 2 cm lateral on each side of the linea alba. The injection sites should be observed at 24 and 48 hr for induration and swelling. The presence of erythema at the injection site is of little or no significance.

NONHUMAN PRIMATES

In monkeys and large apes, *Mycobacterium tuberculosis*, *M bovis*, and *M avium* complex can cause severe disease of the lungs and other organs. Epidemics in primate colonies may be caused by contact with infected human caregivers. Transmission is usually by aerosol with respiratory infection, but the oral route is also possible. Bacilli may also be shed in urine. Old tuberculin is used in skin tests in preference to purified protein derivative (PPD), because it provides greater sensitivity in detecting animals infected with *M tuberculosis* or *M bovis*. Biologically balanced PPDs prepared from *M bovis* or *M avium* can be injected intradermally at separate sites on the abdomen to conduct a comparative test. Skin tests are observed at 24, 48, and 72 hr for induration and swelling. Tuberculins prepared for use in people are not of sufficient potency to elicit a response in nonhuman primates. Treatment of cases of tuberculosis in nonhuman primates has been attempted using drugs that have had success in people, eg, isoniazid, ethambutol, and rifampin. Drug sensitivity tests should be conducted to determine sensitivity of

isolates. Efficacy is limited, and there are overriding arguments against therapy, based on the removal of infected animals, zoonotic risks, and the danger of developing drug resistance. Exacerbations may occur.

FREE-RANGING AND CAPTIVE HOOFED ANIMALS

The major wildlife reservoirs of *Mycobacterium bovis* infection in addition to cervids are African buffalo, wood bison, North American bison, white-tailed and mule deer, lechwe, and elk. Also, brushtail possums and European badgers are considered reservoirs of *M bovis* infection. Other species in which *M bovis* infection has been reported but not implicated as reservoirs and are considered spillover hosts include fennec fox, coyote, Arabian oryx, muntjac, impala, sitatunga, springbok, moles, voles, hares, eland, yak, bactrian camel, wildebeest, European wild goat, large spotted genet, tapir, moose, otters, feral water buffalo, hedgehogs, European wild boar, greater kudu, tiger, white and black rhinoceros, and giraffe. *M tuberculosis* has been isolated from oryx, black rhinoceros, Asian elephant, addax, and Rocky Mountain goats. Tuberculous lesions vary in consistency from purulent to caseous and often involve the lungs and regional lymph nodes, with liver, spleen, and serosal surfaces as other potential sites. Tuberculin skin tests are conducted in the cervical region using *M bovis* purified protein derivative (PPD) containing 5,000 tuberculin units prepared for veterinary use. Nonspecific responses may occur in some species with no history of tuberculosis. Therefore, it may be necessary to use biologically balanced PPDs prepared from *M avium* and *M bovis* injected at separate injection sites. Skin tests are observed for swelling and induration at 48 and 72 hr.

MARINE MAMMALS

Mycobacterium pinnipedii (a seal-adapted variant of *M bovis*) causes tuberculous lesions in fur seals and sea lions. The organism has been isolated from four species of fur seals and two species of sea lions in several countries as well as from some other animals. In seals, the organism causes lesions in the peripheral lymph nodes, spleen, peritoneum, and lungs. The presence of acid-fast organisms in the granulomatous lesions varies. Aerosols are considered the main route of transmission. Because of the zoonotic risk, precautions should be taken when handling these animals. (See also MYCOBACTERIOSIS IN MARINE MAMMALS, p 1863.)

MYCOBACTERIAL INFECTIONS OTHER THAN TUBERCULOSIS

Mycobacteria found in soil and water have been isolated from tissues of animals.

Mycobacterium fortuitum, a rapidly growing organism highly resistant to penicillin G, streptomycin, ampicillin, sulfamethoxazole, and chloramphenicol, has been associated with mastitis in cows, pulmonary infections in dogs, lymph node lesions in pigs and certain exotic animals, and cutaneous lesions in cats and dogs. Drug susceptibility tests indicate the organism is inhibited by capreomycin and by ethionamide. *M chelonae*, another rapidly growing *Mycobacterium* similar to *M fortuitum* in biochemical reactions, has been isolated from contaminated wounds and injection abscesses. These organisms must be distinguished from *M phlei*, *M smegmatis*, and *M vaccae*, which are rarely if ever pathogenic.

Fish and other cold-blooded animals may be infected with *M marinum*, certain serovars of *M avium* complex, or *M intracellulare*, which have been recognized as human pathogens. A photochromogenic organism, *M kansasii*, has been isolated from pigs, cattle, and nonhuman primates. These organisms can be differentiated by biochemical and seroagglutination tests.

M avium paratuberculosis, the cause of Johne's disease, has been isolated from domestic and wild ruminants (see also PARATUBERCULOSIS, p 762). It is a slowly progressive diarrheal disease resulting in weight loss and emaciation. Lesions are most often seen in the ileocecal valve and associated lymph nodes. Diagnosis should be based on an organism-based test. No treatment is available.

M scrofulaceum, a scotochromogen, has been isolated from lymph node lesions in

pigs, cattle, and certain nonhuman primates. *M xenopi*, a slowly growing scotochromogen, has been isolated from pigs, seafowl, and amphibians. These organisms should be differentiated from *M gordonae* and *M flavescens* and from other slowly growing scotochromogenic mycobacteria that are common contaminants of water.

Numerous nonpathogenic, nonphotochromogenic mycobacteria that closely resemble potential pathogens can be isolated from water and soil; *M nonchromogenicum*, *M gastri*, *M triviale*, and *M terrae*, which closely resemble strains of the *M avium* complex, may be differentiated by in vitro laboratory examinations, including molecular techniques.

Although opportunistic mycobacteria usually do not produce progressive disease, they may be important in inducing transient tuberculin skin sensitivity in animals. The application of comparative skin tests, using biologically balanced purified protein derivative tuberculins prepared from culture filtrates of *M bovis* and *M avium*, provides useful information on the possible cause of tuberculin skin sensitivity. Tuberculins prepared for veterinary use, containing ~5,000 tuberculin units per test dose, should be used for skin tests in free-ranging, captive, wild, and exotic animals.

M lepraemurium, a nonphotochromogenic, slow-growing, acid-fast bacillus, causes a disease in cats and rats similar in some respects to leprosy in people. It can be grown on media containing cytochrome C and α -ketoglutarate. *M leprae*, the cause of leprosy in people, has been found in spontaneously occurring disease in armadillos. This organism has not been grown on artificial culture medium; however, *M leprae* DNA can be identified by molecular techniques.

TULAREMIA

Tularemia is a bacterial septicemia that affects >250 species of wild and domestic mammals, birds, reptiles, fish, and people. It is listed as a category A bioterrorism agent because of the potential for fatality, airborne dissemination, and societal disruption if released.

Etiology: The causative bacterium, *Francisella tularensis*, is a nonspore-form-

ing, gram-negative coccobacillus antigenically related to *Brucella* spp. It is a facultative intracellular parasite that is killed by heat and proper disinfection but survives for weeks or months in a moist environment. It can be cultured readily on blood supplemented with cysteine but must be differentiated from other gram-negative bacteria on blood agar. The taxonomic status of *Francisella* has been revised and

debated, but recent consensus establishes the subspecies *F. tularensis tularensis*, associated with type A tularemia; *F. tularensis holarctica*, which causes type B tularemia; and a third type, C, associated with *F. novicida*, which has low virulence and is less common than the other two. Type A has been found predominantly in North America and is more virulent; in people, the mortality rate may be as high as 30% if untreated. Type B is less virulent and occurs in both the Old and New Worlds.

Epidemiology and Transmission:

Among domestic animals, sheep are the most common host, but clinical infection has also been reported in cats, dogs, pigs, and horses. Cats are at increased risk because of predatory behavior and appear to have an increased susceptibility, whereas cattle appear to be resistant. Little is known of the true incidence and spectrum of clinical disease in domesticated animals. Important wild animal hosts for *F. tularensis tularensis* include cottontail and jackrabbits, whereas the most common vectors are the ticks *Dermacentor andersoni* (the wood tick), *Amblyomma americanum* (the lone star tick), *D. variabilis* (the American dog tick), and *Chrysops discalis* (the deer fly). Animal hosts of *F. tularensis holarctica* are lagomorphs, beaver, muskrat, voles, and sheep. Ticks, flies, fleas, and exposure to contaminated water sources are all associated with transmission of this subspecies, which has also been found to persist naturally in a water-associated amoeba.

Natural foci of infection exist in North America and Eurasia. Although found in every state except Hawaii, tularemia is most often reported in the southcentral and western USA (eg, California, Missouri, Oklahoma, South Dakota, and Montana).

Tularemia can be transmitted by aerosol, direct contact, ingestion, or arthropods. Inhalation of aerosolized organisms (in the laboratory or as an airborne agent in an act of bioterrorism) can produce a pneumonic form. Direct contact with, or ingestion of, infected carcasses of wild animals (eg, cottontail rabbit) can produce the ulceroglandular, oculoglandular, oropharyngeal (local lesion with regional lymphadenitis), or typhoidal form. Immersion in or ingestion of contaminated water can result in infection in aquatic animals. Ticks can maintain infection transstadially and transovarially, making them efficient reservoirs and vectors.

The most common source of infection for people and herbivores is the bite of an

infected tick, but people who prepare or eat improperly cooked wild game are also at increased risk. Dogs, cats, and other carnivores may acquire infection from ingestion of an infected carcass. Case reports have implicated cats as a source of infection in people.

Clinical Findings: The incubation period is 1–10 days. The most severely and commonly affected livestock species are sheep; Type A tularemia is particularly pathogenic for lagomorphs, and cats and nonhuman primates have been reported to be infected. The clinical presentation depends on host species, subspecies of the bacteria, and route of infection. Sheep and cats may be subclinically infected or develop bacteremia, fever, and respiratory infection. Cats may also develop ulceroglandular or oropharyngeal disease, presumably through exposure to infected prey items. Clinical signs include increased pulse and respiratory rates, coughing, diarrhea, and pollakiuria with lymphadenopathy and hepatosplenomegaly. Prostration and death may occur in a few hours or days. Sporadic cases are best recognized by signs of septicemia. Outbreaks in untreated lambs may have up to 15% mortality.

Lesions: The most consistent lesions are milium, white to off-white foci of necrosis in the liver and sometimes in the spleen, lung, and lymph nodes. Organisms can be readily isolated from necropsy specimens by use of special media. The infective dose required to transmit this pathogen is extremely low; thus, risk of infection during necropsy or to laboratory personnel is significant, and special procedures and facilities are essential.

Diagnosis: Tularemia must be differentiated from other septicemic diseases (especially plague and pseudotuberculosis) or acute pneumonia. When large numbers of sheep show typical signs during periods of heavy tick infestation, tularemia or tick paralysis (see p 1314) should be suspected. Tularemia should be considered in cats with signs of acute lymphadenopathy, malaise, oral ulcers, and history of recent ingestion of wild prey.

Diagnosis of acute infection is confirmed by culture and identification of the bacterium, direct or indirect fluorescent antibody test, or a 4-fold increase in antibody titer between acute and convalescent serum specimens. A single titer of $\geq 1:80$ by the tube agglutination test is presumptive evidence of prior infection. When tularemia is suspected, laboratory personnel should

be alerted as a precaution to reduce the risk of laboratory-acquired infection. In some jurisdictions, tularemia in animals is reportable to public health authorities.

Treatment and Control: Streptomycin, gentamicin, and tetracyclines are effective at recommended dose levels. Gentamicin should be continued for 10 days. Because

tetracycline and chloramphenicol are bacteriostatic, they should be continued for 14 days to minimize the risk of relapse. Early treatment is important to minimize risk of fatality. Because of the substantial sylvatic (wildlife and tick) component of the *Francisella* life cycle, control is limited to reducing arthropod infestation and to rapid diagnosis and treatment.

VESICULAR STOMATITIS

Vesicular stomatitis is a viral disease caused by two distinct serotypes of vesicular stomatitis virus—New Jersey and Indiana. Vesiculation, ulceration, and erosion of the oral and nasal mucosa and epithelial surface of the tongue, coronary bands, and teats are typically seen in clinical cases, along with crusting lesions of the muzzle, ventral abdomen, and sheath. Clinical disease has been seen in cattle, horses, and pigs and very rarely in sheep, goats, and llamas. Serologic evidence of exposure has been found in many species, including cervids, nonhuman primates, rodents, birds, dogs, antelope, and bats.

Etiology: The viruses are members of the family Rhabdoviridae and genus *Vesiculovirus*. Vesicular stomatitis viruses are the prototypes of the *Vesiculovirus* genus. They are bullet shaped and generally 180 nm long and 75 nm wide. The genomic structure is a single strand of negative-sense RNA composed of five genes (N, P, M, G, and L, representing the nucleocapsid protein, phosphoprotein, matrix protein, glycoprotein, and the large protein, which is a component of the viral RNA polymerase). Although there are many members of the *Vesiculovirus* genus, the New Jersey and Indiana serotypes are of particular interest in the Western hemisphere. These two viruses are similar in size and morphology but generate distinct neutralizing antibodies in infected animals. They have both been isolated in recent outbreaks in the USA.

Epidemiology and Transmission:

Vesicular stomatitis is seen sporadically in the USA. Outbreaks historically occurred in all regions of the country but since the 1980s have been limited to western states and occur seasonally, usually May through October. Outbreaks occurred in the USA in 1995, 1997, 1998, 2004, 2005, 2006, 2009, 2010,

and 2012. The largest outbreak in the past decade occurred in 2005 and affected nine states. Vesicular stomatitis viruses are endemic in South America, Central America, and parts of Mexico but have not been seen naturally outside the Western hemisphere. The virus can be transmitted through direct contact with infected animals with clinical disease (those with lesions) or by blood-feeding insects. In the southwestern USA, black flies (Simuliidae) are the most likely biologic insect vector. In endemic areas, sand flies (*Lutzomyia*) are proven biologic vectors. Other insects may act as mechanical vectors. Exposure to insects that carry the virus is often associated with nearby moving water sources such as creeks or rivers or irrigation of pastures. Experimental studies have shown that feeding of infected insects on mucosal surfaces and nonhaired areas of the body were more often associated with development of lesions at those sites than if insects fed on haired areas of the body. The prevalence of clinical cases in a herd is generally low (10%–20%), but seroprevalence within the herd may approach 100%. Viremia has not been detected in livestock species that exhibit clinical signs of vesicular stomatitis, although experimental studies have shown transmission of virus, presumably via lymphatics, between co-feeding black flies on cattle. Virus is routinely isolated from active lesions in affected animals, and these lesions serve as a source of virus spread by direct contact and contamination of shared feed and water stations. Many vertebrate species have serologic evidence of exposure and may serve as reservoirs of infection. No definitive reservoir or amplifying host of vesicular stomatitis viruses in the USA has been identified.

Clinical Findings: The incubation period is 2–8 days and is typically followed by a fever. By the time animals develop other

signs and are examined, however, they are rarely febrile. Ptyalism is often the first sign of disease. Vesicles in the oral cavity are rarely seen in naturally occurring cases because of rupture soon after formation; therefore, ulcers are the most common lesion seen during initial examination. Ulcers and erosions of the oral mucosa, sloughing of the epithelium of the tongue, and lesions at the mucocutaneous junctions of the lips are commonly seen in both cattle and horses. Ulcers and erosions on the teats are not uncommon in cattle and may result in secondary cases of mastitis in dairy cows. Coronitis with erosions at the coronary band are seen in some cattle, horses, and pigs, with subsequent development of lameness. Crusting lesions of the muzzle, ventral abdomen, sheath, and udder of horses are typical during outbreaks in the western USA. Loss of appetite due to oral lesions, and lameness due to foot lesions, are normally of short duration, because the disease is generally self-limiting and resolves completely within 10–14 days. Virus-neutralizing antibodies to either serotype persist and have been documented in individual horses that had previous clinical disease for >8 yr after an outbreak, but reinfection can occur after a second exposure.

Diagnosis: In most areas, including the USA, vesicular stomatitis is a reportable disease. Samples for diagnostic purposes are generally taken by a foreign animal disease diagnostician or other regulatory veterinarians and are tested by officially designated government laboratories. Diagnosis is based on the presence of typical signs and either antibody detection through serologic tests, viral detection through isolation, or detection of viral genetic material by molecular techniques. Samples for viral isolation may include vesicular fluid, epithelial tags from lesions, or swabs of lesions. Vesicular stomatitis viruses are easily propagated in cell culture. Three commonly used serologic tests are competitive ELISA, virus neutralization, and complement fixation. PCR tests may also be used to identify the virus. Of primary concern in diagnosis is differentiation of vesicular stomatitis from clinically indistinguishable but much more devastating viral diseases, including foot-and-mouth disease in ruminants and swine (see p 629), swine vesicular disease (see p 735), and vesicular exanthema of swine (see p 738). Horses are not susceptible to foot-and-mouth disease. Both noninfectious and infectious causes of oral lesions must be considered.

Treatment, Control, and Prevention:

No specific treatment is available or warranted. Cachexia can be avoided by providing softened feeds. Cleansing lesions with mild antiseptics may help avoid secondary bacterial infections. Management factors suggested to reduce risk of exposure to the virus include limiting time on pasture during insect season, providing shelters or barns during insect feeding times, and implementing other procedures that reduce animal contact with insects, such as application of insecticides. This should include application to the inner surface of the pinna, where black flies feed. If livestock need to be kept on pasture during outbreaks of vesicular stomatitis, then keeping them pastured away from moving surface water (such as streams, irrigation canals, or rivers) may reduce the risk of exposure to *Vesiculovirus*. Affected animals should be isolated, and movement of other animals from the affected premises restricted. Vesicular stomatitis is a reportable disease in most areas, including the USA, so state and federal animal health officials must be notified when it is suspected. Commercially produced vaccines are not available in the USA, but vaccines for livestock are available in some Latin American countries.

Veterinarians act as a part of the surveillance network as they examine animals involved in shows, exhibitions, races, and interstate or international movement in order to write a health certificate (ie, certificate of veterinary inspection). When practitioners observe suspect cases of vesicular stomatitis, they should report to both their state and federal animal health officials. Reporting will prompt a regulatory investigation. Mucosal swab and serum samples from suspected animals are submitted for testing to veterinary diagnostic laboratories. During outbreak years, data regarding laboratory-confirmed cases of vesicular stomatitis, along with the number of premises with cases, are posted on the Web site of the Animal and Plant Health Inspection Service of the USDA.

Zoonotic Risk: The vesicular stomatitis viruses are zoonotic and may cause self-limiting influenza-like disease (headache, fever, myalgia, and weakness) lasting 3–5 days in people working in close contact with the virus (eg, laboratory exposure, direct contact with lesions in infected animals). Rarely, people can develop vesicles on the buccal and pharyngeal mucosa, lips, and nose. More severe signs, including encephalitis, are rare.

AFRICAN HORSE SICKNESS

African horse sickness (AHS) is an insect-borne, viral disease of equids that is endemic to sub-Saharan Africa. It can be acute, subacute, or subclinical and is characterized by clinical signs and lesions associated with respiratory and circulatory impairment.

Etiology and Epidemiology: AHS is caused by African horse sickness virus (AHSV), which is 55–70 nm in diameter and of the genus *Orbivirus* in the family Reoviridae. There are nine immunologically distinct serotypes of AHSV. The virus is inactivated at a pH of <6 (but is stable at higher pH), or by formalin, β -propiolactone, acetylthyleneimine derivatives, or radiation.

In endemic regions of Africa, the appearance of AHS may be preceded by seasons of heavy rain that alternate with hot and dry climatic conditions, which favor transmission by the insect (biting midge) vector. Outbreaks in central and east Africa have occasionally extended to Egypt, the Middle East, and southern Arabia. In 1959–1961, a major epidemic, caused by AHSV serotype 9, extended from Africa through the Near East and Arabia as far as Pakistan and India, causing the deaths of an estimated 300,000 equids. A further epidemic of the same serotype in 1965–1966 centered on northwest Africa (Morocco, Algeria, and Tunisia) but also extended briefly into southern Spain. This outbreak in Spain was eliminated by a vigorous vaccination and slaughter campaign. In July 1987, AHS caused by AHSV serotype 4 was reported in central Spain, due to the importation of infected zebra from Namibia. The outbreak lasted until the cold weather started in October 1987; however, the virus survived the winter and caused disease in southern Spain, Portugal, and Morocco in subsequent years before its elimination in 1991. AHS outbreaks continue to occur in endemic regions of southern and eastern Africa, and in 2007, AHS serotype 2 was reported in West Africa (Nigeria and Senegal), and serotype 7 in Senegal. Outbreaks of AHS caused by any one of several serotypes have recently been reported in Ethiopia.

Transmission: *Culicoides* spp are the principal vectors of all nine serotypes of AHSV, with *C. imicola* usually considered to be the most important. Consequently, AHS is seen during warm, rainy seasons, which favor propagation of the vectors, and

disappears when cold weather stops or significantly reduces vector activity. The virus also has been isolated from the dog tick *Rhipicephalus sanguineus sanguineus*, and the camel tick *Hyalomma dromedarii* during the winter in southern Egypt, where the disease is endemic. AHSV has apparently been transmitted between dogs by infected mosquitoes. Furthermore, dogs, and possibly large African carnivores such as lions and leopards, can be infected by ingestion of meat from AHSV-infected equids. However, it is generally considered that dogs and other large carnivores, ticks, and mosquitoes play little part in the epidemiology of AHS.

Clinical Findings and Lesions: Mortality depends on the virulence of the particular AHSV strain and susceptibility of the host. In naive populations of horses, which are the most susceptible equids, mortality may reach 90% in epidemics. The acute respiratory form is characterized by an incubation period of 3–5 days, interlobular edema, and hydropericardium. Death occurs in ~1 wk. A fever of 40°–40.5°C (104°–105°F) for 1–2 days is followed by dyspnea, spasmodic coughing, and dilated nostrils. The animal stands with its legs apart and head extended. The conjunctivae are congested, and the supraorbital fossae may be edematous. Recovery is rare, and the animal dies of anoxia, congestive heart failure, or both. At necropsy, pulmonary edema is especially visible in the intralobular spaces. The lungs are distended and heavy, and frothy fluid may be found in the trachea, bronchi, and bronchioles. There may be pleural effusion. Thoracic lymph nodes may be edematous, and the gastric fundus may be congested. Petechiae are found in the pericardium, and there is an increase in pericardial fluid; however, cardiac lesions usually are not outstanding. The abdominal viscera may be congested. A frothy exudate may ooze from the nostrils. The pulmonary form is the predominant form in dogs, which are usually infected by ingesting virus-contaminated meat.

The cardiac form of AHS is subacute with an incubation period of 1–2 wk. A fever of <1 wk is followed by edema of the supraorbital fossae. Swelling may extend to the eyelids, facial tissues, neck, thorax, brisket, and shoulders. Death usually occurs within 1 wk and may be preceded by colic. The mortality rate is ~50%. Petechiae

and ecchymoses on the epicardium and endocardium are prominent. The lungs are usually flaccid or slightly edematous. There are yellow, gelatinous infiltrations of the subcutaneous and intramuscular tissues, especially along the jugular veins and ligamentum nuchae. Other lesions include hydropericardium, myocarditis, hemorrhagic gastritis, and petechiae on the ventral surface of the tongue and peritoneum.¹

A mixed pulmonary and cardiac form is most commonly seen in outbreaks, with a mortality rate in horses of ~80%.

Subclinical AHSV infection occurs in partially immune equids, such as those previously vaccinated against the disease, or in equids naturally infected with live-attenuated vaccine strains of AHSV. Subclinical infections are also characteristic in zebras and certain other equids.

Diagnosis: In endemic areas, clinical signs and lesions may lead to a presumptive diagnosis. However, laboratory confirmation is essential for definitive diagnosis and determination of the serotype; the latter is important for control measures. Anticoagulated blood should be obtained at the peak of fever and transported (at 4°C) to the laboratory. Spleen samples collected from freshly dead animals should be kept on ice. Presence of virus is best detected by group-specific reverse-transcriptase polymerase chain reaction (RT-PCR). AHSV also can be isolated by intracerebral inoculation of suckling mice or in mammalian or insect cell cultures. Although not widely available, indirect sandwich ELISA is also useful for rapid identification of AHSV antigen in tissues from animals that have died from acute infection.

Serotyping of AHSV previously relied on virus neutralization tests using type-specific antisera, which take ≥5 days. The recent development of type-specific RT-PCR can now confirm the serotype of an AHSV within 24 hr.

Prevention and Control: There is no specific treatment for animals with AHS apart from rest and good husbandry. Complicating and secondary infections should be treated appropriately during recovery. AHSV is typically noncontagious and spread exclusively via the bites of infected *Culicoides* spp or by the direct inoculation of infectious material (via blood-feeding insects, needles, etc). Various methods of control may be attempted, such as introducing animal movement restrictions to prevent infected animals initiating new foci of infection, and husbandry modification to deny or reduce vector access to susceptible or infected animals (eg, stabling in vector-proof housing). It is rarely possible to completely eliminate populations of vector *Culicoides*, especially in extensive pasture systems.

Live-attenuated virus vaccines are available for immunization of equids against AHS. These are typically based on cell culture-attenuated viruses and generally provide good, but not absolute, protection. Annual revaccination is recommended in regions where these vaccines are used. However, there are increasing concerns regarding use of live-attenuated AHSV vaccines because of their potential reversion to virulence, capacity for transmission by vector *Culicoides* midges, and reassortment of their gene segments with other vaccine and field strains of virus, leading to the creation of novel virus progeny. Inactivated and subunit vaccines avoid these potential drawbacks and, assuming they are commercially available, would likely be used after incursion of AHSV into previously unaffected regions.

Transport of equids from countries where AHSV occurs to virus-free areas is subject to strict regimens of testing and quarantine, although the precise requirements may vary from country to country. The presence of antibodies alone should not preclude such movements as long as AHSV is not present.

EQUINE GRANULOCYTIC EHRLICHIOSIS

Equine granulocytic ehrlichiosis is an infectious, noncontagious, seasonal disease, originally seen in the USA in northern California but now recognized in many states where the tick vector occurs; it is also seen in Europe, Africa, and South America. (See also POTOMAC HORSE FEVER, p 283.)

Etiology, Epidemiology, and Transmission: The causal rickettsial agent was initially termed *Ehrlichia equi*, but based on DNA sequence relationships, the organism is now referred to as *Anaplasma phagocytophilum*. It is not similar or clinically related to anaplasmo-

sis in cattle. The organism has a wide host range; naturally occurring infections have been seen in horses, burros, dogs, llamas, and rodents. A rickettsia infection in people, the human granulocytic anaplasmosis (HGA) agent, caused by a similar strain as the equine infection, has been identified in cases of human illness in the upper midwestern and northeastern states in the USA and many other countries worldwide.

A phagocytophilum frequently infects horses wherever the tick vector (*Ixodes* sp) is present. States in which clinical infection has been confirmed include Connecticut, Illinois, Arkansas, Washington, Pennsylvania, Colorado, Minnesota, New York, Massachusetts, and Florida. It has also been confirmed in British Columbia, Sweden, Great Britain, and South America.

A phagocytophilum resembles the etiologic agents of tickborne fever (see p 772), bovine petechial fever (see p 745), and the HGA agent based on morphology, cell tropism, and 16S rRNA gene sequence data. It is present in cytoplasmic vacuoles of neutrophils and occasionally eosinophils during the acute phase. Blood smears stained with Giemsa or Wright-Leishman stains reveal one or more loose aggregates (morulae or inclusion bodies, 1.5–5 µm in diameter) of blue-gray to dark blue coccoid, coccobacillary, or pleomorphic organisms within the cytoplasm of neutrophils.

The infection can be transmitted experimentally to susceptible horses by whole blood from infected horses or from people with HGA. The incubation period is 1–3 wk. *I pacificus* (the western black-legged tick) and *I scapularis* can transmit *A phagocytophilum* to horses.

The zoonotic risk of infection to people via horses has not been observed to occur. Although horses and people appear to be infected with strains of the same agent, it is believed that human exposure occurs through tick bites, and not by direct transmission from horses to people.

Clinical Findings: Severity of signs varies with age of the horse and duration of the illness. Signs may be mild. Horses <1 yr old may have a fever only; horses 1–3 yr old develop fever, depression, mild limb edema, and ataxia. Adults exhibit the characteristic signs of fever, partial anorexia, depression, reluctance to move, limb edema, petechiation, and icterus. The

fever, which is highest during the first 1–3 days of infection at 103°–104°F (39.5°–40°C), persists at 102°–104°F (39°–40°C) for 6–12 days. Signs become more severe over several days. Rarely, myocardial vasculitis may cause transient ventricular arrhythmias. Other clinical presentations for acute infection have included recumbency and severe myopathy. Any concurrent infection (eg, a leg wound or respiratory infection) can be exacerbated. Cytoplasmic inclusion bodies are few during the first 48 hr and increase to 30%–40% of circulating neutrophils at days 3–5 of infection. The disease is seasonal in California, occurring in the late fall, winter, and spring.

Lesions: Gross petechiation, ecchymoses, and edema develop in the subcutis and fascia. Vasculitis is regional, with the subcutis and fascia of the legs predominantly affected.

Diagnosis: Demonstration of the characteristic cytoplasmic inclusion bodies in a standard blood smear is diagnostic. However, inclusion bodies are difficult to see in the first day or two of fever. PCR can detect *A phagocytophilum* DNA in unclotted blood or buffy coat smears. An indirect fluorescent antibody test can detect rising antibody titers to *A phagocytophilum*. Differential diagnoses include viral encephalitis, primary liver disease, equine infectious anemia, purpura hemorrhagica, and viral arteritis.

Treatment and Control: Oxytetracycline is extremely effective against *A phagocytophilum*, and systemic treatment with tetracycline, 7 mg/kg/day, IV, for 8 days, has eliminated the infection. Penicillin, chloramphenicol, and streptomycin have no inhibitory effect. Horses treated early in infection for shorter durations may relapse within the following few weeks. Horses with severe ataxia and edema may benefit from short-term corticosteroid treatment (dexamethasone, 20 mg/day, for 2–3 days). The risk of laminitis appears to be very low; no laminitis has occurred in clinical cases or experimental infections. Recovered horses are solidly immune for ≥2 yr and are not believed to be carriers. Persistence of infection has been suggested with some European strains, but further verification is required. Tick control measures are mandatory for control of disease. There is no vaccine.

EQUINE INFECTIOUS ANEMIA

Equine infectious anemia (EIA) is a noncontagious, infectious disease of horses and other Equidae. It is caused by an RNA virus classified in the *Lentivirus* genus, family Retroviridae. EIA can present as an acute, subacute, or chronic infection. On occasion, the virus can be a cause of significant morbidity and mortality. The most frequently encountered form of the disease is the inapparent, chronically infected carrier.

Transmission and Pathogenesis:

Under natural conditions, the most important mode of transmission of EIA is by the transfer of virus-infective blood by blood-feeding insects between horses in close proximity. Virus is found free in the plasma or cell associated, principally in monocytes and macrophages of infected animals. Although infection is considered primarily blood borne, all tissues and body fluids are potentially infectious, especially during episodes of clinical disease when viral burdens are high. Transmission of EIA by biting flies is purely mechanical; the virus does not replicate in the vector. The chance of transmission of EIA is directly proportional to the volume of blood retained on the mouthparts of the insect after feeding. In that respect, horse flies, deer flies, and to a lesser extent, stable flies are likely the most efficient vectors. It is also because they are capable of triggering host defensive behavior that interrupts feeding and results in their seeking a new susceptible host to complete their blood meal.

Additionally, EIA can be readily transmitted iatrogenically through use of blood-contaminated syringes, needles, or surgical equipment, or by transfusion of infective blood or blood products. Infrequently, transplacental transmission can occur in infected mares that experience one or more clinical episodes during pregnancy. There is evidence, although circumstantial, from a significant outbreak of EIA in an equine hospital in Ireland, of probable spread of the virus by direct or indirect transfer between horses in stalls sharing the same barn.

A very close relationship exists between presence and severity of clinical signs of EIA and the amount of virus present in infected animals. Viral burdens are highest during febrile episodes of the disease. Many

of the clinical signs associated with the acute form of EIA result from infection of macrophages and the release of pro-inflammatory mediators or cytokines, specifically tumor necrosis factor α , IL-1, IL-6, and transforming growth factor β . This response together with suppression of platelet production are believed to be the factors responsible for the thrombocytopenia that is a characteristic feature of EIA. In addition, immune responses play a major role in the pathogenesis of EIA. Platelets from infected horses have significant amounts of bound IgG or IgM, which leads to their immune-mediated destruction, contributing to both splenomegaly and hepatomegaly.

Clinical Findings: The clinical findings and course of EIA are variable, depending on the virulence of the virus strain, viral dose, and susceptibility of the horse. After an incubation period of 15–45 days or longer in naturally acquired cases of infection, classic cases of the disease progress through three clinical phases. An initial or acute episode lasting 1–3 days is characterized by fever, depression, and thrombocytopenia. Because these signs can be mild and transitory, they are often overlooked. Typically, this initial phase is followed by a prolonged period associated with recurring episodes of fever, thrombocytopenia, anemia, petechiation on mucous membranes, dependent edema, muscle weakness, and loss of condition. The interval between episodes can range from days to weeks or months. In most cases, the episodes of clinical disease subside within a year, and infected horses become inapparent carriers and reservoirs of EIA virus. Many of these horses remain clinically normal.

Although the foregoing represents the most commonly described clinical course of the disease, some outbreaks of EIA can be associated with peracute infection in which the primary viral infection is uncontrolled; this can result in a very high fever, severely reduced platelet counts, and acute depression, leading to death. In view of the wide variation in response seen in natural cases of infection, it is not possible to confirm a diagnosis of EIA based solely on clinical grounds.

Lesions: Gross lesions frequently seen in acute cases of EIA include enlargement of the spleen, liver, and abdominal lymph nodes; dependent edema; and mucosal hemorrhages. Chronic cases of infection are characterized by emaciation, pale mucous membranes, petechial hemorrhages, enlargement of the spleen and abdominal lymph nodes, and dependent edema. Histopathologically, there is a nonsuppurative hepatitis and, in some cases, a glomerulonephritis, periventricular leukoencephalitis, meningitis, or encephalitis. Proliferation of reticuloendothelial cells is evident in many organs, especially in the liver, where there is also accumulation of hemosiderin in Kupffer cells. Perivascular accumulation of lymphocytes can be found in various organs.

Diagnosis: A provisional clinical diagnosis of EIA must be confirmed by demonstration of antibodies to the virus in blood. Although the internationally accepted serologic test is the agar gel immunodiffusion or Coggins test, there is increasing acceptance of a variety of ELISA tests, either competitive or synthetic antigen-based, because they can provide rapid results. Because ELISA tests can give a higher rate of false positives, all ELISA positive results must be confirmed by the Coggins test. When used in combination, ELISA and agar gel immunodiffusion tests provide the highest level of sensitivity combined with specificity. The Western blot is a supplemental test that can be resorted to in cases of conflicting results with other diagnostic tests. A problem with available serologic tests is that they can give negative results when testing sera collected within the first 10–14 days of infection. Whereas the vast majority of horses infected with EIA virus will have seroconverted by 45 days, there have been exceptional cases in which the interval has been ≥ 90 days. Virus detection assays such as the reverse transcription PCR assay are not routinely used to diagnose EIA. Notwithstanding their sensitivity, they may not detect virus in carrier horses with very low viral loads. Although the animal inoculation test is highly sensitive for detection of EIA virus, for logistical and economic reasons, it is no longer in vogue as a means of diagnosis of EIA.

Treatment and Control: No specific treatment or safe and effective vaccine is available. Because equids infected with EIA virus present the only known source of infection, antibody-positive animals should be kept at a safe distance (~ 200 m) from

other equids. The only recognized exception to this rule is the progeny of seropositive mares, which may possess maternal antibodies to the virus after ingesting colostrum. In most cases, passive antibody against EIA virus wanes and is no longer detectable in the Coggins test by 6–8 mo of age; detectable antibody may persist up to 12 mo, however, if ELISA testing is used.

The risk associated with maintaining infected breeding stock varies. Field studies have indicated excellent success in raising test-negative foals from inapparent carriers of EIA virus. The risks of infection in utero increase dramatically if clinical signs of EIA are seen in the mare before parturition. Unfortunately, it is not possible to accurately determine the risk posed by any equid infected by EIA virus. Inapparent carrier horses maintain low-level viremias that may increase under stressful circumstances. As compared with seronegative healthy horses, inapparent carriers have increased serum globulin concentrations and lymphocyte subset changes that are consistent with immune activation or chronic inflammation. Because EIA virus persists in infected equids for life, most regulatory agencies assume all equids seropositive for EIA virus pose the same high risk.

In the USA, seropositive horses must be placed under quarantine within 24 hr after the positive test results are known. The quarantine area must provide separation of at least 200 yd from all other equids. After a confirmatory test is performed, seropositive horses must be permanently identified using the National Uniform Tag code number assigned by the USDA to the state in which the reactor was tested, followed by the letter "A." This identification may take the form of a hot brand, chemical brand, freeze-mark, or lip tattoo, and it must be applied by a USDA representative. Reactor horses must be removed from the herd by euthanasia, slaughter, or quarantine at the premises of origin. They may move interstate only under official permit to a federally inspected slaughter facility or a federally approved diagnostic or research facility, or to return to the premises of origin. After a reactor is detected in a herd, testing for EIA must be performed on all horses on the premises and repeated until all remaining equids on the premises test negative. These horses must be retested at 30- to 60-day intervals until no new cases are found. Quarantine on the premises is released when tests on the entire herd have been negative for at least 60 days after the reactor equids have been removed.

All equids shipped across state lines in the USA must be tested for EIA with a negative result within 12 mo before transport. All equids sold, traded, or donated within a state must have tested negative for EIA no more than 12 mo before change in ownership and, preferably, no more than 60–90 days. All equids entering horse auctions or sales markets are required to have a negative test before sale, or the horse must be held in quarantine within the state until the test results are known.

It is recommended that horse owners implement an EIA control plan for their premises. All horses should be tested every

12 mo as part of a routine health program. More frequent testing may be indicated in areas that perennially have a high incidence of EIA. Owners of equids entering shows or competitive events should present proof to event officials of a negative EIA test. All new equids introduced to a herd should have a negative EIA test before entry or be isolated while tests are pending. Vector control practices, including application of insecticides and repellents and environmental insect control, should be implemented. Good hygiene and disinfection principles should be maintained to prevent iatrogenic infection of horses with contaminated needles, syringes, or equipment.

EQUINE VIRAL ARTERITIS

(Epizootic cellulitis-pinkeye, Equine typhoid, Rotlaufseuche)

Equine viral arteritis (EVA) is an acute, contagious, viral disease of equids caused by equine arteritis virus (EAV). Typical cases are characterized by fever, depression, anorexia, leukopenia, dependent edema (especially of the lower hind extremities, scrotum, and prepuce in the stallion), conjunctivitis, supra- or peri-orbital edema, nasal discharge, respiratory distress, skin rash, temporary subfertility in affected stallions, abortion, and infrequently, illness and death in young foals. A variable percentage of postpubertal colts and stallions become carriers and semen shedders after infection with EAV.

Etiology and Pathogenesis: EAV is a small, enveloped single-stranded positive-sense RNA virus and the prototype virus of the genus *Arterivirus*, family *Arteriviridae*, order *Nidovirales*. It has 10 open reading frames (ORFs), of which ORFs 2a, 2b, 3, 4, 5, 5a, 6, and 7 encode the viral structural proteins. EAV is one of the three most important equine viral respiratory pathogens. The virus is not especially resistant outside the body, and survival $\geq 37^{\circ}\text{C}$ can be short-lived. In contrast, EAV can maintain infectivity in tissues or bodily fluids for extended periods at storage temperatures equal to or below freezing. It can remain viable in frozen semen for many years.

Although only one major serotype of EAV has so far been identified, the prototype Bucyrus strain, genomic and antigenic variation exists among temporally and

geographically different isolates. Pathogenicity also varies among viral strains, with some capable of causing moderate to severe signs of disease whereas others only induce a fever.

After respiratory exposure, EAV invades the upper and lower respiratory tract and multiplies in nasopharyngeal epithelium and tonsillar tissue and in bronchial and alveolar macrophages. Infected cells of the monocytic lineage and CD3^{+} T lymphocytes transport the virus to the regional lymph nodes, where it undergoes a further cycle of replication before being released into the bloodstream. The cell-associated viremia that follows ensures dissemination of EAV throughout the body. By day 6–8, the virus localizes in the vascular endothelium and medial myocytes of the smaller blood vessels, especially the arterioles, and causes a panvasculitis. It can also be found in the epithelium of certain tissues, particularly the adrenals, seminiferous tubules, thyroid, and liver. Vascular lesions include endothelial swelling and degeneration, neutrophilic infiltration, and necrosis of the tunica media of affected vessels. These lesions give rise to edema and hemorrhage, which are believed to result from activation of the proinflammatory cytokines IL-1 β , IL-6, IL-8, and possibly $\text{TNF-}\alpha$. Maximal vascular injury occurs by about day 10, after which lesions begin to resolve.

Based on experimental infection of pregnant mares with the experimentally derived highly virulent Bucyrus strain of

EAV, abortion is believed to result from a myometritis that gives rise to impairment of the placental circulation and death of the fetus. However, this is unlikely to represent the pathogenesis of abortion in naturally acquired cases of EAV infection, which has yet to be determined.

Except in certain infected stallions that become carriers of the virus, EAV is no longer detectable in tissues and body fluids beyond day 28 after primary infection. However, stallions that remain persistently infected harbor the virus principally in certain accessory sex glands, especially the ampulla of the vas deferens, where it can remain for many years. Some carrier stallions may shed EAV from their reproductive tracts for an extended period.

Epidemiology and Transmission:

While the natural and experimental host range of EAV is restricted principally to equids, there are very limited data to suggest the virus may also infect alpacas and llamas. There is no evidence that EAV is transmissible to people. Based on serologic surveys and reported outbreaks of equine viral arteritis, EAV is present in equine populations in many countries worldwide, with the notable exceptions of Japan and Iceland. The prevalence of infection varies widely both between countries and among breeds in the same country. It is frequently highest in Standardbreds and Warmbloods. Despite the widespread global distribution of EAV, laboratory-confirmed outbreaks of EVA are relatively uncommon. However, this situation appears to be changing in more recent years, with an increase in the number of verified occurrences of the disease being reported. A major factor contributing to this change is the continued growth in the volume of international trade in horses and equine semen.

The epidemiology of EVA involves virus, host, and environment-related factors, including variability in pathogenicity among naturally occurring strains of the virus, modes of transmission, occurrence of the carrier state in stallions, and the nature of acquired immunity to infection. Outbreaks of EVA are most often linked to the movement of infected animals or the shipment of virus-contaminated semen. Frequently, viral transmission occurs with minimal if any detectable clinical signs in acutely infected equids.

Transmission of EAV can occur by respiratory, venereal, and congenital routes or by indirect means. Spread by the respiratory route is the principal mode of dissemination of the virus during the acute

phase of infection. It is primarily responsible for transmission of EAV among naive equids kept in close contact (eg, at racetracks, shows, sales, veterinary hospitals, and under conditions of intensive management on breeding farms). EAV can also be transmitted venereally by the acutely infected mare and by the acutely or chronically infected stallion. Mares can be readily infected by the venereal route after breeding to a carrier stallion either by live cover or artificial insemination with fresh-cooled or cryopreserved semen. There is evidence that EAV can be spread through embryo transfer. Infection can also be spread through indirect contact with virus-contaminated fomites (eg, breeding shed equipment, shanks, or twitches) or on the hands or apparel of animal handlers.

The carrier state has been confirmed in sexually mature intact males, specifically postpubertal colts and stallions, but not in mares, geldings, sexually immature colts, or fillies. Establishment and persistence of EAV in the reproductive tract of stallions is testosterone-dependent. The carrier stallion is the natural reservoir of EAV and is responsible for its dissemination and persistence in equine populations. Frequency of the carrier state can vary from <10% to >70%. There is evidence that stallions with CD3⁺ T lymphocytes that are susceptible to EAV infection are at higher risk of becoming carriers than stallions with the CD3⁺ T lymphocyte-resistant phenotype. Persistently infected stallions shed EAV constantly in the sperm-rich fraction of the semen but not in any other secretions or excretions. Duration of the carrier state can range from weeks to many years. Persistent EAV infection clears spontaneously in a variable percentage of stallions, with no evidence of subsequent reversion to a shedding state. Existence of the carrier state does not appear to impair the fertility of infected stallions nor otherwise adversely affect their clinical condition. Carrier stallions also serve as the principal means by which genetic diversification of EAV can occur, with potential emergence of novel viral variants.

Compared with other equine respiratory viruses, EAV stimulates a stronger, longer-lasting immunity that is protective against development of clinical disease, including abortion and establishment of the carrier state in stallions. High levels of neutralizing antibodies that frequently persist for at least 2–3 yr can be stimulated by natural exposure to the virus and by vaccination.

Clinical Findings: Exposure to EAV may result in clinical or asymptomatic infection, depending on the relative pathogenicity of the virus strain involved, viral dose, age and physical condition of the animal, and various environmental factors. Most cases of primary infection are asymptomatic. Onset of the acute phase of EAV infection, whether associated with clinical signs or not, is preceded by an incubation period of 3–14 days, which varies mainly with the route of exposure. The interval is usually 6–8 days after venereal transmission of the virus. Clinical signs can differ in range and severity between disease outbreaks and between affected individuals in the same outbreak. Any combination of the following may be seen: fever lasting 2–9 days, leukopenia, depression, anorexia, limb edema (especially of the lower hindlimbs), and edema of the scrotum and prepuce. Less frequently encountered signs include conjunctivitis, lacrimation and photophobia, periorbital or supraorbital edema, rhinitis and nasal discharge, edema of the ventral body wall (including the mammary glands of mares), an urticarial-type skin reaction (often localized to the sides of the face, neck, or over the pectoral region, although it can be generalized), stiffness of gait, dyspnea, petechiation of mucous membranes, diarrhea, icterus, and ataxia.

Strains of EAV can cause abortion throughout much of pregnancy (3 mo to more than 10 mo). Abortion may occur late in the acute phase or early in the convalescent phase of the infection, with or without prior clinical signs of EVA. In natural outbreaks, abortion rates can vary from <10% to as high as 60%. There is no evidence confirming that mares bred with EAV-infected semen will abort later in gestation. Mares that abort from the virus are already

pregnant at time of exposure; this occurs primarily by the respiratory route through direct proximity with an acutely infected animal. Abortion occurs 1–4 wk later. Mares exposed very late in gestation may not abort but give birth to a foal congenitally infected with the virus. Mares that abort from EAV infection have not been proved to be less fertile.

Stallions with EVA may undergo a period of short-term subfertility. This has been observed in individuals that develop a high and prolonged fever and extensive scrotal edema. Affected stallions may exhibit reduced libido associated with decreases in total and progressively motile sperm, curvilinear velocity, percentage of live spermatozoa, and percentage of morphologically normal spermatozoa. The changes in semen quality are believed to result from increased intratesticular temperature and not from the direct effect of EAV on spermatogenesis and testicular function. There is strong evidence that fever and scrotal edema exert independent effects on semen quality. Semen changes can last for 14–16 wk before returning to normal. No longterm adverse effects on fertility have been seen in fully recovered stallions.

The frequency and severity of clinical illness associated with EAV infection tend to be greater in very young, old, or debilitated individuals and under adverse climatic conditions. Regardless of severity of clinical signs, affected horses invariably make complete recoveries, even in the absence of symptomatic treatment. Mortality in older horses is very rarely encountered in natural outbreaks. However, it can occur in neonatal and in young foals up to a few months of age that succumb from a fulminating pneumonia or pneumoenteritis.

Lesions: The gross and microscopic lesions in fatal cases of EVA reflect the extensive and considerable vascular damage caused by the virus; these descriptions are primarily based on experimental infection with the highly pathogenic Bucyrus strain of EAV. The most significant gross findings include edema, congestion, and hemorrhages, especially in the subcutis of the limbs and abdomen; excess peritoneal, pleural, and pericardial fluid; and edema and hemorrhage of the intra-abdominal and thoracic lymph nodes and of the small and large intestine, especially the cecum and colon. Pulmonary edema, emphysema and interstitial pneumonia, enteritis, and infarcts in the spleen have been reported in naturally acquired fatal cases of the disease in foals.

Equine viral arteritis, scrotal edema. Courtesy of Dr. Peter J. Timoney

Aborted fetuses are often partly autolyzed. Gross lesions are usually absent; if present, they are limited to an excess of fluid in body cavities and a variable degree of interlobular pulmonary edema. The vascular damage and immune-mediated lesions seen in older animals are seldom found in infected fetuses.

The characteristic microscopic lesion seen in cases of EAV infection is a vasculitis, involving primarily smaller arterioles and venules. Histologically, changes can range from vascular and perivascular edema, with occasional lymphocytic infiltration and endothelial cell hypertrophy in mild cases, to fibrinoid necrosis of the tunica media, extensive lymphocytic infiltration, necrosis and loss of endothelium, and thrombus formation in severe cases. Microscopic lesions are frequently not seen in cases of abortion. If present, vasculitis has been seen in the placenta and the brain, liver, spleen, and lungs of the fetus.

Fatal cases of EAV infection in young foals are characterized by interlobular edema, congestion and mononuclear cell infiltration in the lungs, and lymphoid depletion and hemorrhage in lymphoreticular tissues. Focal hemorrhages and necrosis of the intestinal mucosa have been described when there is an associated enteritis.

Diagnosis: The symptomatology of EVA can mimic that of a range of other respiratory and nonrespiratory equine diseases. Accordingly, laboratory examination of appropriate specimens is essential to confirm diagnosis. Equine influenza, equine herpesvirus 1 and 4-related diseases, infection with equine rhinitis A and B viruses or equine adenoviruses, and purpura hemorrhagica are among the more common equine illnesses that clinically resemble EVA. The latter must also be differentiated from equine infectious anemia, toxicosis caused by hoary alyssum (*Berteroa incana*), and allergy-induced urticaria. Several foreign diseases that should be considered in a differential diagnosis of EVA include Getah virus infection, dourine, and African horse sickness (see p 696).

Abortion caused by EAV must be differentiated from that due to equine herpesvirus 1 or 4. A helpful but not always reliable distinguishing feature is that mares that abort because of EAV may display prior clinical signs of EVA, whereas mares that abort because of equine herpesvirus seldom exhibit any premonitory clinical evidence of infection. Furthermore, EAV-infected

fetuses not infrequently are somewhat autolyzed at time of expulsion and very often are devoid of any gross and even microscopic lesions. In contrast, herpesvirus-infected fetuses are invariably fresh and usually display characteristic gross and microscopic lesions.

Laboratory confirmation of a provisional clinical diagnosis of EVA should be pursued without delay in suspected outbreaks. This can be based on virus isolation, detection of viral nucleic acid, visualization of viral antigen by immunohistochemical examination, or demonstration of a recent humoral antibody response by testing paired (acute and convalescent) sera collected 3–4 wk apart.

The most appropriate samples for virus isolation and/or detection of viral nucleic acid by reverse transcriptase-PCR (RT-PCR) are nasopharyngeal swabs or washings and unclotted (citrate or EDTA) blood samples. To optimize the chances of isolation or detection, samples should be collected as early as possible after the onset of clinical signs or suspicion of EAV infection. After collection, swabs should be transferred directly into viral transport medium and shipped refrigerated or frozen in an insulated container via an overnight delivery service to a laboratory capable of testing for this infection. Uncollected blood samples should be transported refrigerated but not frozen.

In suspect cases of EAV-related abortion, virus detection should be attempted from placental tissues and fluids and from fetal lung, liver, lymphoreticular tissues (especially thymus), and peritoneal or pleural fluid. Chorioallantoic membrane and fetal lung are the tissues of choice for recovery of virus. When EAV is suspected in deaths of young foals or older horses, a wide range of tissue specimens, especially the lymphatic glands in the thoracic and abdominal cavities and related organs, should be collected and submitted for laboratory examination, including histologic and immunohistochemical testing.

Detection of the carrier state in a stallion is based initially on determination of the individual's serologic status for EAV. In the absence of a certified history of vaccination, stallions with a serum neutralizing antibody titer $\geq 1:4$ should be considered potential carriers of the virus until proven otherwise, based on an absence of detectable EAV in their semen. Confirmation of the carrier state is based on demonstration of virus in a semen sample containing the sperm-rich fraction of the ejaculate either by isolation

of virus in cell culture or its detection by RT-PCR. Under controlled laboratory conditions, sensitivity of virus isolation and real-time RT-PCR are essentially equivalent for detection of EAV in stallion semen; however, the RT-PCR assay has the advantage of providing a more rapid result. The carrier state can also be determined by test breeding a stallion to two seronegative mares and checking the mares for seroconversion 28 days after breeding.

Of the serologic assays evaluated for detection of antibodies to EAV, the complement-enhanced virus neutralization test continues to be the most reliable for the diagnosis of acute EAV infection and for seroprevalence studies. A number of ELISA tests have been developed, only a few of which offer comparable but not equivalent sensitivity and specificity. None of the available serologic tests can differentiate antibody titers resulting from natural infection from those due to vaccination.

Treatment, Prevention, and Control:

There is no specific antiviral treatment currently available for EVA. Aside from young foals, virtually all naturally affected horses make complete clinical recoveries. Symptomatic treatment (eg, antipyretic, anti-inflammatory, and diuretic drugs) is indicated only in severe cases, especially in stallions. Prompt symptomatic treatment of stallions with a high or prolonged fever and significant scrotal and preputial edema can reduce the likelihood of short-term subfertility. Good nursing care, adequate rest, and a gradual return to normal activity are indicated. There is no effective treatment for EVA-related cases of pneumonia or pneumoenteritis in foals. Because congenitally infected foals are very productive sources of EAV and their chances of survival are essentially nil, early euthanasia should be considered to minimize the risk of further spread of the virus to any susceptible contacts, especially pregnant mares and young foals. Although there is some evidence that temporary down-regulation of circulating testosterone by GnRH immunization or through the use of a GnRH antagonist promotes clearance of EAV from the reproductive tract of carrier stallions, neither strategy has yet been adequately validated.

EVA is a manageable and preventable disease that can be controlled by observance of sound management practices together with a targeted vaccination program. Only one commercial vaccine, a modified-live virus product, is currently available in North America. The vaccine

protects against development of EVA, including abortion, and establishment of the carrier state in stallions. Although the vaccine is safe and immunogenic for stallions and nonpregnant mares, the manufacturers do not recommend its use in pregnant mares, especially in the final 2 mo of gestation or in foals <6 wk of age, unless under circumstances of high risk of exposure to natural infection. Experimental and field studies have shown that there are no adverse consequences to vaccinating pregnant mares up to 3 mo before foaling and during the immediate postpartum period. However, there is a low risk of abortion in mares vaccinated during the last 2–3 mo of pregnancy. Minimizing or eliminating direct or indirect contact of unprotected horses with infected animals or with virus-infective semen is critical to the success of any prevention program.

The primary focus of current control programs is to restrict the spread of EAV in breeding populations and to reduce the risk of outbreaks of virus-related abortion, death in young foals, and establishment of the carrier state in stallions and postpubertal colts. Although EAV has occasionally been responsible for extensive outbreaks of disease at racetracks, shows, sales, and veterinary hospitals, these have been so sporadic that no specific control programs have been developed to prevent such occurrences.

Effective control programs are predicated on observance of sound management practices similar to those recommended for other respiratory infections. These include isolation of new arrivals on a premises for 3–4 wk before allowing them to co-mingle with the resident equine population, maintenance of pregnant mares in small isolated groups, identification of carrier stallions, annual immunization of noncarrier breeding stallion populations, and vaccination of colts at 6–12 mo of age to minimize their risk of becoming carriers later in life. Carrier stallions should be managed separately and bred only to naturally seropositive mares or mares vaccinated against EVA. Because fresh-cooled or frozen semen can be an important source of EAV, it should be tested by a laboratory with appropriate diagnostic expertise to confirm its negative EAV status, especially if imported. When breeding a mare artificially with virus-infective semen, the same precautions apply as if breeding by live cover to a carrier stallion.

In the event of a suspected outbreak of EVA, relevant animal health authorities

should be promptly notified, with affected and in-contact horses isolated, and restrictions immediately imposed on movement of horses onto and off the affected premises. Appropriate specimens should be collected as soon as possible after onset of clinical signs and submitted for laboratory confirmation of a diagnosis of EVA. Breeding activity should be suspended on breeding farms to minimize risk of further spread of the infection. Stalls and

equipment that might have come in contact with infected animals should be thoroughly sanitized. Vaccination of the at-risk equine population on a premises should be seriously considered as a means of restricting further transmission of EAV and of expediting control and resolution of an outbreak. Movement restrictions should not be lifted until at least 3 wk after the last clinical or suspected case of EVA or laboratory-confirmed case of EAV infection.

GLANDERS

(Farcy)

Glanders is a contagious, acute or chronic, usually fatal disease of Equidae caused by *Burkholderia mallei* and characterized by serial development of ulcerating nodules that are most commonly found in the upper respiratory tract, lungs, and skin. Felidae and other species are susceptible, and infections are usually fatal. The organism is infectious for people, with a 95% fatality rate in untreated septicemia cases, and is considered a potential bioterrorism agent. Glanders is one of the oldest diseases known and once was prevalent worldwide. It has now been eradicated or effectively controlled in many countries, including the USA. In recent years, the disease has been reported in the Middle East, Pakistan, India, Mongolia, China, Brazil, and Africa.

Etiology: *Burkholderia mallei*, a clonal gram-negative facultative intracellular obligate pathogen, is present in nasal exudates and discharges from ulcerated skin of infected animals. Glanders is commonly contracted by ingesting food or water contaminated with nasal discharges of carrier animals, by contact with harness components, and by ingestion of meat from affected horses. The organism is susceptible to heat, light, and disinfectants; survival in a contaminated area is limited to 1–2 mo. Humid, wet conditions favor survival. A polysaccharide capsule is an important virulence factor and enhances survival in the environment.

Clinical Findings: After an incubation period of 3 days to 2 wk, acutely affected animals usually have septicemia, high fever (as high as 106°F [41°C]), weight loss, and

subsequently, a thick, mucopurulent nasal discharge and respiratory signs. Death occurs within a few days. The chronic disease is common in horses and is seen as a debilitating condition with nodular or ulcerative lesions of the skin and internal nares. Infected animals may live for years and continue to disseminate the organism. In some, the infection may be latent and persist for long periods.

Nasal, pulmonary, and cutaneous forms of glanders are recognized, and an animal may be affected by more than one form at a time. In the **nasal form**, nodules develop in the mucosa of the nasal septum and lower parts of the turbinates. The nodules degenerate into deep ulcers with raised irregular borders. Characteristic star-shaped cicatrices remain after the ulcers heal. In the early stage, the submaxillary lymph nodes are enlarged and edematous and later become adherent to the skin or deeper tissues.

In the **pulmonary form**, small, tubercle-like nodules, which have caseous or calcified centers surrounded by inflammatory zones, are found in the lungs. If the disease process is extensive, consolidation of the lung tissue and pneumonia may be present. The nodules tend to break down and may discharge their contents into the bronchioles, resulting in extension of the infection to the upper respiratory tract.

In the **cutaneous form** ("farcy"), nodules appear along the course of the lymph vessels, particularly of the extremities. These nodules degenerate and form ulcers that discharge a highly infectious, sticky pus. The liver and spleen also may show typical nodular lesions. Histologically, there

may be vasculitis, thrombosis, and infiltration of degenerating inflammatory cells.

Diagnosis: The typical nodules, ulcers, scar formation, and debilitated condition may provide sufficient evidence for a clinical diagnosis. However, because these signs usually do not develop until the disease is well advanced, specific diagnostic tests should be used as early as possible. Culture of *B. mallei* from lesions confirms the diagnosis. A test for delayed hypersensitivity is performed by intrapalpebral inoculation of mallein, a secreted glycoprotein of *B. mallei* found in culture supernatant. Infected hypersensitive horses develop a purulent conjunctivitis within 24 hr and swelling of the eyelid. Complement fixation is also used to screen for infection. Competitive ELISA is more sensitive than

complement fixation and may become positive as early as 3 days after infection. PCR based on 16S and 23S rRNA gene sequences may be used for specific identification.

Prevention and Treatment: There is no vaccine. Protective immunity involves T cell responses elicited by live attenuated bacteria. Prevention and control depend on early detection and elimination of affected animals, as well as complete quarantine and rigorous disinfection of the area involved. Treatment is given only in endemic areas but does not reliably produce a bacteriologic cure. Doxycycline, ceftazidime, gentamicin, streptomycin, and combinations of sulfazine or sulfamonomethoxine with trimethoprim were effective in the prevention and treatment of experimental glanders.

HENDRA VIRUS INFECTION

Hendra virus was first described in 1994 after an outbreak of acute respiratory disease in a Thoroughbred training stable in Australia in which horses and one person were fatally infected. Sporadic cases continue to occur in eastern Australia, typically presenting as an acute febrile illness and rapidly progressing with variable system involvement, notably acute respiratory and/or severe neurologic disease. Fruit bats (suborder Megachiroptera) are the natural reservoir of the virus. Hendra virus is classified as a biosafety Level 4 agent (defined as posing a high risk of life-threatening disease in people), and the use of safe work practices and personal protective equipment is essential to manage the risk of human exposure. The earlier names of equine morbillivirus and acute equine respiratory syndrome are no longer appropriate.

Etiology and Pathogenesis: Hendra virus is a large, pleomorphic enveloped RNA virus. Although initially considered to be more closely related to members of the genus *Morbillivirus* than to other genera in the family Paramyxoviridae, subsequent studies showed limited sequence homology with respiroviruses, morbilliviruses, and rubuloviruses and negligible immunologic cross-reactivity with other paramyxi-

ruses. Hendra virus is genetically and antigenically closely related to Nipah virus (see p 721), with which it shares >90% amino acid homology. Both viruses have been classified in a new genus, *Henipavirus*, in the subfamily Paramyxovirinae.

It is increasingly evident that Hendra virus strain variation is minimal and that clinical presentation and pathology more likely vary with the route of infection. Historically, interstitial pneumonia of variable severity was the principal finding in naturally infected horses and in experimentally infected horses exposed by the respiratory or parenteral routes. Hendra virus has a specific tropism for vascular tissues, regardless of route of challenge. In early infection, the vascular lesions may include edema and hemorrhage of vessel walls, fibrinoid degeneration with pyknotic nuclei in endothelial and tunica media cells, and numerous giant cells (syncytia) in the endothelium and sometimes the tunica media of affected vessels (both venules and arterioles). The virus becomes more widely distributed in various tissues throughout the body as infection progresses, presumably as a result of a leukocyte-associated viremia. Virus has been demonstrated in the vascular endothelium of subarachnoid and cerebral vessels and in the vasculature of the renal glomerulus and pelvis, lamina propria of the

stomach, spleen, various lymph nodes, and myocardium. When respiratory disease is present, there is progressive destruction of alveolar walls, with the appearance of alveolar and intravascular macrophages. In addition to its vascular tropism, Hendra virus can also be neurotropic, causing neuronal necrosis and focal gliosis. A feature of one outbreak at an equine veterinary clinic in Australia in 2008 was severe neurologic disease and an absence of respiratory disease. Thus, Hendra virus should no longer be regarded as causing predominantly respiratory disease in horses.

Epidemiology and Transmission: Naturally occurring disease caused by Hendra virus has been reported only in horses and people. Experimentally, disease has been produced in cats, hamsters, ferrets, monkeys, pigs, and guinea pigs, but not in mice, rats, rabbits, chickens, or dogs. The clinical response and pathologic findings in cats are very similar to those seen in horses. Hendra virus infection and disease in horses has only been reported in Australia, and events are sporadic and infrequent, with 14 events recorded between 1994 and 2010. Most of these were single horse events. Thus, Hendra virus appears to have limited infectivity, and under field conditions, transmission between infected and noninfected horses occurs infrequently. However, the frequency of Hendra virus infection in horses has increased since 2011, with 18 incidents in 2011, 8 in 2012, 8 in 2013, and 3 in 2014 (up to October), with extended geographic locations (between far north Queensland to north New South Wales, Australia). In July 2011, a dog on a property with horses infected with Hendra virus (in Queensland) was identified as seropositive without any clinical signs. In July 2013, a dog on a property (in New South Wales) with Hendra virus infection in a horse was confirmed to be infected with the same virus. Further research is underway to investigate whether these increased incidents in horses were because of greater public awareness in reporting the disease or whether environmental or ecologic factors triggered this increased number of cases and extended geographic occurrence.

Experimentally, attempted transmission from virus-infected horses to in-contact horses or cats has been unsuccessful. Nonetheless, the possibility of respiratory transmission cannot be excluded. The frothy nasal discharge (originating from the

lungs) sometimes observed terminally in naturally affected horses could plausibly provide a source of virus for aerosol transmission. Hendra virus has been found in the urine, blood, and nasal and oral secretions of naturally infected horses and cats. Based on available field and laboratory data, infection of people or animals appears to require direct contact with virus-infective secretions (lung exudates), excretions (urine), body fluids, or tissues. Although Hendra virus appears to have limited infectivity, the case fatality rate in individuals that become infected is high: 75% in horses, 57% in people.

Available epidemiologic, serologic, and virologic evidence implicates fruit bats as the natural reservoir of Hendra virus. Serologic surveys have revealed a high prevalence of neutralizing antibodies in wild-caught fruit bats (*Pteropus* spp) in Australia and Papua New Guinea. The geographic distribution of the virus in fruit bats appears to be limited to Australia and Papua New Guinea, although a transition of Hendra-like to Nipah-like viruses may occur beyond Australia. Infection in fruit bats (either natural or experimental) causes no evident disease. There is field and experimental evidence of vertical transmission, with isolates recovered from the uterine fluid and fetal tissues of a grey-headed flying fox (*P. poliocephalus*) and a black flying fox (*P. alecto*). The infrequent occurrence and sporadic nature of equine cases suggest that exposure of horses to Hendra virus is, at least in part, a chance event. The modes of transmission between bats, and from bats to horses, are uncertain, as are factors that may facilitate spillover. Hendra virus has been identified in the birthing fluids, placental material, aborted pups, and urine of naturally infected fruit bats and in the urine of experimentally infected fruit bats. The related Nipah virus has been detected in bat urine and on fruit partially eaten by bats. Horses are hypothesized to be infected through contact with food or water contaminated with material from infected fruit bats, but the definitive mechanism remains to be determined.

Clinical Findings: Because of its affinity for endothelial cells, Hendra virus can cause a range of clinical signs in horses. The predominant clinical presentation may depend on which organ system sustains the most severe or compromising endothelial damage.

Hendra virus infection should be considered when there is acute-onset fever and rapid progression to death, possibly

associated with either severe respiratory or neurologic signs; however, the absence of these should not preclude consideration of Hendra virus. Infection is not always fatal, with 25% of known cases having recovered from clinical disease.

Clinical signs that should prompt a veterinarian to consider Hendra virus infection include acute onset of illness, fever, and rapid deterioration. Respiratory signs can include pulmonary edema and congestion, respiratory distress (increased respiratory rate), and terminal nasal discharge, which may be clear initially and progress to stable white or blood-stained froth. Neurologic signs can include "wobbly gait" progressing to ataxia, altered consciousness (apparent loss of vision in one or both eyes, aimless walking in a dazed state), head tilt, circling, muscle twitching (myoclonic spasms have been seen in acutely ill and recovered horses), urinary incontinence, recumbency with inability to rise, terminal weakness, ataxia, and collapse. Other clinical signs may include depression, highly increased heart rate, facial edema, muscle trembling, anorexia, congestion of oral mucous membranes, colic-like symptoms (generally quiet abdominal sounds on auscultation of the abdomen in preterminal cases), and stranguria in both males and females. Proximity to fruit bat roosts or feeding sites should increase the index of suspicion.

Where horses are paddocked, Hendra virus infection is more likely to manifest as a single sick or dead horse than as multiple cases. Most paddock infections have involved a single fatally infected horse with no transmission to in-contact companion horses. However, on several occasions, one or more companion horses have become infected after close contact with the index case before or at the time of death. Where horses are stabled, it appears that Hendra virus has the potential to spread either through close direct contact with infectious body fluids, or through indirect transmission via contaminated fomites, including inadvertent human-assisted transfer. Hendra virus infections in horse stables to date have resulted in multiple horses becoming infected, which appear to have arisen from a horse infected in a paddock or outside yard being brought into the stable.

Lesions: The presence of large endothelial syncytial cells on histopathology is characteristic of Hendra virus infection. Although most prominent in pulmonary capillaries and arterioles, these cells are also seen in other organs (lymph nodes,

spleen, heart, stomach, kidneys, and brain). Widespread fibrinoid degeneration of small blood vessels is seen in many organs, including the lungs, heart, kidneys, spleen, lymph nodes, meninges, GI tract, skeletal muscle, and bladder. Antigen specific for Hendra virus can be demonstrated by immunohistochemical staining in the vascular lesions and along alveolar walls. Intracytoplasmic viral inclusion bodies can be seen in infected endothelial cells by electron (but not light) microscopy. When respiratory disease is predominant, the principal gross lesions are severe edema and congestion of the lungs and marked dilatation of the subpleural lymphatics. The airways are filled with thick froth, which is often blood-tinged. Additional lesions seen in some affected horses include increased pleural and pericardial fluids, congestion of lymph nodes, hemorrhages in various organs, and slight jaundice.

Microscopically, the primary lesions are those of an acute interstitial pneumonia. Severe vascular damage, with serofibrinous alveolar edema, hemorrhage, thrombosis of capillaries, necrosis of alveolar walls, and alveolar macrophages are evident in the lungs.

If neurologic disease is predominant, lesions of nonsuppurative meningitis or meningoencephalitis, including perivascular cuffing, neuronal degeneration, and focal gliosis, have been seen.

Diagnosis: Hendra virus infection should be considered when there is acute onset fever and rapid progression to death, but a nonfatal outcome should not preclude consideration of Hendra virus. Confirmation of the diagnosis is based on laboratory examination of appropriate specimens to detect virus, viral antigen, viral nucleic acid, or specific antibodies. The approach to specimen collection should reflect the serious zoonotic potential of Hendra virus and should incorporate appropriate measures to avoid human exposure. Minimum recommended samples include a blood sample (whole and/or EDTA) and nasal, oral, and/or rectal swabs. These can be taken from both live and dead horses. Necropsy specimens, both fresh and fixed in 10% formalin, of lung, kidney, spleen, liver, lymph nodes, and brain will increase the likelihood of reaching a conclusive diagnosis but also potentially increase the risk of human exposure. The number and type of specimens collected should follow a careful risk analysis by the veterinarian to prevent human exposure and consider

many factors, including personal protective equipment available, training, and prior experience. If there are personal safety concerns, only a minimal set of samples (blood, swabs) should be collected. Submitting a combination of EDTA blood, serum, nasal, oral, and rectal swabs should be sufficient to detect Hendra virus infection in a horse highly suspected to be infected. Recommended procedures for safe handling of suspect Hendra cases are available at the Biosecurity Queensland Web site (www.daff.qld.gov.au).

The virus can be isolated in a range of cell lines; Vero cells are the cell line of choice. Viral cytopathic effect, which typically develops after 3 days, is characterized by syncytia formation in infected cells. Virus isolation and other diagnostic tests involving live virus should only be attempted under biosecurity Level 4 conditions. Serologic confirmation of infection is based on testing acute and convalescent sera collected 2–4 wk apart in a virus neutralization test. Presence of the characteristic vascular lesions on histopathology is highly suggestive of the infection; specificity of the lesions can be confirmed by immunohistochemical labeling with Hendra virus reference antiserum.

African horse sickness can clinically mimic Hendra virus infection and should be considered in the differential diagnosis. Other causes of sudden death that must be excluded include anthrax, botulism, certain bacterial infections (eg, pasteurellosis, equine influenza, peracute equine herpesvirus 1 infection), snake bite, and plant or chemical poisoning.

Treatment, Prevention, and Control:

There is no specific antiviral treatment for Hendra virus infection. A vaccine, containing a noninfectious protein component (G protein) of the virus, has been developed; it was introduced in November 2012 and is available through accredited veterinarians in Australia. Healthy horses can be vaccinated from 4 mo of age with two doses at a 21-day interval, followed by boosters every 6 mo. Studies are being conducted to determine whether the period of booster vaccination can be extended to 1 yr.

Confirmed cases should be euthanized on humane grounds and to limit risk of human exposure. In Australia, euthanasia of recovered seropositive horses is also recommended, because the currently available evidence cannot exclude the possibility of recrudescence in these animals.

Prevention focuses on minimizing contact with fruit bat body fluids/contaminants and includes simple, practical measures such as placing feed and water containers under cover and minimizing the number of bat food trees/shrubs (fruiting and/or flowering) in horse paddocks or excluding horses from the vicinity of such trees/shrubs. Control is based on euthanasia and deep burial of cases; monitoring, isolating, and restricting movement of in-contact animals; and disinfection of potentially contaminated surfaces.

Zoonotic Risk: Human infection with Hendra virus has a 57% case fatality rate. All human infections have occurred from handling infected horses (both live horses and dead horses at necropsy), so great care should be taken to ensure the personal safety of all people in contact with suspect or confirmed equine cases. Neither bat-to-human nor human-to-human transmission has been recorded.

Protocols to minimize risk of human exposure should be implemented on suspicion of Hendra virus infection in a horse, not on confirmation. An outline of the approach developed by Biosecurity Queensland includes the following steps to minimize risk. First, a plan should be made in advance that outlines how Hendra virus risks will be managed by the practice and individual veterinarians in that practice. This includes 1) taking precautions based on suspicion of Hendra virus and not waiting for confirmation of infection; 2) isolating sick or dead horse(s) from people and all other animals, including pets; 3) limiting human contact with in-contact horses to only essential people; 4) promoting personal hygiene (especially hand washing, showering) for in-contact staff; 5) identifying hazards and taking steps to minimize the risks associated with these (eg, if decontaminating an area, avoid generating splashes and aerosols by not using a high-pressure hose); 6) informing people who may be potentially exposed such as owners, handlers, and others (including other veterinarians and veterinary assistants) of the risk and the appropriate procedures to be followed; and 7) referring to relevant animal health and public health authorities.

Second, adequate personal protective equipment should be used: 1) all exposed skin, mucous membranes and eyes should be protected from direct contact; 2) inhalation of airborne particulates should be prevented; 3) regular hand washing and washing of exposed skin with soap should

be promoted; and 4) cuts and abrasions should be covered by water-resistant occlusive dressings that are changed as necessary.

In particular, blood and other body fluids (especially respiratory and nasal secretions,

saliva, and urine) and tissues from sick or dead horses should be treated as potentially infectious and appropriate precautions taken to prevent any direct contact with, splashback of, or accidental inoculation with these body fluids.

AFRICAN SWINE FEVER

African swine fever (ASF) is a highly contagious hemorrhagic disease of pigs that produces a wide range of clinical signs and lesions that closely resemble those of classical swine fever (see p 713). It is an economically important disease that is enzootic in many African countries and the Mediterranean island, Sardinia. In June 2007, ASF was confirmed for the first time in Georgia in the Caucasus region. Since its introduction into Georgia, African swine fever virus (ASFV) has spread rapidly into vast areas of western and southern Russia, where it is currently (2013) circulating out of control in domestic and wild pig populations. The virus has spread to the edges of Europe, with outbreaks reported in both the Ukraine and Belarus in 2013, putting at risk the very large pig populations present in Eastern Europe.

Etiology and Epidemiology: ASFV is a large, enveloped, double-stranded DNA virus that replicates primarily in cells of the mononuclear phagocytic system. It is currently classified as the only member of a family called African swine fever–like viruses (Asfarviridae). The prolonged period during which ASF has been an enzootic disease in Africa is likely to have led to the selection of viruses of varying virulence. Distinct genotypes of ASFV have been differentiated by sequence analysis of the genomes of viruses obtained from different geographic areas over a long time. The virus is highly resistant to a wide pH range and to a freeze/thaw cycle and can remain infectious for many months at room temperature or when stored at 4°C. Virus in body fluids and serum is inactivated in 30 min at 60°C, but virus in unprocessed pig meat, in which it can remain viable for several weeks, can be inactivated only by heating to 70°C for 30 min. Although ASFV can be adapted to grow in cells from different species, it does not replicate readily in any species other than swine.

The disease is limited to all breeds and types of domestic pigs and European wild boar. All age groups are equally susceptible. In Africa, the virus produces inapparent infection in two species of wild swine—warthog (*Phacochoerus aethiopicus*) and bushpig (*Potamochoerus porcus*)—and in the soft tick *Ornithodoros moubata*. When the disease was endemic in southern Spain and Portugal, a different species of soft tick, *O. erraticus*, became infected with the virus. Several other *Ornithodoros* spp that are not usually associated with pigs or wild swine have been infected experimentally. ASF has been reported in a large number of countries in Africa south of the Sahara, either as an enzootic disease or as sporadic epidemics in domestic pigs. The first spread of the disease outside Africa was into Europe (Portugal) in 1957 as a result of waste from airline flights being fed to pigs near Lisbon airport. Although this incursion of disease was almost certainly eradicated, a further outbreak occurred in 1960 in Lisbon, and ASF then remained endemic in the Iberian peninsula until the mid-1990s. Outbreaks of ASF were reported in a number of other European countries during the 20th century, including Malta (1978), Italy (1967, 1980), France (1964, 1967, 1977), Belgium (1985), and the Netherlands (1986). The disease was eradicated from each of these countries but has remained endemic in Sardinia since its introduction in 1978. During the 1970s, ASFV spread to the Caribbean and South America. An outbreak in south Brazil in 1978–1979 was eradicated by stamping out, and Brazil regained its ASF-free status in December 1984.

The spread of ASF out of Africa has been a relatively rare event, but in June 2007 ASF was confirmed in pigs in the former Soviet republic of Georgia in the Caucasus region. Genetic analysis revealed the genotype of the Georgia isolate to be closely related to isolates in circulation in Mozambique, Madagascar, and Zambia. It is therefore

likely that pigs were fed ASFV-contaminated pig meat transported by ship from the southeastern part of Africa. By July 2007, the outbreak had spread to 56 of 61 districts in Georgia; soon after, outbreaks of ASF were reported in neighboring regions, including the autonomous republic of Abkhazia, Armenia, and Nagorno-Karabakh. Later in the year, infection of wild boar was confirmed in the Russian republic of Chechnya. In 2008, the spread of ASF continued into North Ossetia; it then jumped over 1,000 km into Orenburg, illustrating its potential for rapid spread over long distances. By October 2008, a total of 21 outbreaks of ASF had been officially reported in five Russian administrative divisions. From 2009–2013, the virus has continued to spread within the Russian Federation, and there are currently (Oct 2013) two main expanding hotbeds of infection in Russia, one in the southern part of the center of the Rostov region (Oblast) and the other in the Tver region (Oblast) and the adjoining areas. In 2013, outbreaks of ASF were reported in both the Ukraine and Belarus, putting at risk large pig populations in eastern Europe.

Transmission and Pathogenesis: ASFV is maintained in Africa by a natural cycle of transmission between warthogs and the soft tick vector *O. moubata*, which inhabits warthog burrows and from which it is unlikely ever to be eliminated. The spread of virus from the wildlife reservoirs to domestic pigs can be by the bite of an infected soft tick or by ingestion of warthog tissues. Virulent viruses produce acute disease, and all body fluids and tissues contain large amounts of infectious virus from the onset of clinical disease until death. Pigs infected with less virulent isolates can transmit virus to susceptible pigs as long as 1 mo after infection; blood is infectious for as long as 6 wk, and transmission can occur if blood is shed. Pigs usually become infected via the oronasal route by direct contact with infected pigs or by ingestion of waste food containing unprocessed pig meat or pig meat products. The primary route of infection is the upper respiratory tract, and virus replicates in the tonsil and lymph nodes draining the head and neck, with generalized infection rapidly following via the bloodstream. High concentrations of virus are then present in all tissues. The factors that produce the hemorrhagic lesions are not fully defined, but severe disruption to the blood clotting mechanism plays a major role. Virus is excreted mainly from the upper respiratory

tract and is also present in secretions and excretions containing blood.

Pigs that survive infection with the less virulent isolates may be persistently infected and have circulating antibody, although they do not excrete virus or transmit virus to their offspring in utero. Their role in the epidemiology of the disease is not fully understood; however, they are resistant to disease when challenged with related highly virulent isolates, indicating some level of cross-protective immunity between strains.

Clinical Findings and Lesions: Peracute, acute, subacute, and chronic forms of ASF occur, and mortality rates vary from 0 to 100%, depending on the virulence of the virus with which pigs are infected. Acute disease is characterized by a short incubation period of 3–7 days, followed by high fever (up to 42°C) and death in 5–10 days. The least variable clinical signs are loss of appetite, depression, and recumbency; other signs include hyperemia of the skin of the ears, abdomen, and legs; respiratory distress; vomiting; bleeding from the nose or rectum; and sometimes diarrhea. Abortion is sometimes the first event seen in an outbreak. The severity and distribution of the lesions also vary according to virulence of the virus. Hemorrhages occur predominantly in lymph nodes, kidneys (almost invariably as petechiae), and heart; hemorrhages in other organs are variable in incidence and distribution. Some isolates produce an enlarged and friable spleen; straw-colored or blood-stained fluid in pleural, pericardial, and peritoneal cavities; or edema and congestion of the lungs. Some viruses of low virulence have been isolated in Europe and produce nonspecific clinical signs and lesions. Chronic disease is characterized by emaciation, swollen joints, and respiratory problems. This form of the disease is rarely seen in outbreaks.

Diagnosis: ASF cannot be differentiated from classical swine fever (hog cholera) by either clinical or postmortem examination. Samples of blood, serum, spleen, tonsil, and gastrohepatic lymph nodes from suspected cases should be submitted to the laboratory for confirmation. Virus can be isolated by inoculation of primary cultures of pig monocytes, in which it produces hemadsorption of pig red cells to the surface of infected cells. Classical swine fever virus does not replicate in these cells. There are nonhemadsorbing viral isolates, some of which produce virulent disease. These

isolates produce only a cytopathic effect in pig leukocytes. Confirmation of ASF in these cases has to be performed by either PCR or an antigen-detection ELISA. Viral antigen can be detected in infected tissue smears or sections by staining with labeled antibodies (several enzyme-labeled tests are available, eg, immunofluorescence), and viral DNA by PCR or hybridization of nucleic acid probes to tissue sections. The most appropriate tests to detect antibody in serum or tissue fluids are the ELISA and indirect immunofluorescence.

Other differential diagnoses include hemorrhagic bacterial infections and certain types of poisons.

Control: There is no treatment for ASF, and all attempts to develop a vaccine have so far been unsuccessful. Prevention depends on ensuring that neither infected live pigs nor pig meat products are introduced into areas free of ASF. All successful eradication programs have involved the rapid diagnosis, slaughter, and disposal of all animals on infected premises. Sanitary measures must also be applied and include control of movement and treatment of waste food. Subsequently, a serologic survey of all pig farms within a specific control zone must be conducted to ensure that all infected pigs have been identified.

CLASSICAL SWINE FEVER

(Hog cholera, Swine fever)

Classical swine fever is a contagious, often fatal, disease of pigs clinically characterized by high body temperature, lethargy, yellowish diarrhea, vomiting, and a purple skin discoloration of the ears, lower abdomen, and legs. It was first described in the early 19th century in the USA. Later, a condition in Europe termed "swine fever" was recognized to be the same disease. Both names continue to be used, although in most of the world the disease is now called classical swine fever (CSF) to distinguish it from African swine fever (see p 711), which is a clinically indistinguishable disease but caused by an unrelated DNA virus. Because of the severe economic impact of CSF, outbreaks are notifiable to the OIE. CSF has the potential to cause devastating epidemics, particularly in countries free of the disease. In these countries, vaccination is allowed only under emergency circumstances. In case of a new outbreak, strict measures are enforced to control spread, eg, culling of infected and disease suspect herds and strict movement restrictions. This can have severe consequences for the swine industry, especially in densely populated livestock areas. Awareness and vigilance are essential, so that outbreaks are detected early and control measures instituted rapidly to prevent further spread of CSF. The "high risk period," ie, the time between introduction of the virus and detection of the outbreak, must be kept as short as possible.

Etiology and Epidemiology: CSF is caused by a small, enveloped RNA virus in the genus *Pestivirus* of the family Flaviviridae. Classical swine fever virus (CSFV) is antigenically related to the other pestiviruses, mainly to bovine viral diarrhea virus (BVDV, see p 1436) of cattle and to border disease virus (BDV, see p 622) of sheep. These viruses are highly prevalent in bovine and ovine populations and can infect pigs. Although infections of pigs with ruminant pestiviruses in most cases do not lead to clinical disease and are rapidly cleared, infections with both BVDV and BVD induce an antibody response in swine. Therefore, antibody discrimination tests must be applied to differentiate CSF infections from infections caused by ruminant pestiviruses. Transmission of ruminant pestiviruses to pigs usually requires direct contact with cattle, sheep, or goats. CSFV naturally infects members of the Suidae family, ie, domestic and wild pigs.

In the laboratory, CSFV is cultured in cells of porcine origin, notably in the PK-15 cell line (porcine kidney), but does not generally cause a visible cytopathic effect. The virus has only one serotype, although some minor antigenic variability between strains is seen. Strains can be typed for epidemiologic mapping purposes by sequencing the entire viral genome or specific regions of the viral genome (ie, 5' UTR, E2, and NS5B regions) combined with phylogenetic analysis.

CSFV is moderately fragile and does not persist in the environment or spread long distances by the airborne route. However, it can survive for prolonged periods in a moist, protein-rich environment such as pork tissues or body fluids, particularly if kept cold or frozen. Virus survival times up to several years have been observed in frozen pork meat. CSFV may also survive months in chilled or cured cuts.

CSF has a worldwide distribution. It is considered endemic in certain countries of Central and South America, in the Caribbean basin, and in many pork-producing countries in Asia. Australia, New Zealand, Canada, and the USA are free of the disease, as well as most countries of western and central Europe, although sporadic outbreaks occur in Europe. CSF is considered endemic in several countries in eastern Europe. The main source of CSFV infection is the pig, either via infected live animals or via uncooked pork products. In areas where CSF is endemic, the major concern relates to the spread of disease through movement of infected animals, which may lead to widespread outbreaks, particularly in areas where there is large-scale transport of pigs among farms or to slaughter houses. In Europe, CSFV is considered endemic in wild boar populations, and infected wild boars are a source for CSF outbreaks among domestic pigs. However, the most probable source of CSFV infection for wild boars is contaminated garbage or even "spillover" from infected domestic pigs. The outcome of such infections mainly depends on the size and density of the wild boar populations affected. Outbreaks in small populations of wild boars living within natural confines, such as valleys, tend to be self-limiting, and the disease fades away over time. In contrast, infections leading to outbreaks in large areas densely populated with wild boars often become endemic.

Another major risk for CSF outbreaks is the accidental introduction of CSFV into herds through illegally imported pork meat or pork products that often find their way into the porcine food chain via swill feeding. However, CSFV is readily inactivated by heat (ie, cooking), which emphasizes the importance of enforcing regulations for heat treatment of swill feed. In addition, many countries have completely banned swill feeding practices.

Mechanical transmission by vehicles and equipment, as well as by personnel (notably veterinarians) travelling between pig farms, are also significant means of spread of CSF within infected areas. The persistence of

CSFV within herds for long periods has been observed. Infections of sows during pregnancy with low to moderately virulent strains of CSFV may lead to in utero infections of fetuses. These infections lead to litters born persistently infected with CSFV that are carriers of the virus and source for new infections. Persistently infected carrier pigs usually do not show clinical signs but constantly shed CSFV into the environment. Therefore, it is particularly important to consider CSFV infections while investigating herds presenting with unexplained reproductive failures that include clinical manifestations in piglets such as congenital tremor or congenital abnormalities.

Clinical Findings and Lesions: CSF is characterized by fever, hemorrhages, ataxia, and purple discoloration of the skin; however, the clinical presentation varies, depending on host characteristics and the particular virus strain causing the infection. CSF occurs in several forms, including highly lethal, acute, chronic, or subclinical. Acute forms of CSF, associated with highly virulent CSFV strains, are characterized by an incubation period that is typically 3–7 days, with death occurring within 10 days after infection. Fever $>41^{\circ}\text{C}$ (105.8°F) is usually seen and persists until terminal stages of the disease when body temperature drops and becomes subnormal. Constipation followed by diarrhea and vomiting is common.

The principal lesion produced by CSFV infection is a generalized vasculitis, clinically manifested as hemorrhages and cyanosis of the skin, notably at the ears, lower abdomen, and extremities. There may also be a generalized erythema of the skin. Vasculitis in the CNS leads to incoordination (ie, staggering gait) or even convulsions. Histologically, nonsuppurative encephalitis with a characteristic vascular cuffing is common. At necropsy, the principal findings are widespread petechial and ecchymotic hemorrhages, especially in lymph nodes (eg, mandibular and retropharyngeal), tonsils, larynx, kidneys, spleen, urinary bladder, and ileum. Infarction may be seen, particularly in the periphery of the spleen. Subacute and chronic forms of the disease are also characterized by high fever, staggering gait, cough, diarrhea, purple discoloration of the skin, and death. In the subacute form, death generally happens within 20–30 days after infection; in the chronic form, death may occur much later. Subacute and chronic forms of the disease are associated with

CSFV strains of moderate to low virulence, respectively. Low virulence strains can be difficult to detect; the only clinical expression may be poor reproductive performance of sows and the birth of piglets with neurologic defects (eg, congenital tremor). In chronic forms of CSF after an initial acute febrile phase, infected animals may show an apparent recovery but then relapse, with anorexia, depression, fever, and progressive loss of condition (ie, marked weight loss). Macroscopically, in addition to the lesions described above, "button" ulcers may develop in the intestine, particularly near the ileocecal junction. Histologically, atrophy of the thymus and depletion of lymphoid follicles in lymph nodes are seen.

Diagnosis: CSF is first detected by veterinarians in the field. Because clinical signs manifested by CSFV-infected pigs are also seen with other diseases of swine, laboratory confirmation is always required. Clinically, the differential diagnosis varies according to the course of the disease, and primarily includes African swine fever. Hemorrhagic lesions must also be distinguished from those seen in porcine dermatitis and nephropathy syndrome and postweaning multisystemic wasting syndrome. Hemolytic disease of the newborn, porcine reproductive and respiratory syndrome, Aujeszky disease, parvovirus, thrombocytopenic purpura, anticoagulant poisoning (eg, warfarin), and salt poisoning should also be considered as possible differential diagnoses. Septicemic diseases, including salmonellosis, erysipelas, pasteurellosis, actinobacillosis, *Haemophilus suis* infections, and eperythrozoonosis may resemble CSF. Congenital infections with ruminant pestiviruses can resemble CSF reproductive failures caused by low virulence strains of CSFV. Poor reproductive performance in sows can also be associated with pseudorabies, parvovirus, and other noninfectious causes.

Virologic tests are essential to confirm the diagnosis of CSF. Advice on sample submission should be sought from the laboratory. Suitable tissues to detect the presence of the virus are tonsils, lymph nodes (mandibular, retropharyngeal, gastrohepatic, and mesenteric), spleen, kidney, and ileum. Whole blood collected with EDTA as anticoagulant can be used for virus isolation or virus detection, particularly during the viremic phase of the infection. Clotted blood samples (serum) are taken when serologic tests for detection

of CSFV antibodies are pursued. Nasal swabs and/or tonsil scrapings are commonly collected clinical samples used to detect the virus (ie, viral RNA).

Significant amounts of CSFV are shed from infected animals into the environment via the oronasal route, particularly early during infection. Detection of CSFV antigen can be performed using direct immunofluorescence on frozen tissue sections, particularly in tonsil samples using specific antibodies. Antigen detection can also be done using ELISA; however, this assay has low sensitivity and is only useful for screening for the presence of CSFV at the herd level. More commonly, viral nucleic acid detection is done using reverse transcriptase (RT)-PCR. The assay is highly specific and can differentiate CSFV from BVDV and BDV. Standardized methods such as RT-PCR can be scaled up to screen large numbers of samples, giving rapid results while retaining high sensitivity. This is particularly useful to screen herds during an outbreak of CSF.

For virus isolation, cell cultures are inoculated with tissue suspensions or WBCs, fixed after 2–3 days, and the virus is detected using specific antibodies directed against CSFV (eg, fluorescent or enzymatic methods). Final results may not be available for 4–7 days. This method is labor intensive and time consuming. Virus characterization using virus-specific monoclonal antibodies or RT-PCR is performed to differentiate CSFV from the other pestiviruses. Positive results of antigen detection or virus isolation are not confirmed until virus identification is completed. Virus neutralization tests and ELISA tests are available to detect antibodies against CSFV. Because the virus is noncytopathogenic in culture, the neutralization test requires an additional immunostaining step to reveal the presence of neutralizing antibodies. ELISA tests are suitable for large-scale serology when large number of samples are processed, ie, for surveillance purposes. Cross-reactions between pestivirus antibodies are seen in diagnostic tests. The presence of antibodies against ruminant pestiviruses in pigs may hamper the serologic diagnosis of CSF. BVDV or BDV-specific antibodies are sporadically detected in pig populations. Risk factors related with ruminant pestivirus antibodies in pigs are associated with the presence of cattle on the same farm and high density of sheep and/or goats in the area. Some commercial ELISAs can distinguish CSF from BVDV or BDV antibodies, although confirmatory testing is advised usually via neutralizing peroxidase-linked assays.

New generations of CSFV marker vaccines have been developed to make emergency vaccination compatible with control of CSF. The application of a marker vaccine is possible if tests such as ELISA can distinguish between antibodies produced in response to a natural infection and those produced by vaccination. This is the DIVA principle (differentiation of infected from vaccinated animals) that is based on detection of CSFV-specific antibodies that develop in the host only with CSFV infection but not on vaccination with a marker vaccine. These assays have been developed as necessary companion tests for CSF marker vaccines.

Control: CSF is a notifiable disease. Control is usually strictly regulated by local laws that establish strict sanitary measures. No treatment is available. Outbreaks in countries free of CSF are controlled rapidly via culling of infected animals and preemptive slaughter of susceptible animals within determined distances from the focus. Restriction of movement within a well-defined radius from the outbreak is applied to contain spread of the infection. Eventually, emergency vaccination can be authorized to control the further spread of CSFV. Countries will regain their CSF-free status (no antibodies or virus detected) after establishing that CSFV is no longer present in the national pig herd.

Countries free of CSF usually implement preventive measures to avoid outbreaks of CSF by controlling movement of live animals and pork products at borders. Countries free of CSF forbid the use of prophylactic vaccination. In countries where CSF is endemic, prophylactic vaccination is regularly practiced and is mandatory in some cases. Prophylactic vaccination has been used worldwide as a tool to control and eradicate CSF. In these countries, herds affected by an outbreak are quarantined and if possible eliminated. Emergency ring vaccination around the outbreak is done to prevent further spread of CSFV. CSF live attenuated vaccines are safe and highly efficient, being able to induce protection shortly after vaccination (within 3 days after vaccination). Several live attenuated vaccines, such as the Chinese lapinized vaccine (C-strain), the Japanese GPE-strain, and the French Thiverval strain, have been developed and used in different countries. More recently, subunit CSFV vaccines containing only the major viral surface glycoprotein of the virus have been licensed. Although these vaccines have DIVA capabilities, they lack the efficiency of live attenuated vaccines. Oral vaccination of wild boars has been used successfully within the European Union using a live attenuated vaccine delivered via baits. Oral vaccination has been a key strategy to control CSF, particularly where parenteral vaccine delivery is not feasible.

EDEMA DISEASE

(*Escherichia coli* enterotoxemia)

Edema disease is a peracute toxemia caused by specific pathotypes of *Escherichia coli* that affect primarily healthy, rapidly growing nursery pigs. Other names for edema disease include "gut edema" or "bowel edema" because of the prominent edema of the submucosa of the stomach and mesocolon.

Etiology and Pathogenesis: Edema disease is caused by hemolytic *E. coli* that produce F18 pili and Shiga toxin 2e (Stx2e, also known as verotoxin 2e or VT2e). The F18 pili have two major antigenic variants, F18ab and F18ac; F18ab is characteristic of edema disease strains, and F18ac is

associated primarily with enterotoxigenic *E. coli*. A new variant of F18 has been identified on strains of *E. coli* that carry the Stx2e gene, but the role of these strains in edema disease is not known. The Shiga toxin-producing *E. coli* implicated in edema disease most commonly belong to four specific serotypes: O138:K81:NM, O139:K12:H1, O141:K85ab:H4, and O141:K85ac:H4. However, other serotypes of *E. coli* may be implicated, and strains of serogroup O147 have been dominant in parts of the USA. These O147 strains typically carry the H17 flagella, but some have H14 or H4. Some of these O147 strains are not typeable with O147 specific

antiserum but can be identified by their O antigen genes.

Pigs become infected initially by a contaminated environment or the sow. Spread of infection among penmates is facilitated by the large numbers of edema disease-producing *E. coli* that are shed by colonized pigs. Some strains of *E. coli* that cause edema disease also carry genes for enterotoxins and can cause diarrhea as well as edema disease. Ingestion of edema disease strains of *E. coli* is followed by colonization of the intestine in pigs in which intestinal epithelial cells carry receptors for the F18 pili. Expression of the receptors is age-related, so younger pigs are less susceptible to colonization than older pigs. Some pigs carry a specific mutation in a gene required for expression of the receptors and are thereby resistant to infection.

Resistance/susceptibility is determined by a single locus with a dominant susceptibility allele and a recessive resistant allele; it is possible to select resistant pigs, which can be identified by a simple PCR test that identifies presence or absence of the specific mutation. Some concern about selection for resistance to F18+ *E. coli* has been expressed, because a very high association between presence of the marker for resistance to F18+ *E. coli* and presence of the marker for stress susceptibility was shown in Swiss Landrace pigs. However, this association does not exist in Belgian pigs.

Stx2e produced in the intestine of colonized pigs is responsible for the major clinical signs and pathology seen. This cytotoxin inhibits protein synthesis, leading to cell death. The toxin is absorbed from the intestine and targets vascular endothelium in specific sites believed to have high concentrations of the toxin receptors globotriaosyl ceramide and globotetraosyl ceramide. A study showed that edema disease strains of *E. coli* may colonize the mesenteric lymph nodes and produce Stx2e there. This may be an additional site from which the toxin is absorbed into the bloodstream. The Stx2e toxin binds readily to pig RBCs, which may transport the toxin to various sites in the body. Sites highly susceptible to the toxin include the submucosa of the stomach, the colonic mesentery, the subcutaneous tissues of the forehead and eyelids, the larynx, and the brain. Damage to vascular endothelium results in edema, hemorrhage, intravascular coagulation, and microthrombosis.

High-protein diets increase the susceptibility of pigs to the disease. Factors

associated with weaning, including the stresses of mixing pigs, changes in diet, and the loss of milk antibodies from the intestine, appear to be important elements in enhancing the susceptibility of weaned pigs to the disease.

Clinical Findings: Clinical signs range from peracute death with no signs of illness to CNS involvement with ataxia, paralysis, and recumbency. Edema disease usually occurs 1–2 wk after weaning and typically involves the healthiest animals in a group. The disease is seen occasionally in nursing pigs or in adult pigs. The average morbidity is 30%–40%, and the mortality among affected pigs is often as high as 90%. Periorbital edema, swelling of the forehead and submandibular regions, dyspnea, and anorexia are common.

Lesions: Edema disease is primarily a disease of the vasculature, and gross lesions consist of subcutaneous edema and edema in the submucosa of the stomach, particularly in the glandular cardiac region. The edema fluid is usually gelatinous and may extend into the mesocolon. The edema may be accompanied by hemorrhage. Fibrin strands may be found in the peritoneal cavity, and serous fluid may be found in both the pleural and peritoneal cavities. Microscopically, a degenerative angiopathy affecting arteries and arterioles and necrosis of the smooth muscle cells in the tunica media are present. Lesions of focal encephalomalacia in the brain stem are characteristic and thought to result from vascular damage, leading to edema and ischemia.

Diagnosis: A clinical history of peracute death in healthy, well-conditioned, recently weaned pigs, along with observation of periorbital edema and extensive edema of the stomach and mesocolon, are helpful in diagnosis. There may be a characteristic squeal due to edema of the larynx. Diarrhea may precede the signs of edema disease if the *E. coli* responsible also possesses genes for enterotoxins. Characteristically, the stomach is full of dry feed. Diagnosis is easily made in an outbreak in which the full range of clinical signs and pathologic features are likely to occur. It is more difficult when only a few animals are affected or when the disease occurs in an atypical age group. Isolation and characterization of the *E. coli* are required for a definitive diagnosis. Culture of the small intestine and colon typically yields

a heavy growth of hemolytic *E. coli*, but in some cases the organism may no longer be present in the intestine at the time of death. Demonstration that the hemolytic *E. coli* isolated is an edema disease strain may be done by PCR amplification of the genes for the F18 pili and Stx2e. Recently, quantitative PCR for several pig bacterial enteropathogens, including edema disease strains of *E. coli*, was shown to be a rapid and sensitive method for detection and quantification of these bacteria in pig feces. Serotyping of the isolate is useful to track the persistence of a particular type of the organism on a farm. The F18 pili are not readily expressed on organisms that are cultured, but the genes that encode them are easily detected by PCR.

Treatment and Control: Because the onset of disease is often sudden and the course rapid, treatment is often ineffective. ● Oral medication with antibiotics via the drinking water may be used to protect clinically unaffected pigs in a herd in which cases of the disease have been detected. Antibiotic sensitivity should be determined on the isolate from an affected pig; medication should be changed if the initial choice was ineffective. Control is also

difficult. Several experimental approaches have been shown to be effective, but none are economical to date. These methods include feeding a high-fiber and low-protein diet, reducing the amount of feed given to weaned pigs, vaccinating by a systemic route with Stx2e toxoid, oral vaccination with an F18+ nontoxigenic *E. coli*, passive systemic immunization with antitoxin, and passive oral immunization with anti-F18 antibodies. Mucosal immunization with purified F18 fimbriae has proved to be ineffective, possibly because the portion of the F18 fimbria that binds to the intestine is a small fraction of the total fimbrial structure. Incomplete protection was reported after vaccination of pigs with the receptor portion of the F18 fimbriae conjugated with F4 fimbriae. Two important developments are the rapid and inexpensive methods for purification of Stx2e toxin or toxoid and the demonstration that immunization of pregnant sows with Stx2e toxoid resulted in protection of their weaned offspring against a challenge with a lethal dose of Stx2e toxin. The flagella of F18ab edema disease *E. coli* has been shown to be involved in adherence to pig intestinal epithelial cells in vitro and could be a new target for vaccines against edema disease.

ENCEPHALOMYOCARDITIS VIRUS INFECTION

Encephalomyocarditis (EMC) is a significant viral infection of swine and zoologic mammals. It is caused by members of the genus *Cardiovirus* in the family Picornaviridae and recognized in many parts of the world. Although EMC virus (EMCV) isolates from various regions and countries have differed in pathogenicity and virulence, until recently all EMC viruses were considered to exist as a single serotype (EMCV-1). A cardiovirus isolated from a wood mouse in Germany in 2012 was distinguished from EMCV-1 by serologic and molecular means and has been designated EMCV-2. Although EMCV-1 infects a wide variety of hosts, the host range and pathogenicity of EMCV-2 remains to be determined.

Swine may die acutely at any age due to associated myocardial failure or may be affected with near-term abortions, fetal

mummification, and apparent reproductive failure. Type A strains cause porcine reproductive problems, whereas type B strains cause heart failure. With the recognition of porcine reproductive and respiratory syndrome (PRRS) in 1987, however, the overall significance of EMCV-1 as a cause of reproductive disease in swine has been questioned. The high mutation rate of the PRRS arterivirus complicates the maintenance of reliable diagnostic PCR assays for that virus, while a concurrent EMCV infection may be easily detected by virus isolation. Most outbreaks of EMCV infection have been associated with captive animals in swine production units, primate research centers, and zoos. Sudden death is often the first indication of infection. A variety of exotic mammals have been fatally afflicted with EMC in zoologic parks in the USA, Australia, and other parts of the world

and have included African elephants, rhinoceroses, hippopotamuses, sloths, llamas, various antelope species, and many types of nonhuman primates (chimpanzees, orangutans, baboons, monkeys, lemurs, etc.). An episode of lion deaths at a zoo in the USA was associated with the feeding of the carcass of an African elephant that had died of EMC, and a spontaneous outbreak of fatal EMC was reported in free-ranging African elephants at Kruger National Park in South Africa in 1995. Reports of outbreaks of EMCV-associated disease are solicited and recorded at the Pirbright Institute in the UK.

Epidemiology: Cardioviruses are small, nonenveloped viruses that are almost always associated with rodents, and the disease in other mammalian species has often been attributed to spillover from populations of wild mice and rats. These, and presumably other rodent species, shed the viruses in feces and urine, which may contaminate food and water supplies of large mammals. Ingestion of rodents dead or dying of EMC may be another means of infection. Pigs shed virus in nasal secretions and feces during the first 3 days of experimental infection. During this short period, the virus may be transmitted to other pigs by contact. Cardioviruses are resistant to adverse environmental influences and may remain infective for weeks to months under favorable conditions.

Clinical Findings and Lesions: The disease is named for its predilection for the CNS and cardiovascular systems of experimental mice, and both encephalotropic and cardiotropic strains have been defined. In swine and zoologic species, however, acute and subacute deaths are almost always attributed to the destructive effects of the virus on the myocardium, with resultant cardiac insufficiency, pulmonary edema, and frothy transudation into the respiratory tract. Affected animals often appear to have asphyxiated in their own respiratory fluids. Other clinical signs may include fever, anorexia, listlessness, trembling, staggering, dyspnea, and paralysis. Mortality approaching 100% has been described in suckling swine but becomes successively lower in older age groups. Strains of EMC viruses that target the pancreas and are diabetogenic in experimental mice have been recognized, but the significance of this finding for other mammals has not been established.

EMC viruses are known to cross the placenta in swine and have been recovered

from conceptuses in cases of reproductive failure due to near-term abortions (107–111 days of gestation), stillbirths, and mummifications. Reproductive problems have been reported to involve sows of all parities, often persisting in affected herds for 2–3 mo, but the possibly more significant contribution of PRRS should be investigated.

Diagnosis: Because the pale necrotic heart muscle lesions that may be seen in fatal EMC infections are also seen in septic infarction or vitamin E/selenium deficiency, a definitive diagnosis requires virus recovery and identification. Heart, liver, kidney, and spleen collected from acutely dead animals or abortuses are the specimens of choice for virus isolation. Because EMC viruses are very stable, they may be recovered from frozen tissues.

Serologic diagnosis via virus neutralization, hemagglutination-inhibition, or ELISA is possible if acute and convalescent sera are collected, but the frequency of subclinical EMC infections makes single serum determinations of little value in aborting sows. Detection of antibody against EMC viruses in stillborn or large mummified fetuses is significant for fetal infection, however, because maternal immunoglobulins are not passed across the placenta in swine.

Treatment, Control, and Prevention:

There is no specific treatment for EMC, but mortality may be minimized by avoiding stress or excitement in animals at risk. EMC viruses appear to cycle in rodents and are most likely to affect swine and zoo animals when rodent populations are high. Rodent control is thus critical to minimize exposure of susceptible species. Prompt and proper disposal of animals that have died of the disease is also recommended. EMC viruses are inactivated by the judicious use of many disinfectants labeled for livestock use.

Killed vaccines for the prevention of myocarditis in weaned swine have been patented but are no longer commercially available in the USA except as autogenous products. The current impetus for vaccine development has come largely from zoos and amusement parks where EMC has been problematic. Success with a genetically engineered attenuated virus vaccine has been reported in primates, pigs, and various zoologic hoofstock species. Commercial EMCV vaccine production has been limited by the apparent lack of need in most domestic livestock situations.

Zoonotic Risk: EMC viruses have rarely been recognized as the cause of human illness, and the severe myocarditis and acute fatal infections seen in many other species have not been reported in people. Nevertheless, serologic surveys have revealed human

EMCV infections are common in many parts of the world; most are asymptomatic or not recognized. Human disease has been characterized by fever, chills, nausea, headache, nuchal rigidity, delirium, delusions, vomiting, photophobia, and pleocytosis.

GLÄSSER'S DISEASE

(Porcine polyserositis, Infectious polyarthritis)

Pigs can be colonized by different microorganisms before weaning, but some of those early colonizing agents are potentially pathogenic. This is the case with *Haemophilus parasuis*, a commensal organism of the upper respiratory tract of swine that causes severe systemic disease characterized by fibrinous polyserositis, arthritis, and meningitis. Disease has a sudden onset, short course, and high morbidity and mortality. Young animals (4–8 wk old) are primarily affected, although sporadic disease can be seen in adults (eg, introduction of a naive adult to a healthy herd). Survivors can develop severe fibrosis in the abdominal and thoracic cavities, which can result in reduced growth rate and carcass condemnation at slaughter. Glässer's disease is seen worldwide, and its incidence appears to have increased since the introduction of porcine reproductive and respiratory syndrome (see p 729).

Etiology: The causal agent, *H. parasuis*, is a small, gram-negative pleomorphic bacterium of the family Pasteurellaceae that requires V factor (NAD) supplementation but not X factor (hemin) for growth. In the laboratory, *H. parasuis* grows on enriched chocolate agar; it can also be cultured in blood agar with a staphylococcal nurse streak. However, *H. parasuis* is fastidious, and its isolation in pure culture from diseased animals is usually difficult and frequently complicated because of antibiotic treatments. Fifteen serovars of *H. parasuis* have been reported, but a high percentage of the evaluated isolates cannot be typed. Wide differences in serovar virulence have been described. Serovars 1, 2, 4, 5, 12, 13, 14, and some isolates that cannot be typed are usually isolated from systemic disease cases, while serovars 3, 6, 7, 9, and other nontyped isolates are frequently isolated from the upper respiratory tract. The factors involved in

systemic invasion by *H. parasuis* are still unknown. Moreover, the correlation between serovar and virulence is not clear, and strains belonging to the same serovar may vary in virulence. Serotyping also has been used as the basis to establish vaccination criteria, but the cross-protection between different serovars is variable and difficult to predict. Therefore, current methods of *H. parasuis* identification and characterization are primarily genotyping (fingerprinting or sequencing methods). The identification of virulence genes has received increased attention because of the possibility of differentiating strains with pathogenic potential as well as of developing vaccines.

Clinical Findings: Clinical signs are seen mainly in pigs 4–8 wk old, although the age of affected animals may vary, depending on the level of acquired maternal immunity.

Peracute disease has a short course and may result in sudden death without the presence of characteristic gross lesions; petechiae may be seen in some organs in these cases, indicating septicemia.

The typical clinical signs of acute Glässer's disease include high fever (41.5°C [106.7°F]), severe coughing, abdominal breathing, swollen joints, and CNS signs such as lateral decubitus, paddling, and trembling. These signs may be seen jointly or independently. Chronically affected animals may have a reduced growth rate as a result of severe fibrosis in the thoracic and peritoneal cavities.

Dyspnea and coughing not usually associated with Glässer's disease have been described, together with *H. parasuis* isolation from the lungs of pigs with catarrhal purulent bronchopneumonia and even fibrinohemorrhagic pneumonia. However, *H. parasuis* is not considered a significant cause of coughing.

Disease prevalence is modulated by concomitant environmental stressors as well as by viral infections affecting the immune system, mainly porcine reproductive and respiratory syndrome and porcine circovirus type 2 systemic disease.

Lesions: Peracute disease may cause petechiae in some tissues, with no gross lesions observed. Histologically, these pigs show septicemia-like microscopic lesions such as DIC and microhemorrhages. Increased fluid in the thoracic and abdominal cavities, without the presence of fibrin, can also be seen in peracute cases.

Acute systemic infection is characterized by development of fibrinous polyserositis, arthritis, and meningitis. The fibrinous exudate can be seen on the pleura, pericardium, peritoneum, synovia, and meninges and is usually accompanied by an increased amount of fluid. Fibrinous pleuritis may be accompanied by cranio-ventral consolidation (catarrhal-purulent bronchopneumonia). Lack of characteristic gross lesions is also common in swine showing CNS signs. Chronically affected pigs usually have severe fibrosis of the pericardium and pleura, which may or may not be present in the peritoneal cavity.

Diagnosis: Diagnosis is based on observation of characteristic clinical signs and lesions, in association with detection of *H. parasuis* in affected swine by isolation or by molecular methods such as PCR.

Most current diagnostic methods do not differentiate virulent from nonvirulent isolates, so it is important to sample only from systemic sites such as pleura, pericardium, peritoneum, joints, and brain. Isolation of *H. parasuis* from the upper respiratory tract has no relevance in the diagnosis of systemic infection. Samples

collected from clinically affected animals that were euthanized increase the chances of isolation. Recently, a multiplex PCR technique able to differentiate between virulent and nonvirulent isolates has been developed. This technique might be used to prevent introduction of pigs carrying potentially virulent strains onto farms that are free of clinical Glässer's disease.

Differential diagnoses of Glässer's disease include infections by *Streptococcus suis*, *Mycoplasma hyorhinis*, septicemic *Escherichia coli*, *Actinobacillus suis*, *Erysipelothrix rhusiopathiae*, and *Salmonella* Choleraesuis.

Treatment and Control: *H. parasuis* is one of the few gram-negative organisms that can be successfully treated with synthetic penicillin. Other antimicrobials used include ceftiofur, ampicillin, enrofloxacin, erythromycin, tiamulin, tilmicosin, florfenicol, and potentiated sulfonamides. Individual treatments must be given parenterally to see a significant effect, and all pigs in the affected group (not just those showing clinical signs) should be treated. Preventive treatments can be given via water or feed medication. Either commercial or autogenous vaccines can be used to control *H. parasuis* infection, although their efficacy has been variable. The broad range of potentially pathogenic serovars and genotypes has impaired the development of a universal vaccine for *H. parasuis*. Homologous protection between isolates from the same serovar group is relatively satisfactory, whereas heterologous protection is restricted to a few serovars. So far, several "universal" (independent of serovar) vaccine prototypes have been experimentally developed but are not yet commercially available.

NIPAH VIRUS INFECTION

(Porcine respiratory and neurologic syndrome, Barking pig syndrome)

Nipah virus disease is a relatively newly discovered disease of swine and people associated with infection with a novel paramyxovirus named Nipah virus. This disease emerged in Malaysia in 1998 and 1999. It was linked to severe encephalitis among people occupationally exposed to infected pigs in Malaysia and Singapore. The

disease was eradicated from the national commercial swine population by control efforts. Fruit bats of the genus *Pteropus* appear to be reservoirs of the virus.

Etiology and Epidemiology:

The etiologic agent, Nipah virus (genus *Henipavirus*, family *Paramyxoviridae*),

is an enveloped, negative-sense, single-stranded RNA virus. The virus is closely related to Hendra virus (*see* p 707), the only other member of the genus. The human outbreak in Malaysia and Singapore followed contact with infected swine and resulted in encephalitis with ~40% case mortality. The virus is assumed to have been introduced into the swine population from one of the two species of *Pteropus* found with antibodies during investigation of the outbreak. *Pteropus* spp range from the Western Pacific through southeast Asia, and south Asia down through coastal African islands, including Madagascar. Several species of *Pteropus* have been found with antibodies, suggesting that the virus or closely related viruses occur in other areas within the range of this genus of bats. In Malaysia, genetic analysis of virus from human and swine clinical materials strongly supported a single introduction of the virus with spread through the commercial swine population. There was evidence of infection among several other species of domestic animals, including dogs, cats, and horses. Human encephalitis caused by Nipah viruses in south Asia has been a regular occurrence since 2001 in Bangladesh and more recently in adjacent areas of India. In these areas, epidemiology has not supported the role of intermediary domestic species but rather more direct transmission from the flying fox reservoir of the virus. More recently, fruit bats belonging to the family Pteropidae, but not the genus *Pteropus*, were found to harbor related viruses in Africa.

Transmission and Pathogenesis:

Infection in pigs is assumed to have been a transfer from the reservoir bat species to pigs. Once the virus was introduced into an intensive swine husbandry setting, infection of animals within premises was rapid, and serologic tests suggested that nearly all pigs on an affected premise were infected. Transmission between premises was thought to be by poor biosecurity procedures and movement of infected animals. Experimental infection of swine with Nipah virus in a high biosecurity facility in Geelong supported that transmission between swine in close contact occurred readily. In south Asia, infection of people appears to occur by indirect means from the reservoir fruit bats; contamination of sap collected in pots on palm trees is a recurring means of infection in regular cases occurring in Bangladesh. Other similar circumstances, such as contact with trees contaminated by bats or consumption of fruit partially eaten

by bats, are other documented means of infection in Bangladesh. Person-to-person transmission, although not evident in Malaysia, has also occurred in south Asia.

Clinical Findings: Because of the danger of human infection from infected pigs and the emergency setting, clinical observations were not detailed in the field during the original epidemic. Most pigs developed a febrile respiratory disease with a severe cough that led to the local names for the disease—"barking pig syndrome" and "one-mile cough." Encephalitis was also noted, particularly in the sows and boars in affected facilities. The proportion of animals with each form of the disease is uncertain, although the respiratory form predominated. Overall mortality within affected facilities was also not well documented but probably was not >5% among all age groups.

Diagnosis: Laboratory diagnosis can be made by isolation of the virus, identification of the RNA by use of reverse transcriptase-PCR, detection of antigens in tissues by immunohistochemical staining with specific antibodies, or serologic tests such as indirect ELISA and virus neutralization tests. The virus is considered biosafety level 4 in the USA and Australia, and stringent laboratory containment at limited laboratories is a special consideration.

Treatment: Treatment of affected swine was not attempted during the Malaysian emergency. Human patients required intensive care with ventilation support to manage the encephalitis; no specific treatment is available. Ribavirin was administered to some patients, but subsequent studies in laboratory animals suggest that it is ineffective.

Control and Prevention: Control of the epidemic/epizootic in Malaysia was dependent on the initiation of strict quarantine procedures and the slaughter of all swine from affected facilities. Adherence to appropriate biosecurity and quarantine procedures within facilities, as with other contagious diseases, is of paramount importance in preventing spread of the infection. An active surveillance and slaughter program successfully eliminated the virus from the national commercial swine population, which has remained free of infection. Presence of the virus in reservoir species of bats in a wide geographic range emphasizes the importance of good disease surveillance and

biosecurity practices to promote early detection and confine the disease to initial premises should reintroduction occur.

Zoonotic Risk: Transmission of the virus from infected pigs to people was largely in an occupational setting, and a study of risk factors associated with human infection suggests that close contact with live infected swine was the means of infection

of nearly all human Nipah virus infections in Malaysia.

Continued sporadic clusters in horses and subsequent human cases with Hendra virus in Australia, with serious disease in some of these clusters, emphasize the importance of use of appropriate personal protective equipment in veterinary clinical examinations or postmortem procedures when Hendra or Nipah virus infection is suspected.

PORCINE CIRCOVIRUS DISEASES

(Postweaning multisystemic wasting syndrome, Porcine dermatitis and nephropathy syndrome)

A novel, noncytopathogenic, picornavirus-like contaminant in the porcine kidney cell line PK-15 (ATCC-CCL33) was described in 1974. This agent was later shown to be a small, nonenveloped virus containing a single-stranded, circular DNA genome; it was named porcine circovirus (PCV). PCV antibodies in swine were found to be widespread, and experimental infections with this virus in pigs did not result in clinical disease, suggesting that PCV was nonpathogenic.

A new disease was described in Western Canada during the early and mid 1990s. The etiology was unknown, and the condition was named postweaning multisystemic wasting syndrome (PMWS). Affected pigs, mainly nursery pigs, showed primarily poor growth rate, ill thrift, and/or wasting, and they were histopathologically characterized by systemic inflammatory lesions. In the late 1990s, an apparently novel PCV-like virus was isolated from PMWS-affected pigs. The new virus was antigenically and genetically distinct from the PCV contaminant of PK-15 cell cultures. Subsequently, PCV isolates from diseased pigs were designated as porcine circovirus type 2 viruses (PCV2) and the original PCV from PK-15 cell cultures as porcine circovirus type 1.

PCV2 has been further associated with a number of disease syndromes in pigs, so the term porcine circovirus disease (PCVD) was proposed as a collective name. Recently, the terms PCV2-systemic disease (PCV2-SD) and PCV2-reproductive disease (PCV2-RD) have been proposed to replace PMWS and PCV2-associated reproductive failure, respectively. Moreover, it is currently thought that the most important

PCVD is the PCV2-subclinical infection (PCV2-SI), which is linked with growth retardation without overt clinical signs. Porcine dermatitis and nephropathy syndrome (PDNS) is also included as a PCVD, although there is still no proof of PCV2 as the antigen linked with this immunocomplex disease. PCV2 has also been associated with porcine respiratory disease complex, although its impact is probably linked to the occurrence of PCV2-SD. PCV2-SD and PCV2-SI are the PCVDs considered to severely impact swine production worldwide, but the introduction of efficacious vaccines to the market has largely ameliorated their effects.

Etiology and Pathogenesis: Circoviruses are small (17–22 nm in diameter), nonenveloped viruses that contain a single strand of circular DNA. There are two types of porcine circovirus, although only PCV2 is considered pathogenic. Phylogenetic studies have shown that at least three genotypes of PCV2 exist (PCV2 a, b, and c). Recent studies suggested a genotype shift (from a to b; PCV2c has been retrospectively detected in Denmark during the 1980s) coincidental with major outbreaks of PCV2-SD in North America, Japan, and some European countries. It is not clear whether differences in virulence exist among or within PCV2 genotypes.

Serologic surveys show that PCV2 is widespread in swine, independent of the PCV2-SD status of the farm. Results from retrospective serologic studies indicate that PCV2 has been infecting pigs for >50 years so far, and phylogenetic studies indicate that PCV2 has probably circulated in pigs during the past 100 years.

Initially, PCV2-SD was identified in high health herds that were free of most common swine pathogens. However, under field conditions, swine that show signs of PCV2-SD usually are infected with multiple agents, including porcine parvovirus, porcine reproductive and respiratory syndrome virus, *Mycoplasma hyopneumoniae*, *Actinobacillus pleuropneumoniae*, *Pasteurella multocida*, *Haemophilus parasuis*, *Staphylococcus* spp, and *Streptococcus* spp.

Accounts of multiple attempts to experimentally reproduce PCV2-SD have been published. Some early trials (using tissue homogenates from pigs affected with PCV2-SD or a PCV2 isolate) reproduced PCV2-SD-like histologic lesions but not the wasting condition. However, occasional studies subsequently reproduced clinical disease and lesions consistent with PCV2-SD using only PCV2, presumably, as inoculum. Consequently, it was suggested that PCV2 infection, linked to other cofactors, was necessary for the consistent development of full clinical disease. It appears that a number of factors, such as age and source of pigs, environmental conditions, genetics, the nature of the PCV2 inoculum used, and the immunologic status of the pig at PCV2 infection, play a significant role in the consistent experimental reproducibility of the disease. In fact, the more consistent and repeatable PCV2-SD disease models have been obtained using infectious and noninfectious cofactors as triggers. Also, the coinfection of PCV2a and b genotypes has been linked to reproduction of clinical disease under experimental conditions. The mechanisms by which other viruses or immunostimulation may trigger the development of wasting in PCV2--infected pigs is still unknown. High loads of PCV2 in blood, lymphoid, and other tissues and in potential excretion routes are associated with the expression of disease.

When multisystemic disease and wasting is apparent, damage to the immune system is the main feature suggesting that affected pigs have an acquired immunodeficiency. Lymphocyte depletion of lymphoid tissues, changes in peripheral blood mononuclear cell subpopulations, and altered cytokine expression patterns have all been demonstrated in pigs naturally and experimentally affected with PCV2-SD.

The identification of cells that support PCV2 replication has been a matter of controversy. The large amount of PCV2 virus antigen found in the macrophages and dendritic cells of diseased pigs appears to be the result of accumulation of viral

particles. However, epithelial and endothelial cells seem to be the main target for PCV2 replication, as well as a small proportion of macrophages and lymphocytes.

Much less is known regarding the pathogenesis of other PCVDs. PCV2 is able to replicate in fetuses as well as in zona pellicula-free embryos. Moreover, an experiment with embryos exposed to PCV2 and then transferred to receptor sows suggested that infection can lead to embryonic death. Therefore, it is believed that one of the potential outcomes of PCV2 infection in sows could be return to estrus. Transplacental transmission of PCV2 has been demonstrated. However, experiments using pregnant sows inoculated intranasally have yielded variable results. When successful, those studies have shown that PCV2 may cause fetal death, similar to that of porcine parvovirus, with live pigs together with dead piglets and mummies of different sizes.

PDNS is considered a type III hypersensitivity reaction in which the antigen present in the immune complexes is unknown. It has been speculated that PCV2 could be the antigen, but there is no definitive proof that PCV2 causes PDNS lesions. Indirect evidence exists, such as significantly higher serum antibody titers to PCV2 in affected pigs compared with healthy or PCV2-SD-affected pigs.

Epidemiology and Transmission:

PCV2 is considered a ubiquitous virus in countries with and without PCVDs, including PCV2-SD. PCV2 infection and PCV2-SD have also been described in wild boars. The disease has been reported worldwide.

Transmission may be by direct contact with infected pigs. PCV2 has been detected in almost all potential excretion routes such as nasal, ocular, and bronchial secretions; saliva; urine; and feces. The virus can be found in semen, but the practical importance of this is probably negligible. Artificial insemination (AI) of sows with PCV2-infected semen from experimentally inoculated boars did not result in sow infection or fetal infection. However, when such AI was performed with PCV2-spiked semen, reproductive problems were developed. Therefore, it seems that reproductive disease linked to AI is possible, but only when semen has a high virus load, which is unlikely under natural conditions. Although not demonstrated, it is assumed that contact with contaminated fomites, exposure to contaminated feeds or biologic products, multiple use of

hypodermic needles, or biting insects may play a role in transmission.

PCV2 may persist in swine for several months under either experimental or field conditions. Convalescent swine may carry virus for extended periods and be important in disease transmission. PCV2 is fairly resistant to commonly used disinfectants and to irradiation, probably allowing it to accumulate in the environment and be infective for new groups of susceptible pigs if rigorous sanitary measures are not followed. The decline of colostral antibody titer in pigs is associated with onset of PCV2-SD in late nursery or finishing pigs. Transplacental infection with PCV2 has been documented, but it is not known whether pigs infected in utero are able to subsequently develop clinical PCV2-SD.

Some reports have suggested that animals other than swine may be infected with PCV2 or PCV-like viruses. However, results of serologic studies for antibody against PCV in cattle and other livestock have been contradictory, and experimental induction of disease using PCV1 or PCV2 in species of livestock other than swine has not been successful. Mice may be able to replicate and harbor the virus.

Clinical Findings: PCV2-SD is characterized by overt weight loss. Disease often occurs in the fattening units in pigs 8–18 wk old, although the disease can be also seen in older or younger pigs. Morbidity is typically 5%–20% among cohorts in the late nursery or finishing stages. Mortality in swine with signs of PCV2-SD can occasionally be >50%. In addition to death loss, PCV2-SD in finishing pigs may cause a substantial increase in time to reach market weight, resulting in economic loss. Growth retardation, wasting, and dyspnea are the clinical signs seen most frequently in outbreaks. Pallor, anemia, jaundice, diarrhea, and palpable inguinal lymphadenopathy also are seen in some affected pigs. A low-grade fever (104°–106°F [40°–41°C]) that lasts several days may be seen as well. Overcrowding, poor air quality, insufficient air exchange, and commingled age groups seem to exacerbate the course of the disease. Usually, only a few pigs in a group show wasting. The onset of disease may be acute, leading to death within a few days in some pigs. Other pigs show a more chronic disease and fail to gain weight or thrive.

PCV2-SI is believed to occur in pigs that become infected with the virus and suffer from growth retardation (significantly lower average daily weight gain [ADWG]) but not overt clinical signs. In fact, in a farm affected

by PCV2-SD, a variable proportion of pigs developed the systemic disease, while most had only subclinical infection. PCV2-SI had been unnoticed for many years until the advent of vaccines drew attention to this condition. Vaccinated pigs have an increased ADWG compared with nonvaccinated, apparently healthy counterparts. Such difference has been demonstrated to vary between 10–40 g/d, depending on the farm.

PCV2-RD characterized by late-term abortions and stillbirths in the absence or presence of other well-known reproductive pathogens seems to be the hallmark of clinical PCV2 infection in sows. Most of these descriptions come from North America and usually occur in start-up herds. Return to estrus due to embryonic death as a potential outcome of intrauterine PCV2 infection has been suggested based on experimental data. However, there are no field data unequivocally supporting this effect.

PDNS may affect nursery and growing pigs and, sporadically, adult animals. The prevalence of the syndrome in affected herds is relatively low (<1%), although higher prevalences (>20%) have been described occasionally. Pigs with severe acute disease die within a few days after the onset of clinical signs, due to acute renal failure with a significant increase in serum levels of creatinine and urea. Surviving pigs tend to recover and gain weight 7–10 days after the beginning of the syndrome. Affected pigs have anorexia, depression, prostration, stiff gait and/or reluctance to move, and normal temperatures or mild fever. The most obvious sign in the acute phase is the presence of irregular, red-to-purple macules and papules on the skin of the hindlimbs and perineal area, although distribution may be generalized in severely affected animals. With time, the lesions become covered by dark crusts and fade gradually (usually in 2–3 wk), sometimes leaving scars.

Lesions: PCV2-SD is diagnosed by characteristic histopathologic findings in affected pigs. Grossly, lymph nodes may be substantially enlarged and pale on cut surface, the thymus atrophied, and the tonsils thinner than normal. Splenic infarcts also may be present in a low proportion of pigs affected with PCV2-SD. Histopathologic lymphoid lesions are characteristic, showing lymphocytic depletion and granulomatous inflammation, sometimes with the presence of multinucleate giant cells and amphophilic botryoid intracytoplasmic inclusion bodies of different sizes caused by accumulation of PCV2 particles.

Lesions in the lung are common in affected pigs; their severity is influenced by duration of disease and presence of concurrent infections. Gross lung lesions may include failure to collapse, firmness, diffuse pulmonary edema, mottling, and consolidation. Microscopically, a variable degree of lymphohistiocytic interstitial pneumonia to granulomatous bronchiointerstitial pneumonia with bronchiolitis and bronchiolar fibrosis can be seen.

Grossly, the liver may appear icteric and/or atrophic in a low proportion of affected pigs. Interlobular connective tissue may be prominent. Microscopic lesions range from single cell necrosis (apoptosis) with mild lymphocytic infiltration of portal zones to extensive lymphohistiocytic periportal hepatitis with diffuse necrosis of hepatocytes. The kidneys may be enlarged and show scattered to diffuse white foci on the cortical surface. Microscopic lesions include interstitial lymphohistiocytic infiltration. Other lesions seen in affected pigs include gastric ulceration (probably due in part to a prolonged fattening period in chronically affected pigs) and occasional multifocal lymphohistiocytic myocarditis. In severely affected pigs, lymphohistiocytic infiltrates can be seen in virtually all tissues.

PCV2-SI pigs do not show gross lesions attributable to PCV2 infection. These animals may show microscopic lymphoid lesions similar to those seen in pigs with PCV2-SD, although only to a mild degree.

In PCV2-RD, stillborn and nonviable neonatal piglets show chronic passive congestion of the liver and cardiac hypertrophy with multifocal areas of myocardial discoloration. The key histopathologic feature is fibrosing and/or necrotizing myocarditis in fetuses.

PDNS is easy to detect from a clinical point of view because of the red-to-dark macules and papules, which correspond microscopically to necrosis and hemorrhage secondary to necrotizing vasculitis of dermal and hypodermal capillaries and arterioles. Necrotizing vasculitis is a systemic feature, but it is more prominent in the skin, renal pelvis, mesentery, and spleen (splenic infarcts may also be present as a result of necrotizing vasculitis of splenic arteries or arterioles). Apart from skin lesions, pigs that die acutely with PDNS have firm, bilaterally enlarged kidneys, with a fine granular cortical surface and edema of the renal pelvis. The renal cortex displays multiple, small, reddish pinpoint lesions, similar to petechial hemorrhages, which microscopically correspond to enlarged and inflamed glomeruli (fibrinonecrotizing glomerulitis).

Histologically, a moderate to severe nonpurulent interstitial nephritis with dilation of renal tubules is also seen. Usually, both skin and renal lesions are present, but in some cases, skin or renal lesions may occur alone. Lymph nodes may be enlarged and red due to blood drainage from affected zones with hemorrhages (mainly skin). Histopathologically, PCV2-SD-like lesions such as lymphocyte depletion and histiocytic and/or multinucleate giant cell infiltration (although less severe) are usually found in lymphoid tissues of affected pigs, although to a milder degree.

Diagnosis: The PCV2-SD case definition includes three main diagnostic criteria:

- 1) clinical signs of wasting or ill thrift,
- 2) presence of gross and microscopic (moderate and severe) lesions characteristic of the disease, and
- 3) presence of viral antigen or DNA (moderate to high amount) in the microscopic lymphoid lesions.

Visualization of viral DNA or antigen in lesions is usually done using in situ hybridization or immunohistochemistry, respectively, and moderate to high amounts of virus are linked to the disease. A herd case definition has been proposed, which includes two main criteria: 1) significant increase of mortality and number of runt pigs or pigs failing to gain weight or thrive in comparison to previous values for the farm, and 2) fulfillment of the three individual criteria listed above in at least one of five examined pigs. Differential diagnoses include conditions causing increased mortality and growth retardation, such as PRRS, chronic respiratory disease, Glässer's disease, salmonellosis, porcine intestinal adenomatosis, and many others.

Because PCV2 is ubiquitous and the virus replicates in individual pigs for weeks to months, isolation of virus, detection of PCV2 DNA in serum or tissues, or detection of PCV2 antibodies in serum is not sufficient to establish a diagnosis of PCV2-SD. Antibodies against PCV2 may be detected by ELISA, indirect fluorescent antibody, or immunoperoxidase staining of infected cell cultures. Viral isolation can be done on several porcine cell lines (mainly porcine kidney cells) using serum, bronchiolar lavage fluid, or tissue homogenates. Viral DNA can be detected using PCR in most tissues or in serum from affected pigs. Several tissue samples from multiple pigs may be required for detection of virus in cases of chronic disease. Virus quantification in serum by real time quantitative PCR (qRT-PCR) has been suggested as a potential diagnostic method in live pigs. Values of

>107 PCV2 genome copies/mL of serum usually have been linked with PCV2-SD occurrence. However, PCV2 infection is extremely common in clinically healthy pigs, and interpretation of positive qRT-PCR results is not always straightforward.

The diagnostic approach of PCV2-SI is of less interest for clinicians, because lack of overt clinical signs plus demonstration of infection by PCR would be enough to establish such a diagnosis. Values of >105 or 106 PCV2 genome copies/mL of serum usually have been linked with the subclinical infection.

The diagnosis of PCV2-RD should include the following criteria: 1) late-term abortions and stillbirths, sometimes with hypertrophy of the fetal heart, 2) extensive fibrosing and/or necrotizing myocarditis, and 3) high concentrations of PCV2 in the myocardial lesions and other fetal tissues. Differential diagnoses for PCV2-RD include PRRS, porcine parvovirus, pseudorabies (Aujeszky disease), leptospirosis, and other diseases that cause late abortions, stillbirths, and weak piglets. So far, there are no formal criteria to diagnose a putative return to estrus associated with PCV2 infection. However, the occurrence of such signs together with evidence of viral circulation during the clinical episode should be demonstrated.

The case definition for PDNS is relatively simple and includes two main criteria: 1) presence of hemorrhagic and necrotizing skin lesions, mainly located on the hindlimbs and perineal area, and/or swollen and pale kidneys with generalized cortical petechiae, and 2) presence of systemic necrotizing vasculitis as well as necrotizing and fibrinous glomerulonephritis. From a diagnostic point of view, detection of PCV2 is not included in the diagnostic criteria.

Differential diagnosis of PDNS depends on the most significant pathologic outcome. Cutaneous manifestations may be confused with classical and African swine fever, swine erysipelas, septicemic salmonellosis, infection with *Actinobacillus suis*, porcine stress syndrome, transit erythema (urine-soaked floors, chemical burns, etc), and other bacterial septicemias. Differential diagnoses for kidney lesions include classical and African swine fever, swine erysipelas, and septicemic salmonellosis. Serum biochemical analyses may help differentiate PDNS from other diseases; urea and creatinine concentrations are markedly increased.

Treatment and Control: Because PCV2-SD is a multifactorial disease,

effective control measures before the advent of PCV2 vaccines were focused on control or eradication of these triggers. The most widely used control measures were the use of antibiotics to prevent concurrent bacterial infections, improvement of biosecurity and sanitary measures such as isolation of affected pigs and disinfection of pens after their use, decreasing stressors (eg, high stocking density, inadequate ventilation, inadequate temperature control), and control of concomitant viral infections, especially PRRS. Other prevention and control measures used on young pigs before the anticipated time of onset include injection of vitamins, IP injection of serum harvested from finishing pigs, and vaccination against common pathogens.

Currently, control of PCV2-SD as well as PCV2-SI is based on use of PCV2 vaccines. There are four major commercial vaccines worldwide (plus a higher number with regional availability, mainly in southeast Asia). The first commercial vaccine was based on an inactivated PCV2 isolate and was licensed for use in sows and gilts. The same vaccine was later licensed for use in piglets. Subsequently, three more vaccines have been developed, all for use in piglets ~2–3 wk old or older. Two of these are subunit vaccines (PCV2 capsid protein produced in a baculovirus system), and the third is an inactivated virus constructed by replacing the capsid gene of the nonpathogenic PCV1 with that of PCV2. In addition to significantly reducing mortality and runt percentages, these vaccines seem to improve ADWG, batch uniformity, slaughter weight uniformity, and feed conversion rate.

All commercial PCV2 vaccines are based on PCV2a isolates, but cross-protection has been demonstrated against PCV2b. All PCV2 vaccines are able to generate both cellular and humoral immune responses, which are believed to be the key features to control the subsequent PCV2 infection that occurs under field conditions.

No treatment has proved successful for PDNS. Only those epizootic cases with moderate to high morbidity and mortality rates may be important in terms of economic losses. Treatment using a wide range of antimicrobial agents has been unsuccessful. Because the antigen responsible for triggering PDNS is not known, no preventive recommendations are indicated. Importantly, the use of PCV2 vaccines worldwide has significantly reduced occurrence of this condition, emphasizing the putative implication of PCV2 in its pathogenesis.

PORCINE HEMAGGLUTININATING ENCEPHALOMYELITIS

(Vomiting and wasting disease, Coronaviral encephalomyelitis)

Porcine hemagglutinating encephalomyelitis, a viral disease of young pigs, is characterized by vomiting, constipation, and anorexia and results either in rapid death or chronic emaciation (vomiting and wasting). Also, motor disorders due to acute encephalomyelitis (hemagglutinating encephalomyelitis) are often seen during field outbreaks.

Etiology, Epidemiology, and Pathogenesis:

The causal coronavirus, porcine hemagglutinating encephalomyelitis virus (PHEV), is of a single antigenic type, and it grows in several types of porcine cell cultures, in which it causes syncytia. It agglutinates RBCs of several animal species. Pigs are the only natural host. The virus is spread via aerosol. It has no public health significance.

Based on virus detection and/or serology, PHEV Infection has been reported from several countries in Europe and from North and South America (Argentina), Australia, and Asia (China, Taiwan, South Korea); thus, it appears to be widespread. The virus is endemic in most breeding herds, and a herd immunity exists. The infection usually remains subclinical. Immune sows transfer maternal antibodies to their piglets, which are protected until they have developed an age resistance; thus, clinical outbreaks are rare. However, if the virus enters a susceptible herd with neonatal piglets, morbidity and mortality may be high.

The virus first replicates in the nasal mucosa, tonsils, lungs, and to a very limited extent, in the small intestine. From these sites of entry, the virus invades defined nuclei of the medulla oblongata via the peripheral nervous system and subsequently spreads to the entire brain stem, and possibly to the cerebrum and cerebellum. Vomiting is thought to be caused by viral replication in the vagal sensory ganglion. Wasting is due to vomiting and delayed emptying of the stomach, which is the result of virus-induced lesions in the intramural plexus. Infection of cerebral and cerebellar neurons may cause motor disorders.

Clinical Findings: Both clinical syndromes, the vomiting and wasting disease

(VWD) and the encephalitic forms, are confined almost exclusively to pigs <4 wk old. The "VWD form" has an incubation period of 4–7 days. Repeated retching and vomiting are seen. Pigs start suckling but soon stop, withdraw from the sow, and vomit the milk they have ingested. They dip their mouths into water bowls but drink little, possibly indicative of pharyngeal paralysis. The persistent vomiting results in a rapid decline of condition. Neonatal pigs become dehydrated, cyanotic, and comatose and die. Older pigs continue to vomit, although less frequently than in the early stage of the disease. They lose appetite and become emaciated. A large distention of the cranial abdomen can develop. This "wasting" state may persist for 1–6 wk until the pigs die of starvation. Mortality approaches 100% within the litter, and survivors remain permanently stunted.

The "encephalomyelitic form" also starts with vomiting, usually 4–7 days after birth. Vomiting continues intermittently for 1–2 days, but it is rarely severe and does not result in dehydration. After 1–3 days, generalized muscle tremors and hyperesthesia are seen. The pigs tend to walk backward, often ending in a dog-sitting position. They soon become weak, are unable to rise, and paddle their limbs. Blindness, opisthotonos, and nystagmus also occur. After a few days, they become dyspneic, comatose, and die. More recently, some outbreaks have been reported from Taiwan and South Korea in which pigs 30–50 days old showed motor disorders. Morbidity and mortality of the encephalomyelitic form are high (as much as 100%) in neonatal pigs but both decrease with increasing age. Both clinical forms of PHEV infection may be seen during an outbreak on the same farm.

From onset to disappearance, an outbreak on a farm lasts 2–3 wk. Disappearance of disease coincides with the development of immunity in sows in late pregnancy, which subsequently protects piglets via maternal antibodies.

Lesions: Cachexia and abdominal distention are seen in chronically affected pigs. Their stomachs are dilated and filled with gas. Microscopically, perivascular

cuffing, gliosis, and neuronal degeneration are found in the medulla in 70%–100% of pigs with nervous signs and in 20%–60% of pigs with VWD. Neuritis of peripheral sensory ganglia, particularly the trigeminal ganglia, is seen regularly. Degeneration of the ganglia of the stomach wall and perivascular cuffing are found in 15%–85% of pigs with VWD. The lesions are most pronounced in the pyloric gland area.

Diagnosis: A laboratory diagnosis can be made routinely by virus isolation from the brain stem and, to be successful, the pigs are preferably euthanized within 2 days after signs appear. It is difficult to isolate the virus from pigs that have been affected for >2–3 days. Other diagnostic techniques, based on antigen or nucleic acid (RT-PCR) detection, have been developed and applied recently.

A significant rise in antibody titer can be demonstrated in paired serum samples. Because of the rather long incubation period, pigs may start to build up a low antibody titer 2–3 days after the first signs

appear. Therefore, the acute serum must be collected immediately after disease starts.

Differential diagnoses include pseudorabies (*see* p 1300) and teschovirus encephalomyelitis (*see* p 1307). Respiratory signs in older pigs and abortions in sows are part of a pseudorabies outbreak. In teschovirus encephalomyelitis, older pigs are usually involved.

Control: There is no treatment. Once signs are evident, the disease runs its course. Spontaneous recoveries are rare. Piglets born from nonimmune sows during the outbreak can be protected by being injected, at birth, either with hyperimmune serum or, if this is not available, with pooled serum collected from older sows at a slaughterhouse. However, the time lapse between diagnosis and cessation of the disease is usually too short for this procedure to be effective. Maintaining the virus on the farm (thus retaining naturally induced immunity in the sows) avoids outbreaks in piglets.

PORCINE REPRODUCTIVE AND RESPIRATORY SYNDROME

Porcine reproductive and respiratory syndrome (PRRS) was first reported in the USA in 1987. Since then, outbreaks of PRRS and successful isolation of the virus have been confirmed throughout North America and Europe.

Etiology and Epidemiology: The etiologic agent is a virus in the group Arteriviridae. The virus is enveloped and ranges in size from 45 to 80 nm. Inactivation is possible after treatment with ether or chloroform; however, the virus is very stable under freezing conditions, retaining its infectivity for 4 mo at -70°C (-94°F). As the temperature rises, infectivity is reduced (15–20 min at 56°C [132.8°F]).

After infection of a naive herd, exposure of all members of the breeding population is inconsistent, leading to development of naive, exposed, and persistently infected subpopulations of sows. This situation is exacerbated over time through the addition of improperly acclimated replacement gilts and leads to shedding of the virus from

carrier animals to those that have not been previously exposed.

The primary vector for transmission of the virus is the infected pig. Contact transmission has been demonstrated experimentally, and spread of virus from infected seedstock originating from a single source has been described. Introduction of infected seedstock can lead to the introduction and coexistence of genetically diverse isolates of PRRS virus on the same farm. Controlled studies have indicated that infected swine may be longterm carriers, with adults able to shed PRRS virus for up to 86 days after infection, and weaned pigs able to harbor virus for 157 days. Experimentally infected boars can shed virus in the semen up to 93 days after infection.

Aerosol transmission of the virus has been confirmed as an indirect route of transmission and may depend on isolate pathogenicity. Highly virulent isolates that produce high titers of virus in blood and tissues have been shown to be spread via aerosols at a significantly higher frequency

than less pathogenic isolates. Environmental factors, such as wind direction and velocity, significantly impact spread via this route as well. PRRS virus can also be transmitted by fomites, such as contaminated needles, boots, coveralls, transport vehicles, and shipping containers. Farm personnel are not a risk, unless hands are contaminated with blood from viremic pigs. Finally, transmission via certain species of insects (mosquitoes [*Aedes vexans*] and house flies [*Musca domestica*]) has been reported.

Clinical Findings: PRRS appears to have two distinct clinical phases: reproductive failure and postweaning respiratory diseases. The reproductive phase of the disease includes increases in the number of stillborn piglets, mummified fetuses, premature farrowings, and weak-born pigs. Stillbirths and mummies may increase up to 25%–35%, and abortions can be >10%. Anorexia and agalactia are evident in lactating sows and result in increased (30%–50%) preweaning mortality. Suckling piglets develop a characteristic thumping respiratory pattern, and histopathologic examination of lung tissue reveals a severe, necrotizing, interstitial pneumonia. PRRS is capable of crossing the placenta in the third and possibly second trimester of gestation. Piglets may also be born viremic and transmit the virus for 112 days after infection. Performance after weaning is also affected. Infection with PRRS virus results in destruction of mature alveolar macrophages, which has led to the hypothesis that infection results in immune suppression; however, controlled studies indicate that the virus may actually enhance specific parameters of the immune response.

Outbreaks of the reproductive form of PRRS have been reported to last 1–4 mo, depending on the facilities and initial health status of the pigs. In contrast, the postweaning pneumonic phase can become chronic, reducing daily gain by 85% and increasing mortality to 10%–25%. Numerous other pathogens are commonly isolated along with PRRS virus from affected nursery or finishing pigs. Other bacteria such as *Streptococcus suis*, *Escherichia coli*, *Salmonella* Choleraesuis, *Haemophilus parasuis*, and *Mycoplasma hyopneumoniae* have been reported, as well as viruses such as porcine respiratory coronavirus and swine influenza virus. Finally, differences in the clinical response to PRRS virus may also be due to strain variation. Studies have demonstrated the ability of different isolates to induce varying degrees of

interstitial pneumonia in cesarean-derived/colostrum-deprived (CD/CD) piglets after intranasal inoculation.

Diagnosis: The most commonly used serologic assay is the ELISA. It measures IgG antibodies to PRRS virus. It cannot measure the level of immunity in an animal or predict whether the animal is a carrier. Titers are detected within 7–10 days after infection and can persist for up to 144 days. Tests for PRRS virus include PCR, virus isolation, and immunohistochemistry. Nucleic acid sequencing of the open reading frame 5 region of the virus is an excellent tool for epidemiologic investigations in the field to confirm similarity between isolates recovered from different sites. Recently, oral fluid sampling has been widely applied as a means to sample a population of pigs. This method is cost effective and convenient and can be used for both virus and antibody detection at the pen level.

Treatment and Control: Currently, there are no effective treatment programs for acute PRRS. Attempts to reduce fever using NSAIDs (aspirin) or appetite stimulants (B vitamins) appear to have minimal benefit. The use of antibiotics or autogenous bacterins to reduce the effects of opportunistic bacterial pathogens has also been reported; however, results have been mixed.

Prevention of infection appears to be the primary means of control. Understanding the PRRS status of replacement gilts and boars, as well as proper isolation and acclimatization of incoming stock, are critical measures to prevent viral introduction. Pigs should be retested on arrival at the isolation facility and 45–60 days later, before entry to the herd. Elimination of existing infection by multisite production and segregated early weaning has also been described. Although these strategies have had some success, the longterm risks of reinfection appear high. Prevention of viral spread by nursery depopulation has been described. This is successful when virus transmission is not occurring in the sow herd (usually 12–18 mo after initial outbreak), but the nurseries and growing/finishing pigs are still infected. All nursery pigs are removed from the farm to be finished elsewhere. The nurseries are then aggressively washed and disinfected and left empty for 7–14 days, after which they can be used normally. The technique has successfully eliminated PRRS virus from several herds, and pigs have remained

seronegative (for >1 yr) to market age; production in the nurseries has improved, both in growth rate and mortality.

Commercial modified-live vaccines have been licensed and have been effective in controlling outbreaks, reducing shedding, and preventing economic losses.

Elimination of PRRS virus has been demonstrated to be possible on an individual farm basis. Methods such as whole herd depopulation-repopulation, test and removal, and herd closure have been documented as effective methods to eliminate PRRS virus from endemically infected herds. Unfortunately, a number of eradication efforts have failed because of introduction of new isolates through

unidentifiable routes. This has resulted in an increased level of biosecurity on farms. Strict quarantine and testing programs, the purchase of PRRS virus-naïve breeding stock and semen, sanitation of transport vehicles, and strict protocols of fomite and personnel movement between farms are critical components of an effective program. Recent advances in monitoring the status of artificial insemination centers include PCR analysis of blood samples collected from the auricular vein (blood swab). In addition, the application of air filtration to artificial insemination centers and breeding herds has been shown to significantly reduce the risk of airborne entry of the virus.

STREPTOCOCCAL INFECTIONS IN PIGS

Of the bacterial group of gram-positive cocci comprising the genera *Streptococcus*, *Enterococcus*, and *Peptostreptococcus*, streptococci constitute the most significant pathogens of swine. Streptococci are also associated with infectious conditions of people, cattle, sheep, goats, and horses. Relative to pigs, *S suis* (an α -hemolytic *Streptococcus*) is by far the most important agent of infectious diseases in this group, affecting mainly nursing and recently weaned pigs. Septicemia, meningitis, polyserositis, polyarthritis, and broncho-pneumonia are associated with *S suis* infections. *Streptococcus dysgalactiae equisimilis* is considered the most important β -hemolytic *Streptococcus* involved in lesions in pigs, and it has been judged to be of etiologic significance in autopsy reports. *S porcinus*, another β -hemolytic *Streptococcus*, has been associated particularly in the USA with a contagious clinical entity in growing pigs known as streptococcal lymphadenitis, jowl abscesses, or cervical abscesses. Enterococci reside in the intestinal tract and may cause disease in multiple species. In pigs, the *E faecium* species group, mainly *E durans* and *E hirae*, are especially associated with enteritis and diarrhea.

STREPTOCOCCUS SUI INFECTION

S suis is a significant pathogen of swine and one of the most important causes of bacterial mortality in piglets after weaning. It is

considered a normal inhabitant of the upper respiratory tract (especially nonvirulent strains) and can be easily found in tonsils, which are considered a natural niche. It can also be isolated from the reproductive and GI tracts of clinically healthy pigs.

Etiology and Pathogenesis: *S suis* possesses antigens somehow related to Lancefield group D streptococcus, but it is taxonomically far from other members of this group. It is considered a facultatively anaerobic, gram-positive, nonmotile coccus, oriented in chains of varying lengths. *S suis* produces α -hemolysis (incomplete hemolysis) on blood agar and is catalase negative. It has a worldwide distribution, and originally 35 serotypes based on capsular antigens had been described (serotypes 1 to 34 and serotype 1/2). However, there is still some controversy, because serotypes 20, 22, 26, 32, 33, and 34 have been suggested as not being part of the *S suis* species. Nonetheless, the number of serotypes considered as highly virulent is relatively small and depends mainly on geographic location.

Most studies on virulence factors of *S suis* have been performed with serotype 2 only. Type 2 virulent and nonvirulent strains exist, but characterization of virulence factors is still incomplete. Capsular polysaccharide is so far the most important critical virulence factor. However, well encapsulated nonvirulent serotype 2 strains do exist. Some proteins, such as the muramidase-released protein, the extracellular factor,

and the hemolysin (suilysin), constitute virulence-related proteins for serotype 2 strains isolated in Europe and Asia but not for North American strains. So far, there is no single true predictor of pathogenicity. In fact, serotype 2 strains from different continents are phenotypically and genotypically very different. Most strains from Asia and Europe belong mainly to the sequence type or ST1, as characterized by multilocus sequence typing, and are highly virulent. Serotype 2 strains from North America belong to ST25 and ST28, presenting lower virulence capacities, which may explain the importance of other serotypes in this continent, such as serotypes 3 and 1/2.

The mechanisms that enable *S suis* to disseminate throughout the animal are not well understood. The bacterium is able to spread systemically from the nasopharynx, occasionally resulting in septicemia and death. The palatine and pharyngeal tonsils are both potential portals of entry for *S suis*, leading to subsequent hematogenous or lymphogenous dissemination. Survival of the organism once in the bloodstream may be facilitated by the capsular polysaccharide as well as cell wall components, which efficiently hamper phagocytosis. If *S suis* does not cause acute fatal septicemia, bacteria are able to reach the CNS via mechanisms that are only partially elucidated, such as invasion of brain microvascular endothelial cells or through the choroid plexusepithelial cells. In both septicemic and CNS cases, excessive host inflammation seems to play an important role in the pathogenesis of infection.

Epidemiology and Transmission:

S suis is present in all parts of the world in swine intensive areas. Serotypes 1–9 (including serotype 1/2 that shares antigens with serotypes 1 and 2) represent >70% of *S suis* isolates recovered from diseased pigs, mainly in North America where most studies have been done. Serotype 2 is, in general, the most prevalent worldwide, but its importance is lower in North America and higher in Asia and some countries in Europe, such as France. Serotype 9 is the most frequently isolated type in other European countries, such as Spain, Germany, and the Netherlands.

Most clinically healthy pigs are carriers of multiple serotypes of *S suis*, although a few are colonized by virulent strains. Piglets become colonized with *S suis* from vaginal secretions during parturition and while nursing. Asymptomatic carriers serve as a source of infection for their pen mates after they are mixed and commingled in the nursery, when

maternal antibodies are no longer present. Clinical infections are seen mainly in weaned pigs (2–5 wk after weaning), growing pigs, and less frequently, suckling piglets and adult animals. Transmission between herds occurs by the movement and mixing of healthy carrier pigs. The introduction of a highly virulent strain into a naive herd may result in subsequent onset of disease in weaned and/or growing pigs. However, some herds with animals harboring virulent strains but not showing illness may suddenly develop serious clinical disease in the presence of other predisposing factors such as overcrowding, poor ventilation, excessive temperature fluctuations, mixing of pigs with an age spread of >2 wk, and coinfections with other pathogens. Disease outbreaks due to *S suis* infection have been frequently reported with coinfections of porcine reproductive and respiratory syndrome virus (see p 729). *S suis* might also be transmitted via fomites and flies, although probabilities are low. Although *S suis* has been isolated from different mammal species and birds, the importance of such reservoirs is unknown.

Clinical Findings: Even when the carrier rate in pigs is near 100%, the incidence of the disease varies from period to period and is usually <5%. However, in the absence of treatment, mortality rates can reach 20%. The earliest sign is usually fever, which may occur initially without other obvious signs. It is accompanied by a pronounced septicemia that may persist for several days if untreated. During this period, there is usually a fluctuating fever and variable degrees of inappetence, depression, and shifting lameness. In peracute cases, pigs may be found dead with no premonitory signs. Meningitis is the most striking feature and the one on which a presumptive diagnosis is usually based. Pigs in the early stages of meningitis may hold their ears back and squint their eyes. Other early nervous signs include depression, incoordination, and adoption of unusual stances (eg, dog-sitting), which soon progress to inability to stand, paddling, opisthotonos, convulsions, and nystagmus. Swollen joints and lameness are indicative of polyarthritis, which is common in North America. Endocarditis is also a frequent finding in older piglets, with affected pigs dying suddenly or showing signs of dyspnea, cyanosis, and wasting. Signs of respiratory disease may be seen in some outbreaks, although the role of *S suis* as a primary agent of pneumonia, in the absence of other pathogens, remains controversial.

Lesions: Lesions are mainly seen in weaned and growing pigs and are associated with lymphadenopathy, meningitis, arthritis, and endocarditis. Polyserositis similar to that seen in Glässer's disease is sometimes seen. Lesions may include fibrinopurulent exudates in the brain, swollen joints, fibrinous serositis, and cardiac valvular vegetations. Splenomegaly and petechial hemorrhages indicating septicemia are common. Significant microscopic lesions are usually limited to the brain, heart, and joints. The predominant lesions are neutrophilic meningitis and chorioiditis, with hyperemic meningeal blood vessels, and fibrinopurulent or suppurative epicarditis. Evidence of encephalitis, edema, and congestion of the brain may be present. The choroid plexus may have disruption of the plexus brush border, and fibrin and inflammatory cell exudates may be present in the ventricles. Microscopic lesions do not seem to be associated with a given serotype.

Diagnosis: Presumptive diagnosis is generally based on history, clinical signs, age of animals, and gross lesions. Isolation and serotyping of the infectious agent and evaluation of microscopic lesions in affected tissues confirm the diagnosis. After isolation, biochemical identification of *S suis* isolates recovered from diseased animals is possible with a minimum of biochemical tests. Serotyping is important to confirm and implement preventive measures, and several multiplex PCR tests to easily serotype *S suis* strains have been reported (and can be used by any laboratory). Validated and specific serologic tests to detect antibodies are not available for *S suis*. Genetic characterization, including multilocus sequence typing, is done in some laboratories and is particularly useful for epidemiologic studies. For European and Asian strains of serotype 2, detection of the muramidase-released protein, the extracellular factor, and the hemolysin (sullysin) by PCR as an indication of virulence can also be done.

Detection of virulent strains of *S suis* from tonsils or nasal cavities cannot be done, because universal virulence factors are unknown. These sites are highly contaminated, and traditional bacterial isolation has a low sensitivity. Strains isolated from tonsils must be confirmed by PCR as being *S suis*, because biochemical tests are not able to correctly differentiate this bacterial species from other streptococci normally present in the upper respiratory tract of swine.

Differential diagnoses include polyserositis caused by *Haemophilus parasuis* or

Mycoplasma hyorhinis; meningitis caused by *H parasuis*; endocarditis caused by *Erysipelothrix rhusiopathiae*; septicemia caused by *H parasuis*, *Actinobacillus suis*, *Escherichia coli*, *Erysipelothrix rhusiopathiae*, or *Salmonella* Choleraesuis; and polyarthritis caused by other streptococci, staphylococci, *E coli*, or *A suis*.

Treatment, Control, and Prevention:

Prompt recognition of the early clinical signs of streptococcal meningitis, followed by immediate parenteral treatment of affected pigs with an appropriate antibiotic, is currently the best method to maximize survival. The early stages of meningitis may be difficult to detect, so weaned pigs should be observed 2–3 times daily on farms where *S suis* infections are a problem. Resistance of isolates to penicillin has been reported and varies among countries, but extended spectrum β -lactams such as ampicillin and amoxicillin appear to retain some good effectiveness. Treatment can also be administered via the drinking water or in amoxicillin-mediated feed. However, because of the method of spread of the disease, treatment needs to be started quickly. Whichever method of medication is used, treatment should be continued for at least 5 days. Administration of an anti-inflammatory preparation is sometimes recommended to reduce inflammation of affected tissues and improve the overall condition of pigs with *S suis* meningitis. Treatment of sows with antibiotics before farrowing may reduce pathogen transmission to piglets, although results are controversial.

Vaccines available in the field are bacterins (inactivated whole cells), and they have proved to be relatively ineffective in preventing outbreaks. If somehow useful, the protection would be serotype-specific. Because affected animals are in general 6–10 wk old, interference with maternal antibodies should be considered. In addition, the adjuvant used seems to play an important role; a bacterin with a water-in-oil emulsion as an adjuvant provided better results than the same bacterin with an aluminum hydroxide-based adjuvant. Sow vaccination also had poor results.

One main problem is that *S suis* is one of several bacterial pathogens that have been able to defeat eradication efforts in nursing or early weaned pigs, because animals are already colonized immediately after or even during farrowing.

Streptococci are susceptible to the action of aldehyde, biguanide, hypochlorite, iodine, and quaternary ammonium disinfectants.

Zoonotic Risk: Human infections with *S suis* can result in septicemia, meningitis, permanent hearing loss, endocarditis, and arthritis. In Western countries, mortality has been reported to approach 7%, and most cases are related to employment in the swine industry (ie, pig farmers, abattoir workers, persons transporting pork, meat inspectors, butchers, and veterinarians). In Asia, the general population is at risk, and mortality rates can be >20%. *S suis* is considered one of the most common causes of adult meningitis in Thailand, Vietnam, and Hong Kong. Serotype 2 and, to a lesser extent, serotype 14 are mainly involved in human cases. Transmission to people occurs via contamination of skin wounds or mucous membranes by blood or secretions from infected pigs or by consuming raw meat or blood (as is the case in Asia). The disease is considered to be underdiagnosed and underreported in several countries.

STREPTOCOCCUS DYSGALACTIAE EQUISIMILIS INFECTION

Alpha- and nonhemolytic streptococci of Lancefield group C are defined as *S dysgalactiae dysgalactiae*, whereas β -hemolytic streptococci belonging to groups C, G, or L are named *S dysgalactiae equisimilis*.

In swine, β -hemolytic *S dysgalactiae equisimilis* usually belong to Lancefield group C. Although members of the normal flora, they are considered the most important β -hemolytic streptococci involved in lesions in pigs, and these agents were judged to be of etiologic significance in autopsy reports. These streptococci are common in nasal and throat secretions, tonsils, and vaginal and preputial secretions. Vaginal secretions and milk from postparturient sows are the most likely sources of infection for the piglets.

Streptococci enter the bloodstream via skin wounds, the navel, and tonsils. A bacteremia or septicemia occurs, and the organisms then settle in one or more tissues, giving rise to arthritis, endocarditis, or meningitis.

Clinical Findings and Lesions: Infection is usually first seen in pigs 1–3 wk old. Joint swelling and lameness are the most obvious and persistent clinical signs. Increased temperatures, lassitude, roughened hair coat, and inappetence may also be noted. Early lesions consist of periarticular edema; swollen, hyperemic synovial membranes; and turbid synovial fluid. Necrosis of articular cartilage may

be seen 15–30 days after onset and may become more severe. Fibrosis and multiple focal abscessation of periarticular tissues and hypertrophy of synovial villi also occur. Endocarditis occurs but is difficult to diagnose antemortem. Lesions consist of yellow or white vegetations of different sizes, often covering the entire surface of the affected valve.

Diagnosis: Diagnosis of streptococcal septicemia, arthritis, or endocarditis is best accomplished by necropsy and bacteriologic examination of affected pigs. Only small numbers of organisms or no organisms may be isolated from affected joints, especially when inflammation is advanced.

Treatment and Prevention: β -hemolytic streptococci are sensitive to β -lactam antibiotics. Long-acting antibacterial agents may be beneficial, and treatment should be given before inflammation is well advanced. There are no recent reports about vaccination against these streptococci. Autogenous bacterins are sometimes used, and there were reports of a reduced incidence of arthritis when sows were vaccinated before farrowing. However, no recent data have confirmed such information.

Adequate intake of colostrum may ensure that piglets receive protective antibodies. Traumatic injuries to the feet and legs should be minimized by reducing the abrasiveness of the floor surface in the farrowing area.

S dysgalactiae is not recognized as a zoonotic pathogen.

STREPTOCOCCUS PORCINUS INFECTION

(Streptococcal lymphadenitis, Jowl abscess, Cervical abscess)

S porcinus Lancefield group E has been associated in the USA with a contagious clinical entity in growing pigs known as streptococcal lymphadenitis, jowl abscesses, or cervical abscesses. Losses due to this disease in the USA were important in the 1960s, but its incidence has since declined, and the disease is not recognized as an important economic entity in other countries, where the bacterium represents only a few percent of the microorganisms isolated from abscesses in swine. Interestingly, it was recently reported that almost 20% of tonsils from a slaughterhouse were positive for *S porcinus*. Although pathology is not frequently seen, the pathogen is still prevalent in swine.

Transmission is possible by contact or ingestion of food or water contaminated by purulent material from abscesses or feces containing the organism. Organisms infect the pig through the mucosa of the pharyngeal or tonsillar surfaces and are carried to the lymph nodes, primarily of the head and neck region, where abscesses are formed. Abscesses may be seen at slaughter, and enlargement of lymph nodes in the throat region may be evident. *S. porcinus* is also occasionally found in the vaginal mucus of sows and the semen and prepuce of boars. It is generally considered to be a secondary invader.

Scattered miliary abscesses develop in the mandibular, parotid, or retropharyngeal lymph nodes within 7 days after infection. By 21 days, abscesses measuring 5–8 cm in diameter are common; they destroy the internal structure of affected nodes and may extend into adjacent tissues. Developing abscesses may reach the skin, rupture, and drain in 7–10 wk. The drained lesions heal by granulation, leaving a dense, fibrous, subcutaneous tract that resolves after several weeks. Deep-seated abscesses may remain undetected until slaughter and tend not to drain into the pharynx.

S. porcinus is sensitive to penicillins, and antibiotic therapy will usually resolve acute infections if detected. However, antibiotic treatment is not usually successful in treating swine with established abscesses or in eliminating carriers. Resistance to tetracycline has been reported, but pulsing tetracyclines in the feed at the therapeutic level of 400 g/ton is commonly used in an attempt to control this condition. Vaccination (autogenous) is possible but has not been widely used, because cervical abscesses are not a widespread problem.

S. porcinus Lancefield groups P, U, and V have been isolated from lungs, genital organs, and brains of pigs. However, no histologic lesions could be associated with their presence. *S. porcinus* groups P and V have also been associated with abortions in pigs.

Many strains of *S. porcinus* have been recovered from the human female genitourinary tract. However, it has been reported later that these strains belong to a different and new species, *Streptococcus pseudoporcinus* sp nov (novel species).

OTHER STREPTOCOCCAL AND ENTEROCOCCAL INFECTIONS

Bacterial streptococcal strains were isolated from the lungs and kidney of two pigs with lesions associated with pneumonia and septicemia, respectively. The two isolates were recovered from different animals, on different farms located in different provinces of Spain, and in different years. The isolates were classified as a new species, *Streptococcus plurextorum* sp nov (novel species). Other isolates associated with pneumonia were also defined as a new species, *Streptococcus porci* sp nov. So far, there are no data about the habitat and/or virulence properties of these two species.

Enterococci are known as part of the intestinal flora, but some strains can extensively colonize the mucosal surface of the small intestine. Some enterococcal species that show typical adhesion to the apical surface of the enterocytes of the small intestine of young animals have been described as associated with diarrhea in different species, including piglets 2–20 days old. Taxonomic studies have shown that most of these enterococci are members of the *E. faecium* species group, mainly *E. durans* and *E. hirae*.

SWINE VESICULAR DISEASE

Swine vesicular disease (SVD) is typically a transient disease of pigs in which vesicular lesions appear on the feet and snout and in the mouth. SVD is usually mild in nature and may infect pigs subclinically. However, the disease is of major economic importance, because it must be differentiated from foot-and-mouth disease, eradication is costly, and embargoes on export of pigs and pork products are often imposed on nations not free of SVD.

Pigs are considered the only natural host of the virus, although it can infect sheep in close contact with infected pigs and infection of one laboratory worker was reported. SVD has been reported only in Europe and Asia, having been first identified in Italy in 1966 and subsequently in Hong Kong, Japan, Taiwan, and 16 other countries in Europe. Although SVD virus was eradicated from Japan in the mid-1970s and most European countries by the mid-1980s,

it has remained endemic in Italy and caused sporadic outbreaks of disease in other European countries during the 1990s and in Portugal in 2003, 2004, and 2007.

Etiology: The causal agent is an enterovirus of the family Picornaviridae. It belongs to the species Human enterovirus B and is thought to have evolved from the human pathogen coxsackievirus B5, with which it shares a close antigenic and genetic relationship. There is only one serotype of SVD virus, although isolates may be differentiated by antigenic or genetic typing and may differ in virulence. SVD virus is transmitted by direct or indirect contact or by feeding infected pork or pork products. Infection is via the oral route or through skin abrasions and can give rise to viremia, fecal viral shedding, and generalized vesicles that rupture to release large amounts of virus.

Clinical Findings and Lesions: The primary signs are fresh or healing vesicular lesions on the feet, especially the coronary band, and less often other areas such as the mouth, lips, teats, or snout. The lesions may be mild or inapparent, especially when pigs are kept on soft bedding. The lesions are similar to those of foot-and-mouth disease (see p 629), vesicular exanthema of swine (see p 738), and vesicular stomatitis (see p 694); however, affected pigs usually do not lose condition, and the lesions heal rapidly. Nervous signs have been described but are rarely seen in the field. The OIE recommends that any outbreaks of vesicular disease in pigs should be assumed to be foot-and-mouth disease until proved otherwise by laboratory testing.

Diagnosis: Diagnosis is confirmed by laboratory tests on epithelial samples, feces, or serum. Virus detection is by antigen-detection ELISA, virus isolation, or reverse-transcriptase PCR. Serology is by antibody-detection ELISA or virus neutralization test, but low specificity may be a concern, particularly in older animals. In clinical cases, the preferred specimens are lesion material collected in phosphate-buffered saline. Subclinical infection may be detected by testing of pen-floor feces using reverse-transcriptase PCR or virus isolation.

Control: Countries free of the disease can remain so by controlling the import of pigs and pork products or by ensuring that pork products are treated (heat or otherwise) to kill the virus. Feeding of garbage to pigs may be banned or regulated to ensure thorough cooking. Any suspected outbreak should be reported to the appropriate authorities. If SVD does occur, control is by zoosanitary measures, including restrictions on pig movement. There are no commercially available vaccines. Extensive serosurveillance is necessary to detect subclinically infected herds, and seroreactor herds must be followed up by clinical inspection and fecal virus testing. The virus is extremely resistant in the environment and is stable over a wide pH range (2.5–12); thus, disinfection of premises, trucks, and equipment must be thorough. The most effective disinfectants are strong alkalis, although hypochlorites or acid-containing iodophors can be used when organic material is not present.

TRICHINELLOSIS

(Trichinosis)

Trichinellosis is a parasitic disease of public health importance caused by the nematode *Trichinella spiralis*. Human infections are established by consumption of insufficiently cooked infected meat, usually pork or bear, although other species have been implicated. Natural infections are found in wild carnivores; trichinellosis has also been found in horses, rats, beavers, opossums, walrus, whales, and meat-eating birds. Most mammals are susceptible. The number of human cases has declined in the past

50 years due in part to the move to modern production facilities (confinement) that reduces or eliminates exposure to rodents and other wildlife.

Etiology and Epidemiology: The genus *Trichinella* is currently considered a complex of nine species and three additional genotypes (T6, T8, and T9) of undetermined taxonomic status. Other than for the existence of two clades defined by the presence or absence of a collagen

capsule (cyst) surrounding the parasite in the muscle, there are few distinct morphologic differences. Taxon identification is based on characteristics such as reproductive isolation, infectivity to certain hosts, resistance to freezing, geographic cruising range, PCR and DNA sequencing, and isoenzyme analysis. *T. spiralis* (T1) is the most common and widely distributed of the encapsulated species affecting people and domestic animals in temperate regions; it has high infectivity for pigs and rodents, exhibits low resistance to freezing, and is broadly infective for most sylvatic hosts. The other cyst-forming species include *T. nativa* (T2), found in arctic carnivores; *T. britovi* (T3), found throughout the entire European continent, northwest Africa, and southwest Asia; *T. murrelli* (T5), restricted to North America; *T. nelsoni* (T7), found only in eastern Africa; and the most recently named *T. patagoniensis* (T12), found in Argentina. There are three other encapsulated genotypes: *Trichinella* T6, which is very similar to *T. nativa* and is found in carnivores of North America; T8, which shows similarities to *T. britovi* and is present in carnivores of Africa; and T9, which has been identified only in sylvatic hosts from Japan but is genetically more similar to *T. murrelli* of the USA. There are three additional species—*T. pseudospiralis* (T4), *T. papuae* (T10), and *T. zimbabwensis* (T11), which constitute the nonencapsulated clade (lack a cyst in the muscle). *T. pseudospiralis* has a cosmopolitan distribution and is the only species capable of infecting mammals and birds. *T. papuae* was first identified in pigs from Papua New Guinea, but its presence is suspected to extend into Australasia and southeast Asia. *T. zimbabwensis* is present in sub-Saharan Africa. Both *T. papuae* and *T. zimbabwensis* are capable of infecting crocodiles.

Infection generally occurs by ingestion of larvae encysted in muscle. The cyst wall is digested in the stomach, and the liberated larvae penetrate into the duodenal and jejunal mucosa. Within ~4 days, the larvae develop into sexually mature adults. After mating, the females (3–4 mm) penetrate deeper into the mucosa and discharge living larvae (up to 1,500) throughout 4–16 wk. After reproduction, the adult worms die and usually are digested. The young larvae (0.1 mm) migrate into the lymphatics, are carried via the portal system to the peripheral circulation, and reach striated muscle, where they penetrate individual muscle cells. They grow rapidly (to 1 mm) and begin to coil within the cell, usually 1 per cell. Capsule formation begins ~15 days

after infection and is completed by 4–8 wk, at which time the larvae are infective. The cell degenerates as the larva grows, and then calcification occurs (at different rates in various hosts). Larvae may remain viable in the cysts for years, and their development continues only if ingested by another suitable host. The diaphragm, tongue, masseter, and intercostal muscles are among those most heavily involved in pigs.

If larvae pass through the intestine and are eliminated in the feces before maturation, they are infective to other animals.

Clinical Findings and Diagnosis: Most infections in domestic and wild animals go undiagnosed. In people, heavy infections may produce serious illness with three clinical phases (intestinal, muscle invasion, and convalescent) and occasionally death.

Although antemortem diagnosis in animals other than people is rare, trichinellosis may be suspected if there is a history of eating rodents, wildlife carcasses, or raw, infected meat. Microscopic examination of a muscle biopsy sample (usually tongue) may confirm but not necessarily exclude trichinellosis. ELISA is a reliable test to detect anti-*Trichinella* antibodies. Seroconversion may not occur for weeks after infection, although as little as 0.01 larvae per gram of meat can be detected.

Control: Treatment is generally impractical in animals. The objective is to prevent ingestion by any animal, including people, of viable *Trichinella* cysts in muscle (trichinae). In pigs, this may be accomplished with good management that includes controlling rodents, cooking garbage (fed to the pigs) for 30 min at 212°F (100°C), and preventing cannibalism (ie, tail biting) and access to wildlife carcasses.

Inspection of meat for viable trichinae at the time of slaughter (by trichinoscopic or digestion methods) is effective to prevent human infection in many countries. In North America, the assumption is that pork may be infected; therefore, those products that appear as "ready to eat" must be processed by adequate heating, freezing, or curing to kill trichinae before marketing. Other pork should be cooked to assure that all tissue is heated to an internal temperature of 145°F (63°C) for roasts or 160°F (71°C) for ground meats. Freezing pork at an appropriate temperature for an appropriate time is also effective (5°F [–15°C] for 20 days, –9.4°F [–23°C] for 10 days, or –22°F [–30°C] for 6 days). Freezing cannot be relied on to kill trichinae in meat other than pork.

VESICULAR EXANTHEMA OF SWINE

(San Miguel sea lion virus disease)

Vesicular exanthema of swine (VES) is an acute, highly infectious disease characterized by fever and formation of vesicles on the snout, oral mucosa, soles of the feet, coronary band, and between the toes.

VES has been reported only in the USA, and not since 1959, but it remains of historic importance because of its clinical similarity to foot-and-mouth disease. Since 1972, San Miguel sea lion virus (SMSV), a virus indistinguishable from VES virus (VESV), and related caliciviruses have been isolated from marine mammals on the west coast of the USA.

VESV, SMSV, and related viruses are members of the genus *Vesivirus* in the family Caliciviridae. Many immunologically distinct serotypes have been demonstrated (13 types of VESV from pigs and at least 16 types of SMSV from marine sources). In addition, a number of serotypes have been isolated from other host species and named accordingly: bovine, primate, cetacean, walrus, skunk, mink, rabbit, and reptile caliciviruses. In some cases, serotypes initially isolated in terrestrial animals (eg, reptile calicivirus) have subsequently been found in marine mammals. All of these viruses (except for SMSV-8, SMSV-12, and mink calicivirus) form a single virus species, vesicular exanthema of swine virus.

SMSV has also been isolated from vesicular lesions on marine mammals,

seal meat, and perch-like fish in California. SMSV can produce lesions indistinguishable from those of VES in pigs, and the diverse pool of marine caliciviruses on the west coast of the USA are a reservoir of potential swine pathogens. Two marine caliciviruses, serotype SMSV-5 and an unknown virus, have been isolated from vesicular lesions or throat washings of two people with vesicular lesions, but the viruses are considered of minimal significance to public health.

In pigs, the clinical disease is indistinguishable from foot-and-mouth disease (see p 629), vesicular stomatitis (see p 694), and swine vesicular disease (see p 735).

Presumptive diagnosis in pigs is based on fever and the presence of typical vesicles, which break within 24–48 hr to form erosions. Diagnosis can be confirmed by ELISA, reverse-transcriptase PCR, complement-fixation tests, and electron microscopy on epithelial tissue, or after passage in swine tissue cultures. Serum neutralization tests and electron microscopy are also used.

Suspected cases of vesicular exanthema should be reported immediately to the appropriate authorities. Feeding of food scraps (garbage, swill) to pigs is illegal in many countries and can be done only under license and after cooking in the USA.

BLUETONGUE

Bluetongue is an infectious arthropod-borne viral disease primarily of domestic and wild ruminants. Infection with bluetongue virus (BTV) is common in a broad band across the world, which until recently stretched from ~35°S to 40°–50°N. Since the 1990s, BTV has extended considerably north of the 40th and even the 50th parallel in some parts of the world (eg, Europe). The geographic restriction is in part related to the climatic and environmental conditions necessary to support the *Culicoides* vectors. Most infections with BTV in wild ruminants and

cattle are subclinical. Bluetongue (the disease caused by BTV) is usually considered to be a disease of improved breeds of sheep, particularly the fine-wool and mutton breeds, although it has also been recorded in cattle and some wild ruminant species, including white-tailed deer (*Odocoileus virginianus*), pronghorn antelope (*Antilocapra americana*), and desert bighorn sheep (*Ovis canadensis*) in North America, and European bison (*Bison bonasus*) and captive yak (*Bos grunniens*) in Europe.

Etiology and Transmission: Bluetongue virus is the type-species of the genus *Orbivirus* in the family Reoviridae. There are at least 24 serotypes worldwide, although not all serotypes exist in any one geographic area; eg, 13 serotypes (1, 2, 3, 5, 6, 10, 11, 13, 14, 17, 19, 22, and 24) have been reported in the USA and 8 serotypes (1, 2, 4, 6, 8, 9, 11, and 16) in Europe. Distribution of BTV throughout the world parallels the spatial and temporal distribution of vector species of *Culicoides* biting midges, which are the only significant natural transmitters of the virus, as well as the temperatures at which BTV will replicate in and be transmitted by these vectors. Of more than 1,400 *Culicoides* species worldwide, fewer than 30 have been identified as actual or potential vectors of BTV to date. Continued cycling of the virus among competent *Culicoides* vectors and susceptible ruminants is critical to viral ecology. In the USA, the principal vectors are *C sonorensis* and *C insignis*, which limit the distribution of BTV to southern and western regions. In northern and eastern Australia the principal vector is *C brevitarsis*, whereas in Africa, southern Europe, and the Middle East it is *C imicola*. In northern Europe, the major vectors are species within the *C obsoletus-devulfi* complex. In each geographic region, secondary vector species may attain local importance.

Vectors become infected with BTV by imbibing blood from infected vertebrates; transovarial transmission has not been reported. High affinity of the virus to blood cells, especially the sequestering of viral particles in invaginations of RBC membranes, contributes to prolonged viremia in the presence of neutralizing antibody. The extended viremia in cattle (occasionally up to 11 wk), and the host preference of some vector species of *Culicoides* for cattle, provide a mechanism for year-round transmission in domestic ruminants in locations where the vector-free (winter) period is relatively short. Mechanical transmission by other bloodsucking insects is of minor significance.

Vector-borne transmission through *Culicoides* spp is the primary way BTV spreads. Virus concentrations in secretions and excretions are minimal, making direct, indirect, or aerosol transmission unlikely. However, in-contact transmission of BTV serotype 26 has been demonstrated in goats. The significance of this form of transmission in the ecology of this serotype is not known. Semen from viremic bulls can serve as a source of infection for cows through natural service or artificial insemination.

Embryo transfer is regarded as safe, provided that donors are not viremic and an appropriate washing procedure for embryos is used. Transplacental transmission of field strains of BTV from dam to fetus, leading to the birth of viremic calves, is reported in cattle, but the epidemiologic significance of this mechanism is unclear. Accidental infection has been reported in dogs in the USA after administration of a modified-live canine virus vaccine that was contaminated with BTV. Serologic evidence of infection with BTV has been found in wild and captive carnivores in Africa and Europe, perhaps as a result of ingesting virus-infected viscera. The epidemiologic importance of this oral infection mechanism is at present uncertain. Serologic evidence of BTV exposure has been demonstrated in domestic dogs fed commercial diets.

Clinical Findings: The course of the disease in sheep can vary from peracute to chronic, with a mortality rate of 2%–90%. Peracute cases die within 7–9 days of infection, mostly as a result of severe pulmonary edema leading to dyspnea, frothing from the nostrils, and death by asphyxiation. In chronic cases, sheep may die 3–5 wk after infection, mainly as a result of bacterial complications, especially pasteurellosis, and exhaustion. Mild cases usually recover rapidly and completely. The major production losses include deaths, unthriftiness during prolonged convalescence, wool breaks, and reproductive losses.

In sheep, BTV causes vascular endothelial damage, resulting in changes to capillary permeability and subsequent intravascular coagulation. This results in edema, congestion, hemorrhage, inflammation, and necrosis. The clinical signs in sheep are typical. After an incubation period of 4–6 days, a fever of 105°–107.5°F (40.5°–42°C) develops. The animals are listless and reluctant to move. Clinical signs in young lambs are more apparent, and the mortality rate can be high (up to 30%). Approximately 2 days after onset of fever, additional clinical signs may be seen, such as edema of lips, nose, face, submandibular area, eyelids, and sometimes ears; congestion of mouth, nose, nasal cavities, conjunctiva, and coronary bands; and lameness and depression. A serous nasal discharge is common, later becoming mucopurulent. The congestion of nose and nasal cavities produces a “sore muzzle” effect, the term used to describe the disease in sheep in the USA. Sheep eat less because of oral soreness and will hold food in their mouths

to soften before chewing. They may champ to produce a frothy oral discharge at the corners of the lips. On close examination, small hemorrhages can be seen on the mucous membranes of the nose and mouth. Ulceration develops where the teeth come in contact with lips and tongue, especially in areas of most friction. Some affected sheep have severe swelling of the tongue, which may become cyanotic ("blue tongue") and even protrude from the mouth. Animals walk with difficulty as a result of inflammation of the hoof coronets. A purple-red color is easily seen as a band at the junction of the skin and the hoof. Later in the course of disease, lameness or torticollis is due to skeletal muscle damage. In most affected animals, abnormal wool growth resulting from dermatitis may be seen.

Clinical signs in cattle are rare but may be similar to those seen in sheep. They are usually limited to fever, increased respiratory rate, lacrimation, salivation, stiffness, oral vesicles and ulcers, hyperesthesia, and a vesicular and ulcerative dermatitis. Susceptible cattle and sheep infected during pregnancy may abort or deliver malformed calves or lambs. The malformations include hydranencephaly or porencephaly, which results in ataxia and blindness at birth. White-tailed deer and pronghorn antelope develop severe hemorrhagic disease leading to sudden death. Pregnant dogs abort or give birth to stillborn pups and then die in 3–7 days.

Diagnosis and Lesions: The typical clinical signs of bluetongue enable a presumptive diagnosis, especially in areas where the disease is endemic. Suspicion is confirmed by the presence of petechiae, ecchymoses, or hemorrhages in the wall of the base of the pulmonary artery and focal necrosis of the papillary muscle of the left ventricle. These highly characteristic lesions are usually obvious in severe clinical infections but may be barely visible in mild or convalescent cases. These lesions are often described as pathognomonic for bluetongue, but they have also been seen occasionally in other ovine diseases such as heartwater, pulpy kidney disease, and Rift Valley fever. Hemorrhages and necrosis are usually found where mechanical abrasion damages fragile capillaries, such as on the buccal surface of the cheek opposite the molar teeth and the mucosa of the esophageal groove and omasal folds. Other autopsy findings include subcutaneous and intermuscular edema and hemorrhages, skeletal myonecrosis, myocardial and intestinal

hemorrhages, hydrothorax, hydropericardium, pericarditis, and pneumonia.

In many areas of the world, BTV infection in sheep, and especially in other ruminants, is subclinical. Laboratory confirmation is based on virus isolation in embryonated chicken eggs or mammalian and insect cell cultures, or on identification of viral RNA by PCR. The identity of isolates may be confirmed by the group-specific antigen-capture ELISA, group-specific PCR, immunofluorescence, immunoperoxidase, serotype-specific virus neutralization tests, serotype-specific PCR, or hybridization with complementary gene sequences of group- or serotype-specific genes. For virus isolation, blood (10–20 mL) is collected as early as possible from febrile animals into an anticoagulant such as heparin, sodium citrate, or EDTA and transported at 4°C (39.2°F) to the laboratory. For longterm storage when refrigeration is not possible, blood is collected in oxalate-phenolglycerin (OPG). Blood to be frozen should be collected in buffered lactose peptone and stored at or below –70°C (–94°F). Blood collected at later times during the viremic period should not be frozen, because lysing of the RBCs on thawing releases the cell-associated virus, which may then be neutralized by early humoral antibody. The virus does not remain stable for long at –20°C (–4°F). In fatal cases, specimens of spleen, lymph nodes, or red bone marrow are collected and transported to the laboratory at 4°C (39.2°F) as soon as possible after death.

A serologic response in ruminants can be detected 7–14 days after infection and is generally lifelong after a field infection. Current recommended serologic techniques for detection of BTV antibody include agar gel immunodiffusion and competitive ELISA. The latter is the test of choice and does not detect cross-reacting antibody to other orbiviruses, especially anti-EHDV (epizootic hemorrhagic disease virus) antibody. Various forms of the serum neutralization test, including plaque reduction, plaque inhibition, and microtiter neutralization, can be used to detect type-specific antibody.

Prevention and Control: There is no specific treatment for animals with bluetongue apart from rest, provision of soft food, and good husbandry. Complicating and secondary infections should be treated appropriately during the recovery period.

Prophylactic immunization of sheep remains the most effective and practical control measure against bluetongue in

endemic regions. Attenuated and inactivated vaccines against BTV are commercially available in some countries. Three polyvalent vaccines, each comprising five different BTV serotypes attenuated by serial passage in embryonated hens' eggs followed by growth and plaque selection in cell culture, are widely used in southern Africa and elsewhere, should epizootics of bluetongue occur. A monovalent (BTV type 10) modified-live virus vaccine propagated in cell culture is available for use in sheep in the USA. Use of vaccines with different serotypes does not provide consistent cross-protection. Live-attenuated vaccines should not be used during *Culicoides* vector seasons, because these insects may transmit the vaccine virus(es) from vaccinated to nonvaccinated animals, eg, other ruminant species. This may result in reassortment of genetic material and give rise to new viral strains. Abortion or malformation, particularly of the CNS, of fetuses may follow vaccination of ewes and cows with attenuated live vaccines during the first half and the first trimester of pregnancy, respectively. Passive immunity in lambs usually lasts 2–4 mo.

The control of bluetongue is different in areas where the disease is not endemic.

During an outbreak, when one or a limited number of serotypes may be involved, vaccination strategy depends on the serotype(s) causing infection. Use of vaccine strains other than the one(s) causing infection affords little or no protection and is not recommended. The potential risk from vaccine virus reassortment with wild-type viral strains, virus spread by the vectors to other susceptible ruminants, and reversion to virulence of vaccine virus strains or even the production of new BTV strains of uncertain virulence should also be considered. The use of inactivated vaccines in BTV incursions into northern Europe has played a major part in controlling virus spread in those regions where significant cover (>80%) has been achieved.

Control of vectors by using insecticides or protection from vectors may lower the number of *Culicoides* bites and subsequently the risk of exposure to BTV infection. However, these measures alone are unlikely to effectively halt a bluetongue epidemic and should be regarded as mitigation measures to be used alongside a comprehensive and vigorous vaccination program.

BOVINE EPHEMERAL FEVER

(Three-day sickness)

Bovine ephemeral fever is an insect-transmitted, noncontagious, viral disease of cattle and water buffalo that is seen in Africa, the Middle East, Australia, and Asia. Inapparent infections can develop in Cape buffalo, hartebeest, waterbuck, wildebeest, deer, and possibly goats. Low levels of antibody have been recorded in several other antelope species and giraffe, but the specificity has not been confirmed.

Etiology and Epidemiology: Bovine ephemeral fever virus (BEFV) is classified as a member of the genus *Ephemerovirus* in the family Rhabdoviridae (single-stranded, negative sense RNA). The virus is ether-sensitive and readily inactivated at pH levels below 5 and above 10. Although no evidence of immunogenic diversity is reported, antigenic variation

has been demonstrated using panels of monoclonal antibodies and by epitope mapping. Several closely related ephemeroviruses (including Berrimah virus, Kimberley virus, Malakal virus, Adelaide River virus, Obodhiang virus, Puchong virus, kotonkan virus, and Koolpinyah virus) have been identified. However, of these, only kotonkan virus (isolated in Nigeria) has been associated with clinical ephemeral fever in cattle.

BEFV can be transmitted from infected to susceptible cattle by IV inoculation; as little as 0.005 mL of blood collected during the febrile stage is infective. Although the virus has been recovered from several *Culicoides* species and from Anopheline and Culicine mosquito species collected in the field, the identity of the major vectors has not been proved. Transmission by contact or fomites does not occur. The virus does not appear to

persist in recovered cattle, which often have a lifelong immunity.

The prevalence, geographic range, and severity of the disease vary from year to year, and epidemics occur periodically. During epidemics, onset is rapid; many animals are affected within days or 2–3 wk. Bovine ephemeral fever is most prevalent in the wet season in the tropics and in summer to early autumn in the subtropics or temperate regions (when conditions favor multiplication of biting insects); it disappears abruptly in winter. Virus spread appears to be limited by latitude rather than topography or availability of susceptible hosts. Morbidity may be as high as 80%; overall mortality is usually 1%–2%, although it can be higher in lactating cows, bulls in good condition, and fat steers (10%–30%). However, reported overall mortality rates have exceeded 10% in outbreaks in several countries in recent years.

Clinical Findings: Signs, which occur suddenly and vary in severity, can include biphasic to polyphasic fever (40°–42°C [104°–107.6°F]), shivering, inappetence, lacrimation, serous nasal discharge, drooling, increased heart rate, tachypnea or dyspnea, atony of forestomachs, depression, stiffness and lameness, and a sudden decrease in milk yield. Clinical signs are generally milder in water buffalo. Affected cattle may become recumbent and paralyzed for 8 hr to >1 wk. After recovery, milk production often fails to return to normal levels until the next lactation. Abortion, with total loss of the season's lactation, occurs in ~5% of cows pregnant for 8–9 mo. The virus does not appear to cross the placenta or affect the fertility of the cow. Bulls, heavy cattle, and high-lactating dairy cows are the most severely affected, but spontaneous recovery usually occurs within a few days. More insidious losses may result from decreased muscle mass and lowered fertility in bulls.

Lesions: Bovine ephemeral fever is an inflammatory disease. The most common lesions include polyserositis affecting pleural, pericardial, and peritoneal surfaces; serofibrinous polysynovitis, polyarthritis, polytenosynovitis, and cellulitis; and focal necrosis of skeletal muscles. Generalized edema of lymph nodes and lungs, as well as atelectasis, also may be present.

Diagnosis: Diagnosis is based almost entirely on clinical signs in an epidemic.

All clinical cases have a neutrophilia with the presence of many immature forms, although this is not pathognomonic. Serofibrinous inflammation in the tendon sheaths, fascia, and joints, together with pulmonary lesions, may substantiate a presumptive diagnosis.

Laboratory confirmation is by serology, rarely by virus isolation. Whole blood should be collected from sick and apparently healthy cattle in affected herds and must be sufficient to provide two air-dried blood smears, 5 mL of whole blood in anticoagulant (not EDTA), and ~10 mL of serum. A differential WBC count on blood smears can either support or refute a presumptive field diagnosis.

Virus is best isolated by inoculation of mosquito (*Aedes albopictus*) cell cultures with defibrinated blood, followed by transfer to baby hamster kidney (BHK-21 or BHK-BSR) or monkey kidney (Vero) cell cultures after 15 days. Suckling mice may also be used for primary isolation by intracerebral inoculation. Isolated viruses are identified by PCR, neutralization tests using specific BEFV antisera, and ELISA using specific monoclonal antibodies. The neutralization test and the blocking ELISA are recommended for antibody detection and give similar results. A 4-fold rise in antibody titer between paired sera collected 2–3 wk apart confirms infection.

Treatment and Control: Complete rest is the most effective treatment, and recovering animals should not be stressed or worked because relapse is likely. Anti-inflammatory drugs given early and in repeated doses for 2–3 days are effective. Oral dosing should be avoided unless the swallowing reflex is functional. Signs of hypocalcemia are treated as for milk fever (see p 988). Antibiotic treatment to control secondary infection and rehydration with isotonic fluids may be warranted.

Attenuated virus vaccines appear to be effective but should be used only in endemic areas. Inactivated virus vaccines have not produced longterm protection against experimental challenge with virulent virus and cannot guarantee lasting immunity, but they may boost the immunity produced by live virus vaccine. Although a subunit vaccine that protects against field and laboratory challenge has been described, it is not commercially available. The efficacy of vector control remains uncertain, because the insect vectors have not been fully identified. There is no evidence that people can be infected.

BOVINE LEUKOSIS

(Bovine lymphosarcoma, Leukemia, Malignant lymphoma)

Lymphosarcoma in cattle may be sporadic or result from infection with bovine leukemia virus (BLV); the latter is often referred to as an enzootic bovine leukosis. Sporadic lymphosarcoma in cattle is unrelated to infection with BLV. Despite the lack of association, animals with sporadic lymphosarcoma may possibly be infected with the virus. Sporadic lymphosarcoma manifests in three main forms: juvenile, thymic, and cutaneous. Juvenile lymphosarcoma occurs most often in animals <6 mo old, thymic lymphosarcoma affects cattle 6–24 mo old, and cutaneous lymphosarcoma is most common in cattle 1–3 yr old.

Etiology, Transmission, and Epidemiology: Enzootic bovine leukosis is caused by BLV, an exogenous C-type oncogenic retrovirus of the BLV-human T-lymphotropic virus group. BLV has a stable genome, does not cause chronic viremia, and has no preferred site of proviral integration. Despite the lack of preferred proviral integration sites, the tumors generated by the virus in a single individual are typically monoclonal and have a single integration site. The virus escapes the immune response by low levels of viral replication. It appears that replication is blocked at the transcriptional level, but the mechanism is not completely understood.

The prevalence of BLV infection varies from country to country. Many European countries, Australia, and New Zealand have

eradication programs in place that have led to negligible rates of BLV infection. Although voluntary control programs are in place in the USA, prevalence is high compared with much of the rest of the world. The most recent surveys in the USA estimate that 44% of dairy and 10% of beef cattle are infected with the virus. Prevalence tends to increase on dairies with increasing herd size, while the converse is true in beef cattle. In general, the prevalence of viral infection increases with age.

Cattle are infected with BLV through the transfer of blood and blood products that contain infected lymphocytes. Once infected, cattle develop a lifelong antibody response, primarily to the gp51 envelope protein and the p24 capsid protein. B lymphocytes harbor the integrated provirus but rarely express viral proteins on their cell surface. The exact site of viral replication and expression that drives the immune response remains elusive.

Under experimental conditions, most routes of viral exposure can successfully transmit infection. However, many of these settings are unlikely to be encountered naturally. Many bodily fluids, including urine, feces, saliva, respiratory secretions, semen, uterine fluids, and embryos, have been examined for their ability to transmit BLV and are considered to be noninfectious. Only on rare occasion has virus been found in these fluids. Colostrum from BLV-positive cows contains virus and has been found to be infectious experimentally. However, colostrum also contains large amounts of antibody, and it is believed that the protective effects of colostrum antibody outweigh the infectious potential when colostrum is administered in a normal fashion.

Most BLV transmission is horizontal. Close contact between BLV-negative and BLV-positive cattle is thought to be a risk factor. Many common farm practices have been implicated in viral transmission, including tattooing, dehorning, rectal palpation, injections, and blood collection. Vectors such as tabanids and other large biting flies also may transmit the virus. Vertical transmission may occur transplacentally from an infected dam to the fetus, intrapartum by contact with infected blood, or postpartum from the dam to the calf through ingestion of infected colostrum.

Cutaneous lymphosarcoma. Courtesy of Dr. Peter Constable.

Any material that is blood contaminated or lymphocyte rich has the potential to infect animals with BLV.

Pathogenesis: There are three main outcomes in cattle infected with BLV. Most animals remain persistently infected with no outward signs of infection. Approximately 29% of BLV-infected cattle develop persistent lymphocytosis, while <5% of BLV-infected cattle develop lymphosarcoma.

Persistent lymphocytosis is sometimes referred to as a preneoplastic syndrome, but there is no convincing evidence that affected cattle have an increased risk of developing lymphosarcoma. The lymphocytes present in persistent lymphocytosis are not neoplastic, although they may have mild reactive changes consistent with normal blood smears in cattle. Persistent lymphocytosis is considered a benign condition associated with BLV infection. For this reason, it is often overlooked. However, these cows may serve as a reservoir of infection. The increased lymphocyte count is attributed to a 45-fold increase of infected CD5⁺ and a 99-fold increase in infected CD5⁻ B cells. It has been suggested that cows with persistent lymphocytosis may be at greater risk of passing BLV infection on to their calves in utero and may show decreased milk production and alteration of milk components.

Lymphosarcoma is rarely seen in animals <2 yr old and is most common in the 4- to 8-yr-old age group. Less than 5% of BLV-infected cattle develop lymphosarcoma. Lymphosarcoma, including both sporadic and enzootic forms, is one of the main causes of condemnation of adult dairy cows at slaughter.

Clinical Findings: Clinical signs associated with development of lymphosarcoma are highly variable, because the affected organ(s) will dictate the predominant clinical signs.

Juvenile lymphosarcoma is often characterized by a sudden onset of diffuse lymphoid hyperplasia with or without visceral organ involvement. Weight loss, fever, tachycardia, dyspnea, bloat, and posterior paresis have all been described with this form of lymphosarcoma. Profound lymphocytosis (>50,000/ μ L) often accompanies this fatal form of bovine lymphosarcoma. Thymic lymphosarcoma may involve the cervical or intrathoracic thymus, or both. Clinical signs associated with this form of lymphosarcoma depend heavily on the location and size of the tumor. A cervical swelling may be evident.

Dyspnea, bloat, jugular distention, tachycardia, anterior edema, and fever have been documented. The affected cell population is an immature, poorly differentiated lymphocyte. Cutaneous lymphosarcoma presents as cutaneous plaques, 1–5 cm in diameter, on the neck, back, rump, and thighs. Regional lymph nodes may also be enlarged. This form of lymphosarcoma may undergo spontaneous remission; however, relapses may occur.

Lesions: Animals with BLV-associated lymphosarcoma commonly show lesions in the central or peripheral lymph nodes, leading to lymphadenopathy. Lesions of the abomasum may lead to signs of cranial abdominal pain, melena, or abomasal outflow obstruction. Pelvic limb paresis progressing to paralysis can occur in animals with extradural spinal lesions. Retrobulbar lesions cause protrusion of the globe, resulting in exposure keratitis and eventually proptosis. Lesions of the right atrium may be mild and undetectable clinically, or may cause arrhythmias, murmurs, or heart failure. Uterine lesions may lead to reproductive failure or abortion. Lesions of the internal organs typically involve the spleen, liver, or kidneys and ureters. Lesions of the spleen are often initially asymptomatic but may result in rupture of the spleen and exsanguination into the peritoneal cavity. Lymphosarcoma of the liver is often asymptomatic but may lead to jaundice and liver failure. Disease of the kidney and ureter can lead to abdominal pain and the subsequent development of hydronephrosis or hydronephrosis and clinical signs associated with renal failure.

Lymphosarcoma may appear as yellow-tan, discrete nodular masses or a diffuse tissue infiltrate. The latter pattern results in an enlarged, pale organ and can be easily misinterpreted as a degenerative change rather than neoplasia. Histologically, the tumor masses are composed of densely packed, monomorphic lymphocytic cells.

Diagnosis: Lymphosarcoma is often included on the differential diagnosis list for many diseases because of the wide range of clinical findings. Viral infection is diagnosed by serology or virology; persistent lymphocytosis is identified by hematology, and neoplastic tumors are identified by histologic examination of biopsies. Positive serology or virology for BLV confirms viral infection but not the presence of lymphosarcoma.

Serology is the most common and reliable way to diagnose infection with BLV. Agar gel immunodiffusion is still recognized by most countries as the official import/export test,

but ELISA is the most common test for routine diagnostic use. Serology is unreliable in calves that have ingested colostrum from BLV-positive cows because of the passive acquisition of maternal antibodies that typically wane by 4–6 mo of age. PCR is a sensitive and specific assay for diagnosis of BLV infection in peripheral blood lymphocytes. This test can identify proviral DNA of BLV in the lymphocytes of infected animals and differentiate positive from negative calves in the presence of maternal antibodies.

The diagnosis of lymphosarcoma must be made by cytology or histopathology. Cytologic diagnosis is sometimes difficult because of the frequency of blood contamination of the aspirates.

Treatment and Control: There is no treatment for viral infection or for lymphosarcoma in cattle, although parenteral corticosteroids can transiently decrease the severity of clinical signs. Eradication programs have been developed but success has been variable, primarily because of the expense and high prevalence of infection among cattle in the USA relative to the economic cost of disease. The most commonly recommended eradication protocol is as follows: 1) identify infected animals using a serologic test, 2) cull seropositive animals immediately, 3) retest the herd in 30–60 days, 4) use PCR to test young calves and as a complementary test to clarify test results in herds with a low prevalence of infection, and 5) repeat testing and cull until the entire herd tests negative. Testing is then repeated every 6 mo. The herd is declared free when there have been no positive tests for 2 yr. Additions to the herd should have two negative tests 30 and 60 days before arrival.

When test and cull programs are economically untenable, test and segregation programs have been recommended but are rarely implemented. These programs necessitate running two completely separate operations and require additional

resources, including money, time, and available workforce.

Prevention: Eliminating the movement of blood from infected animals to naive animals is the cornerstone of prevention protocols. In calves, feeding colostrum from seronegative cows is often advocated. However, most epidemiologic evidence suggests that the protective effect of colostral antibody outweighs the risk of infections, particularly in high prevalence herds. The replacement of whole milk feeding with high-quality milk replacer may also be considered. Bloody milk should never be fed to calves.

Cautery or other bloodless methods of dehorning should be used. Equipment used for castration, tattooing, ear tagging, or implanting should be adequately cleaned and disinfected between animals.

Transmission can be decreased in adult cattle by changing rectal sleeves in between cows. Artificial insemination or embryo transfer (using negative recipients) may limit transmission. In beef herds, the use of a negative bull may limit transmission, but natural service is an uncommon method of viral transmission unless breeding is traumatic.

Additional recommendations include disinfection of equipment that has come in contact with blood or body tissue. Single use, disposable needles should always be used for blood collection and IM injections. It is preferable to use single-use disposable needles for vaccination, but the risk of transmitting BLV virus via SC vaccination is low. Handling facilities that become contaminated with blood should be cleaned between animals. Fly control helps minimize the potential for tabanid-associated transmission. Blood transfusions and vaccines containing blood, such as those used for babesiosis and anaplasmosis, are particularly potent ways to spread the disease, and donors must be carefully screened.

BOVINE PETECHIAL FEVER

(Ondiri disease)

Bovine petechial fever is a rickettsiosis of cattle characterized by high fever, hemorrhages, and edema. Its occurrence has been confirmed in the highlands of

Kenya and Tanzania at altitudes >5,000 ft (1,500 m), although it is considered likely to occur in neighboring countries with similar topography. The importance of bovine

petechial fever lies in its threat to dairy development in the highlands of eastern Africa, but no outbreak has been reported for more than a decade.

Etiology and Epidemiology: The disease is caused by *Ehrlichia ondiri*, an intracellular rickettsia that resides in cytoplasmic vacuoles of circulating leukocytes. The organism can multiply after experimental infection in cattle, sheep, goats, bushbuck, duiker, impala, Thomson's gazelles, and wildebeest, and hence, probably in most domestic and wild ruminants. *E. ondiri* is believed to be endemic in wild ruminants, particularly bushbuck, and it sporadically overflows into domestic cattle grazing forest edges or scrubs.

The disease is restricted to scrub or forest edge areas that have heavy shade, a thick litter layer that provides high relative humidity, and a residual population of bushbuck and duiker, the two wild ruminants believed to be the main amplifying and reservoir hosts. It is seen sporadically throughout the year in imported breeds of cattle. It is not known how the disease is transmitted. As in other rickettsial infections, an arthropod vector is suspected, but extensive attempts to incriminate ticks, biting insects, and mites have failed.

Pathogenesis: The route of infection is not known, but *E. ondiri* can be seen in circulating granulocytes (neutrophils and eosinophils) and monocytes while cattle are ill, and in the spleen at necropsy. Electron microscopic studies have shown that *E. ondiri* can also infect endothelial and Kupffer cells, and it may be free in capillary lumens in the heart. It is believed that *E. ondiri* initially multiplies in the spleen, with subsequent spread to other areas. Damage to the vascular endothelium would explain the hemorrhages and edema, as in many other rickettsial infections.

Clinical Findings: The disease is characterized by a high, fluctuating fever, apathy, lowered milk yield, and widespread petechiation of mucous membranes. After an incubation period of 4–14 days, animals develop a high fever; 2–3 days later, most animals appear dull, and petechiae may be seen on mucous membranes, particularly the lower surface of the tongue and the vaginal mucosa. These hemorrhages enlarge over several days and then regress

as the animal begins to recover. Marked conjunctival edema and hemorrhage ("poached egg eye") are characteristic in some severe cases. The conjunctival sacs are swollen and everted around a tense and protruding eyeball, and there may be blood in the aqueous humor. Pregnant cows may abort, most likely from the high fever. Other clinical signs are absent. The case mortality rate in untreated cases can be as high as 50% in imported animals or in animals newly introduced to the area. Latent infections develop after recovery in some animals, especially in indigenous stock and in bushbuck. After recovery from the disease, affected cattle are immune against experimental challenge for ~2 yr.

Lesions: Typically, eosinopenia and lymphopenia are marked, followed by an equally pronounced neutropenia. Anemia is characteristically a sequela, and organisms can be demonstrated in Giemsa-stained smears of blood or spleen. At necropsy, widespread serosal and mucosal hemorrhages and edema are accompanied by lymphoid hyperplasia. Organs frequently affected include the heart, GI tract from the forestomach to the colon, liver, gallbladder, kidneys, and urinary bladder. The edema is characterized by gelatinous fluid in the intermuscular connective tissue, lymph nodes, and abomasum. No characteristic histologic abnormalities have been described, but there is vascular proliferation with prominent endothelial swelling and mild mononuclear infiltration.

Diagnosis: In areas where the disease is endemic, a history of movement to forest edge areas, coupled with clinical signs and postmortem lesions, allows for a presumptive diagnosis. Definitive diagnosis requires demonstration of the causal organism in Giemsa-stained smears of blood or spleen or by electron microscopy. *E. ondiri* stains blue with Giemsa and can be seen as small bodies (0.4 μm), larger bodies (1–2 μm), groups of small and large bodies, and groups or morulae of small bodies. They are seen in cytoplasmic vacuoles and are most commonly seen in neutrophils. Tissue suspensions (spleen) can also be inoculated into susceptible cattle or sheep. Blood smears from the recipient animal should be made daily for as long as 10 days, by which time *E. ondiri* should be detectable in neutrophils. The disease is difficult to differentiate from other hemorrhagic diseases of cattle such as Rift Valley fever,

acute trypanosomosis (hemorrhagic *Trypanosoma vivax*), acute theileriasis, heartwater, hemorrhagic septicemia, and bracken fern poisoning.

Treatment and Control: Dithiosemicarbazone and tetracyclines have been used

successfully to treat early experimental cases but are ineffective in advanced cases. The former is said to be more effective. In endemic areas, the disease can be prevented by avoiding areas associated with previous cases. However, this may not always be practical.

CAPRINE ARTHRITIS AND ENCEPHALITIS

Caprine arthritis and encephalitis (CAE) virus infection is manifested clinically as polysynovitis-arthritis in adult goats and less commonly as progressive paresis (leukoencephalomyelitis) in kids. Subclinical or clinical interstitial pneumonia, indurative mastitis ("hard udder"), and chronic wasting have also been attributed to infection with this virus. Most CAE virus infections, however, are subclinical. Infection with the CAE virus decreases the lifetime productivity of dairy goats and is a barrier to exportation of goats from North America.

CAE virus infection is widespread among dairy goats in most industrialized countries but rare among indigenous goat breeds of developing countries unless they have been in contact with imported goats. In countries such as Canada, Norway, Switzerland, France, and the USA, seroprevalence of CAE virus is >65%.

Etiology, Epidemiology, and Pathogenesis: The CAE virus is an enveloped, single-stranded RNA lentivirus in the family Retroviridae. There are several, genetically distinct isolates of the virus that differ in virulence.

The CAE virus of goats is closely related to the ovine lentiviruses causing ovine progressive pneumonia and maedi-visna in North America and Europe, respectively. Cross-species transmission is possible through feeding of infected milk and colostrum. Therefore, the ovine and caprine lentiviruses are now commonly referred to as small ruminant lentiviruses.

CAE virus infection is widespread in dairy goat breeds but uncommon in meat- and fiber-producing goats. This has been attributed to genetics, management practices such as feeding colostrum and milk from a single dam to multiple kids, and industrialized farming practices (eg,

frequent introductions of new animals into a herd). Prevalence of infection increases with age but is not influenced by sex. Most goats are infected at an early age, remain virus positive for life, and develop disease months to years later.

The chief mode of spread of CAE is through ingestion of virus-infected goat colostrum or milk by kids. The feeding of pooled colostrum or milk to kids is a particularly risky practice, because a few infected does will spread the virus to a large number of kids. Horizontal transmission also contributes to disease spread within herds and may occur through direct contact, exposure to fomites at feed bunks and waterers, ingestion of contaminated milk in milking parlors, or serial use of needles or equipment contaminated with blood. Unlikely methods of transmission, as indicated by experimental studies, include in utero transmission to the fetus, infection of the kid during parturition, and infection through breeding or embryo transfer.

The pathogenesis of CAE is not fully understood. Virus-infected macrophages in colostrum and milk are absorbed intact through the gut mucosa. Infection is subsequently spread throughout the body via infected mononuclear cells. Periodic viral replication and macrophage maturation induces the characteristic lymphoproliferative lesions in target tissues such as the lungs, synovium, choroid plexus, and udder. Persistence of the CAE virus in the host is facilitated by its ability to become sequestered as provirus in host cells. Infection induces a strong humoral and cell-mediated immune response, but neither is protective.

Clinical Findings: Clinical signs are seen in ~20% of CAE virus-infected goats during their lifetime. The most common manifestation of infection is polysynovitis-arthritis,

which is primarily seen in adult goats but can occur in kids as young as 6 mo old. Signs of polysynovitis-arthritis include joint capsule distention and varying degrees of lameness. The carpal joints are most frequently involved. The onset of arthritis may be sudden or insidious, but the clinical course is always progressive. Affected goats lose condition and usually have poor hair coats. Encephalomyelitis is generally seen in kids 2–4 mo old but has been described in older kids and adult goats. Affected kids initially exhibit weakness, ataxia, and hindlimb placing deficits. Hypertonia and hyperreflexia are also common. Over time, signs progress to paraparesis or tetraparesis and paralysis. Depression, head tilt, circling, opisthotonos, torticollis, and paddling have also been described. The interstitial pneumonia component of CAE virus infection rarely produces clinical signs in kids. However, in adult goats with serologic evidence of CAE virus infection, chronic interstitial pneumonia that leads to progressive dyspnea has been documented. The “hard udder” syndrome attributed to CAE virus infection is characterized by a firm, swollen mammary gland and agalactia at the time of parturition. Milk quality is usually unaffected. Although the mammary gland may soften and produce close to normal amounts of milk, production remains low in many goats with indurative mastitis.

Lesions: Pathologic lesions of CAE virus infection are generally described as lymphoproliferative with degenerative mononuclear cell infiltration. Lesions in joints are characterized by thickening of the joint capsule and marked proliferation of synovial villi. In chronic cases, soft-tissue calcification involving joint capsules, tendon sheaths, and bursae is not uncommon. Severe cartilage destruction, rupture of ligaments and tendons, and periarticular osteophyte formation have also been described in advanced cases. Microscopic features of articular lesions include synovial cell hyperplasia, subsynovial mononuclear cell infiltration, villous hypertrophy, synovial edema, and synovial necrosis. Gross lesions associated with the neurologic form of CAE include asymmetric, brownish pink, swollen areas, most commonly in the cervical and lumbosacral spinal cord segments. Histopathologically, these lesions are characterized by multifocal, mononuclear cell inflammatory infiltrates and varying degrees of demyelination. On gross examination, lungs of affected goats are firm and gray-pink with

multiple, small, white foci, and do not collapse. The bronchial lymph nodes are invariably enlarged. Histologic findings include chronic interstitial pneumonia with mononuclear cell infiltration in alveolar septae and in perivascular and peribronchial regions. In does with udder induration, mononuclear infiltration of periductal stroma obliterates normal mammary tissue.

Diagnosis: A presumptive diagnosis can be based on clinical signs and history. Infectious arthritis caused by *Mycoplasma* spp and traumatic arthritis are differential diagnoses for arthritis induced by CAE virus. Differential diagnoses for the progressive paresis and paralysis exhibited by young kids should include enzootic ataxia, spinal cord abscess, cerebrosplinal nematodiasis, spinal cord trauma, and congenital anomalies of the spinal cord and vertebral column. If the neurologic examination indicates brain involvement, polioencephalomalacia, listeriosis, and rabies should be considered as possible causes. The pulmonary form of caseous lymphadenitis may have a similar clinical presentation to the pulmonary form of CAE in adult goats.

Both an agar gel immunodiffusion test and ELISA for CAE virus are considered sufficiently reliable for use in control programs. The agar gel immunodiffusion test is reported to be more specific but less sensitive than the ELISA. A positive test result in an adult goat implies infection but does not confirm that the clinical signs are caused by CAE virus. Kids infected at birth develop a measurable antibody response 4–10 wk after infection. However, positive test results in kids <90 days old usually reflect colostral antibody transfer. Negative test results do not reliably exclude CAE virus infection, because the time for postinfection seroconversion is variable and occasional goats have a very low titer that may not be detectable. Low antibody titers are common in late pregnancy. Because of the limitations of serologic testing, definitive diagnosis of clinical CAE requires demonstration of characteristic lesions in biopsy specimens or at necropsy. Virus isolation or PCR to demonstrate presence of viral antigen in tissues may be used to further substantiate the diagnosis.

Treatment and Control: There are no specific treatments for any of the clinical syndromes associated with CAE virus infection. However, supportive treatments may benefit individual goats. The condition of goats with the polysynovitis-arthritis may

be improved with regular foot trimming, use of additional bedding, and administration of NSAIDs such as phenylbutazone or aspirin. Goats with encephalomyelitis can be maintained for weeks with good nursing care. Antimicrobial therapy is indicated to treat secondary bacterial infections that may complicate the interstitial pneumonia or indurative mastitis components of CAE virus infection. Providing high-quality, readily digestible feed to goats positive for CAE virus may delay the onset of the wasting syndrome.

In commercial herds, one or more of the following have been recommended for

control of CAE: 1) permanent isolation of kids beginning at birth; 2) feeding of heat-treated colostrum (45°C [113°F] for 60 min) and pasteurized milk; 3) frequent serologic testing of the herd (semiannually), with identification and segregation of seronegative and seropositive goats; and 4) eventual culling of seropositive goats. If the control program includes segregation of herds into seropositive and seronegative groups, groups should be separated by a minimum of 6 ft (1.8 m), and shared equipment should be disinfected using phenolic or quaternary ammonium compounds.

COLISEPTICEMIA

(Septicemic colibacillosis, Septicemic disease)

Septicemia caused by *Escherichia coli* is a common disease of neonatal calves, and to a lesser extent lambs. It may present with signs of acute septicemia or as a chronic bacteremia with localization.

Etiology and Epidemiology: The disease is caused by specific invasive serotypes of *E. coli* that possess virulence factors enabling them to cross mucosal surfaces, overcome the bactericidal plasma factors, and produce bacteremia and septicemia. The main determinant of the disease is deficiency of circulating immunoglobulins as the result of a failure in passive transfer of colostral immunoglobulin.

Colisepticemia is seen during the first weeks of life, with the highest incidence in animals 2–5 days old. Bacteremia and septicemia in calves and lambs are most commonly associated with *E. coli* and to a lesser extent *Salmonella* spp. Approximately 30% of diarrheic calves with severe systemic clinical signs were found to be bacteremic or septicemic, with *E. coli* the most commonly isolated pathogen from blood cultures.

Transmission and Pathogenesis:

It is assumed that the primary source of the infection is the feces of infected animals, including the healthy dams and neonates, and diarrheic newborn animals, which act as multipliers of the organisms. Invasion occurs primarily through the nasal and

oropharyngeal mucosa but can also occur across the intestine or via the umbilicus and umbilical veins. Septicemic strains of *E. coli* produce endotoxin, which results in shock and rapid death. There is a period of subclinical bacteremia that, with virulent strains, is followed by rapid development of septicemia and death from endotoxemic shock. A more prolonged course, with localization of infection, polyarthritis, meningitis, and less commonly uveitis and nephritis, is seen with less virulent strains. Chronic disease also develops in calves that have acquired marginal levels of circulating immunoglobulin. The organism is excreted in nasal and oral secretions, urine, and feces; excretion begins during the preclinical bacteremic stage. Initial infection can be acquired from a contaminated environment. In groups of calves, transmission is by direct nose-to-nose contact, urinary and respiratory aerosols, or as the result of navel sucking or fecal-oral contact.

Clinical Findings and Diagnosis:

In the peracute and acute disease, the clinical course is short (3–8 hr), and signs are related to development of septic shock. Fever is not prominent, and the rectal temperature may even be subnormal. Listlessness and an early loss of interest in sucking are followed by depression, poor response to external stimuli, collapse, recumbency, cold extremities, and coma.

Tachycardia, a weak pulse, and prolonged capillary refill time are seen. The feces are loose and mucoid, but severe diarrhea is not seen in uncomplicated cases. Tremor, hyperesthesia, opisthotonos, and convulsions are seen occasionally, but stupor and coma are more common. Mortality approaches 100%. With a more prolonged clinical course, the infection may localize. Polyarthritis, ophthalmitis, omphalophlebitis, and meningitis may occur within the first week of the initial bacteremic phase.

No single laboratory parameter is considered reliable for early diagnosis of septicemia. A moderate but significant leukocytosis and neutrophilia are seen early, but leukopenia is more common in severe and advanced cases. A left shift of neutrophils and signs of toxicity of neutrophils as well as hypoglycemia are common findings. Because failure of transfer of passive immunity is the single most important predisposing factor, subnormal serum IgG and total protein concentrations are common. Subnormal platelet counts are the result of a consumptive coagulopathy. In cases of arthritis, the joint fluid has an increased inflammatory cell count and protein concentration. With meningitis, the CSF shows pleocytosis and an increased protein concentration; organisms may be evident on microscopic examination. Less commonly, other bacteria, including other Enterobacteriaceae, *Streptococcus* spp, and *Pasteurella* spp, produce septicemic disease in young calves. These organisms are more common in sporadic cases than as causes of outbreaks. They produce similar clinical disease but can be differentiated by culture. As with colisepticemia, the primary determinant of these infections is a failure of passive transfer of colostral immunoglobulins.

The diagnosis is based on history and clinical findings, demonstration of a severe deficiency of circulating IgG, and ultimately, demonstration of the organism in blood or tissues.

Treatment: Treatment requires aggressive antimicrobial, fluid, and anti-inflammatory therapy. Although blood cultures are recommended to retrospectively confirm the diagnosis, antimicrobial therapy must be initiated immediately in any animal suspected of being septic. Because there is no time for sensitivity testing, the initial choice should be a bactericidal drug that has a high probability of efficacy against gram-negative organisms. Administration IV of large

volumes of balanced electrolyte solutions over several hours is essential to correct hypovolemia and assure adequate peripheral tissue perfusion; fluids should include glucose to correct hypoglycemia. The beneficial effect of NSAIDs has been attributed to their anti-inflammatory, antipyretic, and analgesic properties. Glucocorticoids have also been proposed to treat septicemia, although their benefits for treatment of sepsis are less well established.

Control and Prevention: Calves that acquire adequate concentrations of immunoglobulin from colostrum are resistant to colisepticemia. Therefore, prevention depends primarily on management practices that ensure an adequate and early intake of colostrum. The adequacy of the farm's practice of feeding colostrum should be monitored, and corrective strategies applied as required. In North American Holstein dairy herds, natural sucking does not guarantee adequate concentrations of circulating immunoglobulins, and calves should be fed 2–4 L of first-milking colostrum containing a minimal total mass of 100 g of IgG, using a nipple bottle or an esophageal feeder, within 2 hr of birth; this is followed by a second feeding at 12 hr. A cow-side immunoassay test can assist in selection of colostrum with adequate immunoglobulin concentration. Although the circulating concentration of immunoglobulin required to protect against colisepticemia is low, high concentrations are desirable to decrease susceptibility to other neonatal infectious diseases.

When natural colostrum is not available for a newborn calf, commercial colostrum substitutes containing 25 g of IgG will provide sufficient immunoglobulin for protection against colisepticemia if fed early in the absorptive period. Plasma containing at least 4 g and preferably 8 g of IgG, administered parenterally, will provide some protection for older calves that have not been fed colostrum and are unable to absorb immunoglobulins from the intestine. Small-volume hyperimmune serum is of benefit only when it contains antibody specific to the particular serotype associated with an outbreak. The risk of early infection should be minimized by hygiene in the calving area and disinfection of the navel at birth. To minimize transmission, calves reared indoors should be in separate pens (without contact) or reared in calf hutches.

CRIMEAN-CONGO HEMORRHAGIC FEVER

Crimean-Congo hemorrhagic fever (CCHF) is a severe hemorrhagic viral disease of people acquired from infected ticks, tissues of infected wild or domestic animals, and from human patients with the disease.

Etiology and Epidemiology: The etiologic agent, CCHF virus (genus *Nairovirus*, family Bunyaviridae), is an enveloped negative-sense, trisegmented, single-stranded RNA virus. The virus has been reported in a wide area from South Africa through southern Europe, Eurasia, and into parts of western China. The virus is principally associated with ticks of the genus *Hyalomma*, although it has also been isolated from other genera of ixodid ticks. The global distribution of the virus roughly approximates that of *Hyalomma* spp ticks. Recent analyses of the genome of the virus suggest that there is significant genetic diversity somewhat correlated with geographic origin of the virus. However, anomalies to this pattern suggest that dispersal of host ticks by migratory wildlife such as birds or the movement of livestock (by people) may act to perturb the "normal" geographic distribution of CCHF virus subpopulations.

Transmission and Pathogenesis: The virus replicates in the host tick as it passes from larval through adult stages (transstadial transmission), and it can also be transmitted from one generation to the next (transovarial transmission). Thus, the tick not only is a vector but also can be a reservoir of the virus via vertical transmission. Small rodents, lagomorphs, and birds have all been incriminated as sources of infection of immature stages of the tick, while most *Hyalomma* spp ticks are multihost and use larger vertebrates as the host for the adult stage of their life cycle.

Clinical Findings and Diagnosis: In experimental inoculations, sheep and cattle become infected but develop only transient and mild increases of body temperature with little evidence of clinical disease. Viremia levels and duration are relatively low and short, and antibodies are detectable shortly after cessation of viremia. Reverse transcriptase-PCR assays can detect the virus, but primer design should match the viruses found in the region in which human patients, or other materials, have originated. Some tests (principally IgG ELISA) can detect antibodies for the remainder of the life of the animal, while other tests, such as complement fixation and indirect fluorescent antibody, can detect antibodies for shorter periods after infection. Antibody prevalence in adult livestock species in endemic regions can be >50%.

Treatment: The antiviral drug ribavirin has been used in treatment of human disease in South Africa, although placebo-controlled trials have not been completed. Lack of significant clinical disease in livestock warrants no treatment considerations.

Control and Prevention: Control strategies for human infection include the avoidance of tick bites through the use of repellents and appropriate protection when slaughtering or grooming animals. Movement of naive animals into endemic areas provides opportunity for vertebrate amplification of the virus and increasing occupational risk to butchers and hide preparers; tick control when naive animals and endemic stock are mixed is paramount. Medical personnel should use appropriate barrier nursing techniques and universal (standard) precautions when handling suspect patients.

HEARTWATER

(Cowdriosis)

Heartwater is an infectious, noncontagious, tickborne rickettsial disease of ruminants. The disease is seen only in areas infested by ticks of the genus *Amblyomma*. These include regions of Africa south of the Sahara

and the islands of the Comores, Zanzibar, Madagascar, Sao Tomé, Réunion, and Mauritius. Heartwater was introduced to the Caribbean, and it and its vector (*A. variegatum*) are endemic on the islands of

Guadeloupe and Antigua. *A. variegatum*, but not the rickettsia, has since spread to several other islands despite attempts at eradication. Possible spread to the mainland threatens the livestock industry of regions from northern South America to Central America and the southern USA. In heartwater endemic areas in southern Africa, it is estimated that mortalities due to the disease are more than double those due to bacillary hemoglobinuria (red water, *see* p 601) and anaplasmosis (*see* p 18) combined. Cattle, sheep, goats, and some antelope species are susceptible to heartwater. In endemic areas, some animals and tortoises may become subclinically infected and act as reservoirs. Indigenous African cattle breeds (*Bos indicus*), especially those with years of natural selection, appear more resistant to clinical heartwater than *B. taurus* breeds.

Etiology and Transmission: The causative organism is an obligate intracellular parasite, previously known as *Cowdria ruminantium*. Molecular evidence led to reclassification of several organisms in the order Rickettsiales, and it is now classified as *Ehrlichia ruminantium*. Under natural conditions, *E. ruminantium* is transmitted by *Amblyomma* ticks. These three-host ticks become infected during either the larval or nymphal stages and transmit the infection during one of the subsequent stages (transstadial transmission). The progeny of an infected female tick are most probably not infective (ie, there is no epidemiologically significant transovarial transmission). This and the fact that ticks are indiscriminate feeders probably play a role in the low infection rate in tick populations.

E. ruminantium can be propagated experimentally by serial passage, either by inoculating infective blood into, or by feeding infected nymphal or adult stages of a vector tick on, susceptible animals. The organism can also be propagated in tissue culture, most reliably in endothelial cells, but also in primary neutrophil cultures and macrophage cell lines. At room temperature, infective material loses its infectivity within a few hours, but the organism, together with suitable cryoprotectants, may be viably preserved in liquid nitrogen for years.

Immunity to heartwater appears to be chiefly, if not exclusively, cell mediated, because spleen cells from an immune donor inoculated into susceptible recipients protects, whereas serum from an immune donor fails to protect recipients when

challenged. There is no, or only partial, cross-protection between different stocks (strains) of *E. ruminantium*. Most of these stocks are infective for, but cannot be serially passaged in, mice; however, a few are pathogenic to mice infected by the IV route.

Pathogenesis: The pathogenesis of heartwater has not been elucidated; however, the tick probably infects the host via organisms in the saliva or regurgitated gut content while feeding. Replication of the *E. ruminantium* organisms in the tick probably occurs in the intestinal epithelium and is significantly amplified. Once in the host, the organisms may replicate first within the regional lymph nodes with subsequent dissemination via the bloodstream to invade endothelial cells of blood vessels elsewhere in the body. In domestic ruminants, there does seem to be a predilection for endothelial cells of the brain. Organisms can often be found in colonies (commonly but mistakenly referred to as morulas) within the cytoplasm of endothelial cells. Colonies can vary in size, as can the organisms that reside in them. Generally, small-sized organisms are found in larger colonies and vice versa. The smaller organisms are usually referred to as elementary bodies and represent the infective stage, the larger organisms as reticulated bodies and the proliferative stage, and those in between as intermediate bodies.

During the febrile stage, and for a short while thereafter, the blood of infected animals is infective to susceptible animals if subinoculated. Signs and lesions are associated with functional injury to the vascular endothelium, resulting in increased vascular permeability without recognizable histopathologic or even ultrastructural pathology. The concomitant fluid effusion into tissues and body cavities precipitates a fall in arterial pressure and general circulatory failure. The lesions in peracute and acute cases are hydrothorax, hydropericardium, edema and congestion of the lungs and brain, splenomegaly, petechiae and ecchymoses on mucosal and serosal surfaces, and occasionally hemorrhage into the GI tract, particularly the abomasum. The typically straw-colored effusions are high in large-molecular-weight proteins, including fibrinogen; hence, this fluid readily clots on exposure to air. The amount of effusion seen, particularly in body cavities, is not necessarily proportionate to the concentration of parasitic colonies detected in endothelial cells.

Clinical Findings: The clinical signs are dramatic in the peracute and acute forms. In peracute cases, animals may drop dead within a few hours of developing a fever, sometimes without any apparent clinical signs; others display an exaggerated respiratory distress and/or paroxysmal convulsions. In the acute form, animals often show anorexia and depression along with congested and friable mucous membranes. Respiratory distress slowly develops along with nervous signs such as a hyperaesthesia, a high-stepping stiff gait, exaggerated blinking, and chewing movements. Terminally, prostration with bouts of opisthotonus; "pedaling," "thrashing," or stiffening of the limbs; and convulsions are seen. Diarrhea is seen occasionally. In subacute cases, the signs are less marked and CNS involvement is inconsistent.

Diagnosis: In clinical cases, heartwater must be differentiated from a wide range of infectious and noninfectious diseases, especially plant poisonings, that manifest with CNS signs. In acute clinical cases in endemic areas, clinical signs alone may suggest the etiology, but demonstration of colonies of organisms in the cytoplasm of capillary endothelial cells is necessary for a definitive diagnosis. Traditionally, this is done with "squash" smears of cerebral or cerebellar gray matter stained with Romanowsky-type stains. Low concentration Giemsa stain developed for 30 min gives the best color differentiation and batch-to-batch consistency. Organisms in autolyzed material lose their stainability, and diagnosis then becomes difficult.

For the "brain squash smear," a piece of gray matter ($\sim 3 \times 3$ mm) is macerated between two microscope slides; the softened material is then spread like a blood smear with the material pushed rather than pulled along. A slight lifting of the spreader slide about every 5–10 mm creates several thick ridges across the slide, from which capillaries are arranged straight and parallel in the thin sections of the smear for easier examination. The endothelial cells of all the capillaries on a smear should be carefully scrutinized for presence of the dark purple colonies made up of clusters of individual organisms (granules) of *E. ruminantium*. The size of the granules can vary between animals, or smears from the same animal, or even between colonies on the same smear, but is usually uniform within a particular colony.

Using immunoperoxidase staining methods, a definitive diagnosis can be made on any formalin-fixed tissue samples, even from autolyzed carcasses. The contrasting color makes the search for and identification of the rickettsial colonies much quicker, although the substructure of the colonies should be identified before the diagnosis is confirmed. Because of the nature of the test, false-positive reactions may arise with some closely related organisms. On brain squash smears, *Chlamydia pecorum* can be confused with *E. ruminantium*, but histopathology or the immunoperoxidase technique allow differentiation. Serodiagnosis of animals previously exposed to the disease, ie, recovered from subclinical or clinical infection, still poses problems. Several tests are in use, including several indirect fluorescent antibody and ELISA tests. All serologic tests, including an ELISA that uses recombinant antigen, are plagued by cross-reactions with sera from animals infected with one of several *Ehrlichia* or *Anaplasma* organisms (false positive) and the fact that immune cattle on repeated exposure may become seronegative (false negative). DNA probes, available at research institutions, can be used together with PCR technology. A combination of a pCS20 probe and probes to 16S ribosomal RNA of several of the stocks are used routinely to examine samples from animals when permits for movement of animals from endemic to nonendemic areas are required. Real-time PCR has also come into use.

Treatment, Control, and Prevention:

Oxytetracycline at 10 mg/kg/day, IM, or doxycycline at 2 mg/kg/day will usually effect a cure if administered early in the course of heartwater infection. A higher dosage of oxytetracycline (20 mg/kg) is usually required if treatment begins late during the febrile reaction or when clinical signs are evident. In such cases, the first treatment should preferably be given slowly IV. A minimum of three daily doses should be given regardless of temperature; if fever persists, oxytetracycline treatment should continue for a fourth and fifth day. If the fever still does not abate, a potentiated sulfonamide at 15 mg/kg/day, IM, has been successful. The withdrawal times for milk and meat after treatment with doxycycline, short- or long-acting oxytetracycline, and sulfonamides must be observed based on local regulations.

Corticosteroids have been used as supportive therapy (prednisolone

1 mg/kg, IM), although there is debate as to the effectiveness and rationale for their use.

Diazepam may be required to control convulsions.

Affected animals must be kept quiet in a cool area with soft bedding and be totally undisturbed; any stimulation can preempt a convulsive episode and subsequent death.

Vaccination can help with the control of heartwater; however, it is neither easily administered nor monitored and gives variable to no cross-protection to the various *E. ruminantium* stocks. The "infection and treatment method" for immunization is in use in southern Africa, where infected sheep blood containing fully virulent organisms of the Ball 3 stock is used for infection, followed by monitoring of rectal temperature and antibiotic therapy after a fever develops. In certain circumstances, the "controlled" infection is followed by preventive "block treatment" without temperature recording (cattle on day 14 [susceptible *B. taurus* breeds] or day

16 [for the more resistant *B. indicus* breeds], sheep and Angora goats on day 11, and Boer and crossbreed goats on day 12). Young calves (<4 wk old), lambs, and kids (<1 wk old) have an innate age-related resistance to heartwater, so if challenged by natural or induced infections within this time period, most recover spontaneously and develop a reasonable immunity.

Control of tick infestation is a useful preventive measure in some instances but may be difficult and expensive to maintain in others. Excessive reduction of tick numbers, however, interferes with the maintenance of adequate immunity through regular field challenge in endemic areas and may periodically result in heavy losses.

Chemoprophylaxis involves a series of oxytetracycline injections to protect susceptible animals from contracting heartwater when introduced into endemic areas while also allowing them to develop a natural immunity.

HISTOPHILOSIS

Histophilosis, or *Histophilus somni*-associated disease, is a common disease in North American cattle. It also has been reported to occur sporadically in beef and dairy cattle worldwide. *H. somni* predominantly causes an acute, often fatal, septicemic disease that can involve the respiratory, cardiovascular, musculoskeletal, or nervous systems, either singly or together in confined cattle. The reproductive system is often affected without clinical signs or other systemic involvement; however, herd infertility has been reported to occur more frequently.

Etiology and Transmission: *H. somni* is a gram-negative, nonmotile, nonspore-forming, nonencapsulated, pleomorphic coccobacillus that requires an enriched medium and a microaerophilic atmosphere for culture. Hemolysis on blood agar occurs within 48 hr due to an exotoxin produced by most disease-causing isolates. Pathogenic and nonpathogenic strains have been differentiated. The virulence of the organism may vary by region and age group.

H. somni is considered a commensal of bovine mucous membranes. Pathogenic and nonpathogenic strains of *H. somni* are found in the sheath and prepuce of males, the vagina of females, and in the nasal passages of both sexes. Nasal and urogenital secretions are believed to be sources of the organism. The organism may colonize the respiratory tract, presumably after inhalation, and gain access to the bloodstream via that route. Colonization of the male and female reproductive tracts may involve venereal spread.

Epidemiology: Recently weaned calves are at higher risk of infection and death from histophilosis than are previously weaned older calves, yearlings, or mature animals. The risk of infection with *H. somni* is highest early in the feeding period, with "high-risk" calves in confinement establishing peak titers to *H. somni* at ~21–23 days after arrival. Although calves are generally exposed to *H. somni* earlier in the feeding period, the average time on feed for calves that die of histophilosis has been reported to be 30–60 days. Sudden death due to peracute septicemia usually occurs within 21 days

after arrival, although it may occur throughout the feeding period. Reproductive disease manifestations, including granular vulvovaginitis, abortion, and mastitis, can affect individual beef and dairy cattle or more of the herd.

Pathogenesis: Septicemia is likely required for most forms of histophilosis. Strains of *H somni* that cause disease adhere to the endothelium of vessels, resulting in contraction, exposure of collagen, platelet adhesion, and thrombus formation. The primary disease mechanism likely involves a thrombus, rather than a thromboembolism as once thought. Some bacterial strains may adhere to the endothelium in vessels of the pleura, myocardium, pericardium, synovium, or a variety of other tissues (eg, brain, larynx). Interruption of the blood supply in those areas results in the formation of an infarction with destruction of tissue and the formation of a necrotic sequestrum. The development of clinical signs is associated with the extent of organ system involvement. The susceptibility of individual animals and variations in the preference of strains of the organism for vessels in different tissues may be important in the development of the different forms of the disease, but these have not been extensively studied.

The apparent preference of *H somni* for different organ systems has defined the changing character of histophilosis. Initially, the disease presented primarily as an encephalitic syndrome that changed to one in which pleuritic and myocardial forms predominated. Anecdotal observations suggest that the organism may be changing again (eg, from a focal to a more generalized myocarditis). Recent microbiologic examinations of the organism have identified a variety of mechanisms that contribute to its diverse virulence and ability to withstand treatment.

Reproductive disease has not been associated with systemic infection; the inflammation appears to be more local, even though the pathogenesis in these situations is not well understood.

Clinical Findings: Sudden death is usually the first indication of *H somni* infection in a group of confined animals and is often mistaken by the stock attendants as evidence of a digestive tract upset such as bloat. A profound depression has been described as the most noticeable clinical sign of encephalitic histophilosis. Other findings are determined by the system(s)

involved and may include rapid respiration, stiffness, muscle weakness, ataxia, lameness, and severe behavioral changes. Animals affected with pleuritic histophilosis are usually found dead without any treatment history; if alive, they may exhibit extreme dyspnea. Animals with myocarditis display very poor exercise tolerance and may collapse and die when movement to a handling facility is attempted. Animals with the encephalitic form and early depression rapidly proceed to recumbency, with occasional signs of hyperesthesia before death. Animals found dead and confirmed with *H somni* infection often have a history of treatment for undifferentiated fever or depression in the previous 14 days.

Closer individual examination usually reveals a febrile animal. Polypnea and/or dyspnea may be evident overtly and are easily confirmed by auscultation. Hypoxemia associated with a malfunctioning pulmonary or cardiovascular system can be easily confused with other clinical signs such as depression or even blindness. A sterile blood sample obtained from an untreated animal at this time tests positive for *H somni* in a high percentage of cases.

Lesions: Feedlot cattle that die of possible histophilosis should be examined at necropsy. These animals may exhibit an array of postmortem findings, including fibrinous pleuritis without bronchopneumonia, a focal myocardial lesion (often in the papillary muscle of the left ventricle), fibrinous pericarditis, bronchopneumonia, polyarthritis, and a fibrinous laryngitis. Less common gross postmortem lesions include polyserositis, fibrinous gonitis, and a fibrinopurulent meningitis. Probably the most common lesion seen in the feedyard is that of "left heart failure" associated with a marked necrotic sequestrum in the myocardial wall.

In animals that survive long enough to allow the pathology to progress, the fibrinous portion of the lesions becomes fibrotic, and the infarctions or sequestrae in the heart or larynx liquefy and wall off to become an abscess. Lesions of the reproductive tract may include suppurative vaginitis, cervicitis, and endometritis.

Diagnosis: A definitive diagnosis is based on sampling and examination of affected tissues collected during a necropsy or clinical examination. A diagnosis at necropsy of "left heart failure" with a concomitant myocardial lesion or a

carcass in which the thoracic space is filled with fluid and fibrin with little pneumonia is considered definitive for histophilosis. Historically, isolation of the organism from CSF, brain, blood, urine, joint fluid, or other sterile, internal organs or fluids has been used to confirm the diagnosis. Because *H somni* is a commensal of the mucous membranes of cattle, the bacterium should be isolated in predominant or pure culture from the respiratory or urogenital tract to be considered a significant etiologic agent. This may be difficult, because antimicrobial treatment often interferes with recovery of the organism. The characteristic histologic lesion is suppurative with heavy infiltrations of neutrophils in all tissues where localization of the bacteria occurs. Currently, the diagnosis is usually confirmed with molecular techniques such as immunohistochemical staining of H&E-stained tissues or a fresh lesion swab subjected to a specific PCR test.

Treatment and Prevention: A major hindrance to successful treatment of individual histophilosis cases is the difficulty in identifying affected animals early in the course of disease because of its often rapidly fatal nature. Antimicrobial treatment is most effective in the early stages of disease. Florfenicol (20 mg/kg, IM, repeated in 48 hr, or 40 mg/kg, SC, once) may be the antimicrobial of choice if histophilosis is the tentative diagnosis in an individual animal.

Evidence supporting the use of prophylactic or metaphylactic treatment

with a sustained-action antimicrobial or an oral antimicrobial supplement in the feed on arrival at the feedlot or in the face of occurring cases to reduce histophilosis mortality is scant. This contrasts with the evidence that *H somni* is susceptible in vitro to a wide range of antimicrobials, including florfenicol, tilmicosin, tulathromycin, tetracyclines, trimethoprim-sulfadoxine, fluoroquinolones, and ceftiofur. Historically, the precise mechanism by which the organism is able to avoid systemic antimicrobial blood levels has not been well understood. Recently, it has been postulated that as *H somni* proliferates, it forms biofilms that allow it to adhere to the endothelium and to withstand an otherwise adequate level of an antimicrobial.

Bacterins containing different strains of the organism have been used to immunize cattle against *H somni*. A favorable humoral response generated by a single immunization with a commercial vaccine has been shown to be improved when boosted with a second immunization. Calves initially immunized before "turn out" (estimated age to be 2 mo) will respond to a second immunization anamnestically on their arrival at the feedlot after weaning. Although protection with current bacterins and immunogens against histophilosis morbidity and mortality has been reported, the ability of immunization to consistently spare cattle from the disease is compromised when immunization and challenge occur at the same time (ie, arrival at the feedlot).

HEMORRHAGIC SEPTICEMIA

Hemorrhagic septicemia (HS) is an acute, highly fatal form of pasteurellosis that affects mainly water buffalo, cattle, and bison. It is considered the most economically important bacterial disease of water buffalo and cattle in tropical areas of Asia, particularly in southeast Asia, where water buffalo populations are high. Disease is most devastating to smallholder farmers where husbandry and preventive practices are poor and free-range management is common. HS is also an important disease in Africa and the Middle East, with sporadic

outbreaks occurring in southern Europe. The only confirmed outbreaks of HS in the Americas occurred in bison in Yellowstone National Park, most recently from 1965–1967. Natural disease occurs infrequently in pigs, sheep, and goats and has been reported in camels, elephants, horses, donkeys, yaks, and various species of deer and other wild ruminants.

Etiology: Classical HS as defined by the OIE is caused by *Pasteurella multocida* serotypes B:2 and E:2 (Carter and Hedde-

ston classification system). Serotype B:2 has been identified in most areas where the disease is endemic, whereas serotype E:2 has been found only in Africa. Septicemic pasteurellosis that is clinically similar to HS can be caused by a wide variety of other *P multocida* serotypes and has been reported worldwide.

Transmission, Epidemiology, and Pathogenesis:

The tonsils of up to 5% of healthy water buffalo and cattle are colonized by small numbers of *P multocida* serotype B:2 or E:2, which can be shed during periods of stress. Common stressors associated with outbreaks include high temperature and humidity, concurrent infection (blood parasites or foot and mouth disease), poor nutrition, or work stress. Although outbreaks can occur at any time, disease is most prevalent during the rainy season. Increased outbreaks associated with high rainfall are most likely due to the multiple stressors present during this time and the moist conditions, which prolong the survival time of the organism in the environment. Infection occurs by contact with infected oral or nasal secretions from either healthy carrier animals or animals with clinical disease, or by ingestion of contaminated feed or water. Infection begins in the tonsil and adjacent nasopharyngeal tissues. Subsequently, bacteremia leads to dissemination and rapid growth of bacteria in various locations, tissue injury, a host cytokine response, and release of lipopolysaccharides that results in a rapidly progressing endotoxemia. Clinical signs can appear 1–3 days after infection, and death can occur within 8–24 hr after the first signs develop. In endemic areas, HS affects older calves and young adults, and morbidity and mortality are variable. In nonendemic areas, epizootics can occur with high morbidity and mortality that can reach 100%. Water buffalo tend to be more susceptible and have more severe clinical disease than cattle. Recovery can stimulate acquired immunity to homologous and often heterologous strains of *P multocida*, and some of these animals become healthy carriers that can provide a source of infection for future outbreaks.

Clinical Findings: Many cases of HS are peracute and result in death within 8–24 hr. These animals often have fever, hypersalivation, nasal discharge, and difficult respiration, but because of the short duration of

disease these signs may easily be overlooked. Acute disease can persist up to 3 days, and less often 5 days, and is characterized by fever of 104°–106°F (40°–41.1°C), apathy or restlessness and reluctance to move, hypersalivation, lacrimation, nasal discharge that begins as serous and progresses to mucopurulent, subcutaneous swelling in the pharyngeal region that extends to the ventral neck and brisket (and sometimes the forelegs), progressive respiratory difficulty, cyanosis, terminal recumbency, and possibly abdominal pain with diarrhea.

Lesions: The characteristic lesion of HS is swelling of the subcutis and muscle of the submandibular region, neck, and brisket by clear to blood-tinged edema fluid. Serous to serofibrinous fluid may also be present in the thorax, pericardium, and abdominal cavity. There is typically widespread congestion with petechiae and ecchymoses in tissues and on serosal surfaces. Hemorrhages are often most prominent in the pharyngeal and cervical lymph nodes. Pulmonary congestion and edema, sometimes with interstitial pneumonia, and gastroenteritis may occur in some cases.

Diagnosis: Clinical diagnosis of HS in endemic areas is based on history, lapses in vaccination, environmental conditions, and the characteristic clinical signs and lesions of disease. Although typical outbreaks of HS are not difficult to recognize in endemic regions, acute salmonellosis, anthrax, and noninfectious toxicities should also be considered. Sporadic cases are more difficult to diagnose clinically and could be confused with blackleg, lightning strike, or snakebite. A definitive diagnosis of HS is based on isolation of *P multocida* serotype B:2 or E:2 (or other less common serotypes recognized by the OIE as causing HS) from the blood and tissues of an animal with typical signs. Various other *P multocida* serotypes can cause HS-like disease in cattle and water buffalo, which must be differentiated from classical HS. The passive mouse protection test using specific B:2 and E:2 immune rabbit sera has been used in Asia and Africa to identify these serotypes. More precise tests, such as indirect hemagglutination, coagglutination, counter immunoelectrophoresis, and immunodiffusion tests have also been used in some laboratories. More recently, molecular techniques, including pulsed field gel electrophoresis, southern blots, and

PCR-based protocols, have been used to differentiate between capsular and somatic serotypes. The PCR techniques are most feasible for use in endemic areas and can be used with various samples, including blood, tissues, or bacteria from broth or plate cultures.

Treatment and Prevention: Antimicrobials are effective against HS if administered very early in the disease. However, because HS progresses rapidly, therapy is often unsuccessful. During outbreaks, any animal with a fever should be treated with IV antimicrobials as soon as possible to quickly obtain systemic bactericidal antimicrobial concentrations. Various sulfonamides, tetracyclines, penicillin, gentamicin, kanamycin, ceftiofur, enrofloxacin, tilmosin, and chloramphenicol have been used effectively to treat HS. However, plasmid- and chromosomal-mediated multidrug resistance seems to be increasing for some strains of *P. multocida*, and resistance to tetracyclines and penicillin has been reported for serotype B:2.

Killed vaccines are most commonly used for prevention and include bacterins, alum-precipitated and aluminum hydroxide gel vaccines, and oil-adjuvant vaccines. In animals >3 yr old, an initial two doses, 1–3 mo apart, is recommended, followed by booster vaccinations once or twice yearly. The oil-adjuvant vaccine provides protection for 9–12 mo and is given

annually. Although it provides the best immunity, it is unpopular in the field because of its viscosity and difficulty of administration. Oil-based vaccines combined with tween 80 or saponin have also been used in attempts to increase the ease of administration or immune protection. The commonly used alum-precipitated and aluminum hydroxide gel vaccines have shorter durations of immunity, and twice yearly booster vaccinations are recommended. It is important that the vaccines are made from the strains of *P. multocida* circulating in the regions of intended use to obtain maximal effectiveness. Attenuated or modified-live vaccines have been used with some success. A live avirulent vaccine prepared from a *P. multocida* serotype B:3(4) of fallow deer origin seems effective and is recommended for use by the Food and Agricultural Organization of the United Nations (FAO) in southeast Asia. Various modified-live and subunit vaccines made from either purified or recombinant bacterial components have also been investigated experimentally.

Zoonotic Risk: The *P. multocida* serotypes that cause HS have not been recovered from human infections. However, because many serotypes of *P. multocida* have the potential to infect people, appropriate precautions should be taken when dealing with suspected cases of HS or HS-like disease.

MALIGNANT CATARRHAL FEVER

(Malignant head catarrh, Snotsiekte, Catarrhal fever, Gangrenous coryza)

Malignant catarrhal fever (MCF) is an infectious systemic disease that presents as a variable complex of lesions affecting mainly ruminants and rarely swine. It is principally a disease of domestic cattle, water buffalo, Bali cattle (banteng), American bison, and deer. In addition to these farmed animals, MCF has been described in a variety of captive ruminants in mixed zoologic collections. In some species, such as bison and some deer, MCF is acute and highly lethal, capable of affecting large numbers of animals. With occasional exceptions, the disease in cattle

normally is seen sporadically and affects single animals. MCF is typically fatal; however, there are outbreaks in which several animals are affected, with evidence of recovery and mild or inapparent infections in some cases. It also occasionally presents as chronic alopecia and weight loss. Its distribution is essentially worldwide, mirroring that of the principal carriers, domestic sheep and wildebeest. MCF has long been a major problem in farmed deer operations, and in recent years has emerged as a severe threat to the commercial bison industry.

Etiology: MCF results from infection by one of several members of a group of closely related ruminant gammaherpesviruses of the *Rhadinovirus* genus. Although the MCF group of ruminant rhadinoviruses currently comprises approximately 10 known members, only a few are known to be pathogenic under natural conditions. The principal carriers and their viruses are sheep (ovine herpesvirus-2), wildebeest (alcelaphine herpesvirus-1), and goats (caprine herpesvirus-2). Another strain of unidentified origin has caused MCF in white-tailed deer. Virtually all clinical cases are caused by the sheep or wildebeest viruses.

The viruses are maintained within the sheep and wildebeest populations in similar but not identical patterns. Lambs are infected usually at 3–6 mo of age by aerosol transmission from other individuals within the flock and begin to actively shed virus at ~6–9 mo of age. Shedding decreases at ~10 mo, with adults shedding at a much lower rate than adolescents. Wildebeest calves, in contrast, are infected in the perinatal period by horizontal and occasional intrauterine transmission, and actively shed virus until 4–6 mo of age. Transmission is by transfer of virus-laden nasal secretions by direct contact or poorly defined airborne routes. Transmission from sheep to cattle has been demonstrated at distances of at least 70 m in cattle and at distances of up to 5.1 km in bison. In Africa, most wildebeest-associated MCF is seen around the time of wildebeest calving; however, sheep-associated MCF (SAMCF) does not follow the same pattern. Ewes do not shed virus in placental tissues or secretions and do not experience more frequent shedding episodes around lambing time. The only rational and established factors contributing to seasonality of SA-MCF are climatic influences on virus survival and the age-related shedding patterns in lambs. The epidemiology of the caprine MCF virus appears similar to that of sheep.

The severity of SA-MCF outbreaks depends on factors such as the total numbers, population density, and species of susceptible hosts involved; the closeness of contact; and the amount of shed virus available for transmission. Cases usually are seen sporadically in European breeds of cattle (*Bos taurus*), because they are a relatively resistant species. By contrast, Bali cattle, bison, and some but not all cervid species (eg, white-tailed deer, Pere David's deer) are highly susceptible. Infectious dose of virus is a primary determinant of infection and clinical disease, with bison being >1,000 times more susceptible to

infection than cattle. As agricultural systems involving bison and deer production have developed, MCF has become more troublesome. It is a leading cause of infectious disease losses on New Zealand deer farms. In bison exposed to large numbers of adolescent sheep, losses can be devastating. Approximately 800 head died in one outbreak in the USA in 2003. The incubation period is variable and ranges from 14 to >200 days from initial exposure.

Among animals that survive, infection is lifelong. Some susceptible species, including cattle and bison, may be latently infected. Recrudescence of latent infections is possible and must be considered for cases with no known history of contact with carriers.

MCF is transmitted only between carriers and clinically susceptible animals. Affected animals do not transmit MCF to their cohorts.

Clinical Findings: Acute MCF cases caused by ovine herpesvirus-2 and alcelaphine herpesvirus-1 are similar clinically and pathologically. Disease course may range from peracute to chronic. Cases in deer and bison are often peracute with sudden death. Deer that survive for a few days and bison usually develop hemorrhagic diarrhea, bloody urine, and corneal opacity before expiring. High fever (106°–107°F [41°–41.5°C]) and depression are common. Other possible signs include catarrhal inflammation; erosions and mucopurulent exudation affecting the upper respiratory, ocular, and oral mucosa; swollen lymph nodes; lameness; and CNS signs (depression, trembling, hyporesponsiveness, stupor, aggressiveness, convulsions). Historically, MCF has been described as having several “forms”—mild, peracute, head and eye, intestinal, etc. There is little basis for this division and it is of little utility. Variation in organ system involvement sometimes can be seen in the same outbreak and is at least partially related to survival time after disease onset. On average, the time to death in European cattle breeds is somewhat longer than in deer, bison, water buffalo, and Bali cattle. In cattle, swollen lymph nodes and severe eye lesions (panophthalmitis, hypopyon, corneal opacity) are more frequent, and hemorrhagic enteritis and cystitis less frequent, than in deer and bison. Peripheral (centripetal) corneal opacity is an important clinical sign suggestive of MCF in cattle. Skin lesions (erythema, exudation, cracking, crust formation) are common in animals that do not succumb quickly.

Hematologic changes are variable, and an inflammatory leukogram may not be present, even in febrile animals with severe lesions. As many as 25% of cattle experience chronic disease, and sometimes the disease waxes and wanes. Mortality rates in clinically affected animals generally approach 95%. However, in limited circumstances, survival in cattle can be higher, although survivors can rarely return to normal production.

In a few outbreaks, the goat MCF virus (caprine herpesvirus-2) induced disease in white-tailed and Sika deer. These cases were subacute to chronic, with weight loss, dermal inflammation, and alopecia as the primary signs. Whether this strain of virus causes disease in species other than deer is not known.

Lesions: The disease is systemic, and lesions may be found in any organ, although severity and frequency varies greatly. The principal lesions are inflammation and necrosis of respiratory, alimentary, or urinary mucosal epithelium; subepithelial lymphoid infiltration; generalized lymphoid proliferation and necrosis; and widespread vasculitis. Mucosal ulcerations and hemorrhages are common. Hemorrhages may be present in many parenchymatous organs, particularly lymph nodes. A classic but not pathognomonic histologic lesion is fibrinoid necrosis of small muscular arteries, but vessels of all types may be inflamed, including those in the brain. Prominent white nodules representing intramural and perivascular proliferation may be apparent, particularly in the kidneys.

Diagnosis: Diagnosis of MCF is based on clinical signs, gross and histologic lesions, and laboratory confirmation. Primary differential diagnoses include bovine viral diarrhea/mucosal disease, rinderpest,

infectious bovine rhinotracheitis, and East Coast fever (theileriosis). When CNS involvement is prominent, MCF can resemble rabies and the tickborne encephalitides. A history of contact with a carrier species (sheep, goats, or wildebeest) can be helpful, although recrudescence cases can be seen without such a history. Reliable and specific laboratory assays for antibody and for viral DNA are available. The test of choice for clinical diagnosis is PCR to detect viral DNA. Preferred tissues for testing are anticoagulated blood, kidney, intestinal wall, lymph node, and brain.

Serology is used to survey healthy animals and is indicative only of infection—latent infection among susceptible animals may render serology alone inconclusive evidence of current disease. Several seroassays are available, including viral neutralization, immunoperoxidase, immunofluorescence, and ELISA. The polyclonal assays are hampered by cross-reactivity. The monoclonal-based competitive ELISA is currently the most specific and detects antibody against all of the known MCF group viruses. Only PCR can discriminate between the different viruses.

Treatment and Control: The prognosis is grave. No treatment has been found to provide any consistent benefit. Stress reduction of subclinical or mildly affected animals is indicated. No vaccine is currently available. Sheep can be produced that are free of virus by early weaning and isolation. The only other effective control strategy is separation of carriers from susceptible species. When large numbers of potent shedders are present, such as in lamb feedlots, distances >1 km may be necessary to protect highly susceptible species such as bison.

NAIROBI SHEEP DISEASE

Nairobi sheep disease (NSD) is a tickborne viral disease of sheep and goats characterized by fever and hemorrhagic gastroenteritis, abortion, and high mortality. The disease was first identified near Nairobi, Kenya, in 1910, and NSD virus was shown to be the causative agent in 1917. The disease is endemic in Kenya, Uganda, Tanzania, Somalia, Ethiopia, Botswana, Mozambique,

and Republic of Congo. Human infections are rare; however, accidental infections have been reported among laboratory workers, resulting in fever, joint aches, and general malaise. The African field rat (*Arvicathus abyssinicus nubilans*) is a potential reservoir host. NSD is a reportable disease in the USA and is one of the OIE listed diseases.

Etiology and Transmission: NSD virus is classified in the genus *Nairovirus*, family Bunyaviridae, and is possibly the most pathogenic virus known for sheep and goats. It is identical to or closely related to Ganjam virus, a tickborne infection of sheep, goats, and people in India. Genetic and serologic data demonstrate that Ganjam virus is an Asian variant of NSD virus. Both Ganjam and NSD viruses are phylogenetically more closely related to Hazara virus than Dugbe virus. In addition, the NSD virus is serologically related to Dugbe virus, another tickborne infection in cattle, and to Crimean-Congo hemorrhagic fever virus (see p 751). It is transmitted transovarially and transstadially by the brown ear tick, *Rhipicephalus appendiculatus*, in which it can survive up to 800 days. The unfed adult ticks can transmit NSD virus for >2 yr after infection. Other *Rhipicephalus* spp and *Amblyomma variegatum* ticks also may transmit the disease. The virus is shed in urine and feces, but the disease is not spread by contact.

Clinical Findings: In natural outbreaks, disease usually occurs 5–6 days after susceptible animals move to areas infested with *R. appendiculatus*. Clinical signs begin with a steep rise in body temperature (41°–42°C [105.8°–107.6°F]) that persists for 1–7 days. Leukopenia and viremia usually coincide with the febrile phase. Diarrhea usually appears 1–3 days after the onset of fever and worsens as infection progresses. Illness is manifest by depression; anorexia; mucopurulent, blood-stained, nasal discharge; occasional conjunctivitis; and fetid dysentery that causes painful straining. Pregnant animals frequently abort. In peracute and acute cases, the time between the appearance of disease and death is usually 2–7 days but may be as long as 11 days in less acute cases. Experimental infection has shown that indigenous Persian fat-tailed and European breeds of sheep are equally susceptible; however, mortality rate in the field is as high as 70%–90% for indigenous breeds of sheep and 30% for exotic and cross-breeds. The clinical signs in goats are similar to those in sheep but less severe, although 80% mortality has been reported. The presence of colostral immunity not only protects lambs and kids from early exposure to infection but also allows development of active immunity, enabling survival in tick-infested areas.

Lesions: The most striking features on external examination of the carcass are the

hindquarters soiled with feces (or a mixture of blood and feces) and dehydration, especially in animals with prolonged scouring. Also common are conjunctivitis and dried crusts around the nostrils as a result of nasal discharge. Necropsy findings include enlarged and edematous lymph nodes; mild splenomegaly; and hemorrhages in the GI (particularly the abomasum), respiratory, and female genital tracts, as well as in the gallbladder, spleen, and heart. Petechial and ecchymotic hemorrhages in the mucosa of the cecum and colon frequently appear as longitudinal striations and are sometimes the only lesion evident. Subserosal hemorrhages may be seen in the cecum, colon, gallbladder, and kidneys. Conjunctivitis with dried crusts around the nostrils is often noted. Common histopathologic lesions are hyperplasia of lymphoid tissues, myocardial degeneration, nephrosis, and coagulative necrosis of the gallbladder.

Diagnosis: The occurrence of a disease in sheep or goats with high mortality accompanied by a tick infestation is suggestive, especially if it follows movements into endemic areas or changes in tick populations that have been induced by heavy and prolonged rainfall. Confirmation of suggestive signs and lesions requires detection of virus or viral antigen and antibodies. The preferred specimens are plasma from febrile animals, mesenteric lymph nodes, spleen, and serum. Personal protective equipment should be used when conducting a necropsy and handling the agent in the laboratory. Mouse inoculation and cell cultures can be used for primary isolation of virus. Sheep are the most sensitive animals for isolation, whereas a baby hamster kidney cell line and lamb or hamster kidney cell cultures are the most sensitive cells. Agar gel immunodiffusion, complement fixation, and ELISA can be valuable for detection of antigen in the infected tissues or tissue culture. New probes have been developed targeting the S and L segments of Dugbe virus and can potentially be used as a rapid diagnostic tool for NSD. Antibodies in infected or recovered animals can be detected by immunodiffusion, complement fixation, indirect fluorescent antibody tests, hemagglutination, and ELISA.

Differential diagnoses include peste des petits ruminants (see p 766), Rift Valley fever (see p 768), heartwater (see p 751), and salmonellosis (see p 195).

Treatment and Control: No specific antiviral agent is available for treatment. Unaffected animals in the flock may be treated with acaricides (eg, pyrethroids in a grease, cypermethrin “pour-on” products, various dip preparations). Longterm tick control is not cost-effective in endemic areas.

In endemic areas, clinical signs are not seen unless susceptible animals are introduced. Such animals should be vaccinated, as should those exposed when

the range of the tick vector extends. Two types of experimental vaccines have been developed—a modified-live virus vaccine attenuated in mouse brain and an inactivated oil adjuvant vaccine. A single dose of the modified-live vaccine produces rapid immunity; however, revaccination is necessary to maintain full protection. Two doses of the inactivated vaccine are required to elicit good protection. Neither of these vaccines is produced commercially.

PARATUBERCULOSIS

(Johne's disease)

Paratuberculosis is a chronic, contagious granulomatous enteritis characterized in cattle by persistent diarrhea, progressive weight loss, debilitation, and eventually death. It is considered a listed disease by the OIE, meaning it is a priority disease for international trade. The etiologic agent, *Mycobacterium paratuberculosis*, also known as *Mycobacterium avium* subsp *paratuberculosis*, is believed capable of infecting and causing disease in all other ruminants (eg, sheep, goats, llamas, deer) and in captive and free-ranging wildlife. The infection has also been recognized in omnivores and carnivores such as wild rabbits, foxes, weasels, pigs, and nonhuman primates. Distribution is worldwide. National control programs include those established in Australia, Norway, Iceland, Japan, The Netherlands, Denmark, Ontario, Canada, and the USA. The highest published prevalence is in dairy cattle, with 20%–80% of herds infected in many of the major dairy-producing countries. Limited information is available about the prevalence in other species. The disease is of economic importance for the goat industry in Spain and the sheep industry in Australia.

Etiology and Pathogenesis:

M paratuberculosis is excreted in large numbers in feces of infected animals and in lower numbers in their colostrum and milk. It is resistant to environmental factors and can survive on pasture for >1 yr; survival in water is longer than in soil. The infection is usually acquired through the fecal-oral route; the dose needed to infect an animal is not known. Introduction of the disease into a noninfected herd is usually through herd

expansion or replacement purchases; the infection is introduced via subclinically infected carriers.

Infection is acquired early in life—often soon after birth—but clinical signs rarely develop in cattle <2 yr old, because progression to clinical disease occurs slowly. Resistance to infection increases with age, and cattle exposed as adults are much less likely to become infected. Infection is acquired by ingestion of the organism when nursing on contaminated teats; consumption of milk, solid feed, or water contaminated by the organism; or licking and grooming behavior in a contaminated environment. In the later, bacteremic stages of infection, intrauterine infections can be seen. After ingestion and uptake in the Peyer's patches of the lower small intestine, this intracellular pathogen infects macrophages in the GI tract and associated lymph nodes. It is possible that some animals may eliminate infection through a cell-mediated immune response that encourages microbiocidal activity in macrophages, but the frequency with which this occurs is unknown. In most cases, the organisms multiply and eventually provoke a chronic granulomatous enteritis that interferes with nutrient uptake and processing, leading to the cachexia typical of advanced infections. This may take months to years to develop and is usually paralleled by a decline in cell-mediated immunity, a rise in serum antibody, and bacteremia with dissemination of the infection beyond the GI tract. Fecal shedding begins before clinical signs are apparent, and animals in this “silent” stage of infection are important sources of transmission.

Clinical Findings: Paratuberculosis in cattle is characterized by weight loss and diarrhea in the late phases of infection, but infected animals can appear healthy for months to years. In cattle, diarrhea may be constant or intermittent; in sheep, goats, and other ruminants, diarrhea may not be seen. It typically does not contain blood, mucus, or epithelial debris and is passed without tenesmus. Throughout weeks or months, the diarrhea becomes more severe, further weight loss occurs, coat color may fade, and ventral and intermandibular edema may develop due to a protein-losing enteropathy. This leads to low concentrations of total protein and albumin in plasma, although gamma globulin levels are normal. In dairy cattle and goats, milk yield may drop or fail to reach expected levels. Animals are alert, and temperature and appetite are usually normal, although thirst may be increased. The disease is progressive and ultimately terminates in emaciation and death. In infected herds, the mortality rate may be low for a number of years, but as many as 50% of animals may be infected subclinically with associated production losses. The disease in sheep and goats is similar, but diarrhea is not a common feature, and advanced cases may shed wool easily. In cervids (deer and elk), the course of the disease may be more rapid.

Lesions: A diverse array of pathology may be seen in infected animals, ranging from a complete lack of gross lesions to a thickened and corrugated intestine with enlarged and edematous neighboring lymph nodes. Often, there is no correlation between clinical signs and the severity of lesions. Carcasses may be emaciated, with loss of pericardial and perirenal fat in more advanced, cachectic cases. Intestinal lesions can be mild, but typically the distal small-intestinal wall is diffusely thickened with a nonulcerated mucosa thrown into prominent transverse folds. Lesions may extend proximally and distally to the jejunum and colon. Serosal lymphangitis and enlargement of mesenteric and other regional lymph nodes are usually apparent. Histologically, there is a diffuse granulomatous enteritis characterized by the progressive accumulation of epithelioid macrophages and giant cells in the mucosa and submucosa of the gut. Sparse to myriad acid-fast organisms may be seen within the macrophages. Often, there is no correlation between clinical signs and the severity of lesions. Sheep, goats, and deer sometimes develop foci of caseation with calcification in the intestinal wall and lymph nodes.

Diagnosis: There are many commercially available tests for paratuberculosis, each with their own advantages, disadvantages, and appropriate application. The assays focus on detecting the organism in feces or tissue (culture, PCR), on finding evidence of cellular immune response to infection (skin testing, interferon- γ), or on detecting antibody to *M paratuberculosis* antigens (ELISA). Use of different tests in combination can increase diagnostic sensitivity. Given the biology of the infection and the need to manage it on a herd basis, diagnostic information should be gathered for a group of animals rather than for an individual case. An animal showing signs of disease is more likely to provide diagnostic evidence of the infection (shedding, antibody production) than an animal at the preclinical stage of infection. Necropsy with culture and histopathology on multiple tissues is the gold standard for definitive diagnosis. Ziehl-Neelsen stains of tissue samples for acid-fast bacteria usually reveal abundant mycobacteria in lesions; however, in some cases, a careful search still may not reveal their presence. Acid-fast staining of an impression smear made from the ileum of a cow with typical pathology is a quick, low-cost (albeit insensitive) method to arrive at a preliminary diagnosis. Biopsy of full-thickness sections of ileum and regional lymph nodes for culture and histopathology may provide a definitive diagnosis; however, this approach is usually restricted to particularly valuable animals. *M paratuberculosis* has been isolated from a wide variety of tissue sites, but the mesenteric and ileocecal lymph nodes, ileum, and liver are most frequently recommended for diagnostic sampling.

Serologic tests are rapid, low-cost methods for antemortem confirmation of a clinical diagnosis; sensitivity is >85% in clinically affected animals. They are also useful to detect infection in clinically normal cattle in the later stages of infection that are shedding large numbers of *M paratuberculosis*; sensitivity is ~45%. Of the serologic tests, those based on ELISA technology offer the highest sensitivity and specificity and are best used to determine the infection prevalence in a herd. Quantitative use of ELISA to identify animals for selective culling or isolation in herds may be a cost-effective strategy for disease control; higher ELISA values are associated with higher probabilities of infection and higher rates of fecal shedding. Fecal culture is more

sensitive and more specific than serology, but the organism grows very slowly (2–4 mo) and the assay is more costly than serology. Pooling of fecal samples (eg, five samples per pool) or culture of manure from farm sites where cattle commingle (environmental sampling) can establish a herd's infection status at a lower cost, despite some reduction in test sensitivity. Proficiency at isolation of this pathogen varies significantly among laboratories. Use of a laboratory that has passed a proficiency test is recommended. Most strains infecting sheep will not grow on solid media but may be isolated using liquid culture media systems. Genetic probes for an element specific for *M paratuberculosis* DNA, such as IS900, can be used in conjunction with culture or directly on fecal samples. Commercial PCR kits are as sensitive and specific as fecal culture and much more rapid. Cost of culture and PCR is comparable.

Tests of cell-mediated immunity, such as the intradermal Johnin test, lymphocyte transformation test, and interferon- γ , are used more on a research basis and may be negative in advanced clinical cases. The genome of *M paratuberculosis* has been described and may provide the basis for new diagnostic assays.

Tests that have fallen out of favor because of reports of low sensitivity and/or specificity are microscopic examination of Ziehl-Neelsen–stained fecal samples and the IV Johnin test. The complement fixation (CF) test also reportedly is less accurate than other serologic tests. The CF test is still required by many countries for importation of animals, although many of the reagents used in the CF test are made to different specifications in different countries, resulting in a lack of standardization.

Control: No satisfactory treatment is known. Control requires good sanitation and management practices aimed at limiting the exposure of young animals to the organism. Calves, kids, or lambs should be birthed in areas free of manure, removed from the dam immediately after birth in the case of dairy cattle, bottle-fed colostrum that has been pasteurized or obtained from dams that test negative, and then reared segregated as much as possible from adults and their manure until >1 yr old. Use of milk replacer is recommended instead of waste milk unless the milk has been pasteurized.

A routine testing program for adults can help focus efforts in controlling the disease. Low-cost tests (eg, ELISA) have the greatest cost benefit for commercial dairy herds that are confirmed infected by culture or PCR. Animals testing positive, particularly heavy shedders or that have strong-positive ELISA results, should be sent to slaughter as soon as economically feasible. Retesting at least annually should be continued until herd tests indicate a low (<5%) infection prevalence. Because intrauterine infection can occur, more aggressive control programs include culling of calves from dams that have or develop signs of the disease. Herd replacements should be obtained from herds believed to be free of the disease, and the replacements themselves should be tested before introduction to the new herd. More general procedures to minimize fecal contamination on the farm can also help, eg, elevating food and water troughs, providing piped water in preference to ponds, and harrowing frequently to disperse feces on pasture. Herd owners should be advised that paratuberculosis control takes at least 5 yr.

The formulation of *M paratuberculosis* vaccines varies by manufacturer. In many countries, their use is subject to approval by regulatory agencies and may be restricted to heavily infected herds. Vaccination of calves <1 mo old can reduce disease incidence but does not prevent shedding or new cases of infection in the herd. Vaccination thus does not eliminate the need for good management and sanitation. In the goat industry in Spain and Australia, vaccination has increased productive herd life. Cattle inoculated with an inactivated whole-cell, mineral-oil vaccine develop granulomas, one to several inches in diameter, at the site of inoculation (brisket) and may react positively on subsequent tuberculin tests. Accidental self-inoculation can result in severe acute reactions with sloughing and chronic synovitis and tendinitis.

Zoonotic Risk: There are conflicting data on the involvement of the causative organism in Crohn disease, a chronic granulomatous enteritis of unknown cause in people. However, *M paratuberculosis* is consistently detected by PCR in people with Crohn disease. This fact, coupled with its broad host range, including nonhuman primates, indicates that paratuberculosis should be considered a zoonotic risk until the situation is clarified.

PASTEURILLOSIS OF SHEEP AND GOATS

Pasteurella and *Mannheimia* organisms are β -hemolytic, gram-negative, aerobic, nonmotile, nonsporeforming coccobacilli in the family Pasteurellaceae. This family tends to inhabit the mucosal surfaces of the GI, respiratory, and genital tract of mammals. Many are known as opportunistic secondary invaders. Some species show preferences for specific surfaces and hosts. Updating of phylogenetic data has resulted in renaming based on gene sequence analysis. As a result, *P. haemolytica* biotypes A and T were reclassified as *M. haemolytica* (biotype A) and *P. trehalosi* (biotype T). More recently, *P. trehalosi* has been reclassified as *Bibersteinia trehalosi*. Each isolate of *M. haemolytica* and *B. trehalosi* is designated with a biotype and serotype. *M. haemolytica* A2 is the most common strain isolated from sheep and goat respiratory pasteurellosis, although A6, A13, and Ant have been reported in sheep and Ant in goats. *M. haemolytica* A2 is routinely reported from cases of mastitis in sheep. *B. trehalosi* T3, T4, T10, and T15 have been most often associated with the systemic or septicemic form of pasteurellosis affecting lambs. These serotypes have been regrouped to *B. trehalosi* biotype 2, and a new biotype 4 has been added. *B. trehalosi* is often isolated from the lungs of sheep, goats, and cattle, but pathogenicity is variable and may be incidental. *P. multocida* has also been reported as a cause of pneumonic pasteurellosis in sheep and goats and has been isolated in herd outbreaks of septic arthritis. *M. haemolytica* is the most commonly isolated bacteria in clinical cases, followed closely by *B. trehalosi*, with *P. multocida* seen less frequently.

Etiology and Pathogenesis: *M. haemolytica* and *B. trehalosi* are distributed worldwide, and diseases caused by them are common in sheep and goats of all ages, although the prevalence of serotypes may vary by region and flock. *M. haemolytica*, *B. trehalosi*, and *P. multocida* are common commensal organisms of the tonsils and nasopharynx of healthy sheep and goats. The presence of multiple *Pasteurella* spp may serve to keep the bacterial populations in check, because there appears to be some interference with growth when multiple species are present. For these organisms to cause infection, a combination of stressors, including heat, overcrowding, exposure to

inclement weather, poor ventilation, handling, and transportation, leaves sheep and goats susceptible to respiratory viral infections. Parainfluenza 3, adenovirus type 6, respiratory syncytial virus, possibly bovine adenovirus type 2, ovine adenovirus types 1 and 5, and reovirus type 1 cause primary respiratory infections that are rarely life threatening but predispose to secondary *M. haemolytica* infections. Respiratory infections with *Mycoplasma ovipneumoniae* and *Bordetella parapertussis* have also been reported to be associated with secondary *M. haemolytica* infections. The combination of stressors and primary infections are thought to break down the mucosal barrier integrity of the lower respiratory tract, allowing *M. haemolytica* to colonize, proliferate, and induce significant tissue damage.

The virulence of *M. haemolytica* and *B. trehalosi* is mediated by the action of several factors, including endotoxin, leukotoxin, and capsular polysaccharide, that afford the bacteria advantages over host immunity. The leukotoxin is particularly important in the pathogenesis, because it is specifically toxic to ruminant leukocytes, resulting in fibrin deposition in lungs and on pleural surfaces. The lipopolysaccharide endotoxin contributes to adverse reactions in the lungs and also leads to systemic circulatory failure and shock. The capsular polysaccharide prevents the phagocytosis of the bacteria and assists in attachment to the alveolar epithelial surface. Survival of the acute phase of pneumonic pasteurellosis depends on the extent of lung involvement and damage in the lower respiratory tract. Sheep and goats that recover may have chronic respiratory problems, including reduced lung capacity and weight gain efficiency if $\geq 20\%$ of the lung was damaged. In one review, there was no association between virulence and the presence of hemolysis on blood agar culture plates.

Clinical Findings and Lesions: *B. trehalosi* mainly causes septicemia and systemic pasteurellosis in sheep < 2 mo old. The systemic form of pasteurellosis caused by *B. trehalosi* is characterized by fever, listlessness, poor appetite, and sudden death in young sheep. The organism is thought to move from the tonsils to the

lungs and pass into the blood. This results in septicemia and localization of the infection in one or more tissues such as the joints, udder, meninges, or lungs. *P. multocida* has been reported to be isolated from poly-arthritis in young lambs. *M. haemolytica* has been reported from cases of mastitis, especially in sheep. All of these bacteria can cause a severe fibrinonecrotic pneumonia in sheep and goats. The disease is characterized by acute onset of illness, very high fevers, dyspnea, anorexia, and often death.

Diagnosis: The differentiation of pasteurellosis from other causes of respiratory disease is based on the high mortality and rapid progression to death. Diagnosis of pneumonic and septicemic forms of pasteurellosis is based on necropsy examination, gross and histopathologic findings, and isolation of organisms from a range of tissues. Lesions include subcutaneous hemorrhage; epithelial necrosis of the tongue, pharynx, esophagus, or occasionally the abomasum and intestine; enlargement of tonsils and retropharyngeal lymph nodes; and peracute, multifocal, embolic, necrotizing lesions in the lung and liver. There is better correlation with PCR analysis of lung tissue than with microbial culture in identifying the presence of *M. haemolytica*, *B. trehalosi*, and *P. multocida*.

Treatment: Early identification of respiratory disease and introduction of effective antibiotic therapy is necessary. Death losses are high in severely affected animals. Antimicrobial susceptibility patterns of *M. haemolytica*, *B. trehalosi*, and *P. multocida* have shown resistance to penicillins (all three organisms), sulfadimethoxine (*P. multocida*), and tetracyclines (*B. trehalosi*). Ampicillin, ceftiofur, danofloxacin, enrofloxacin, florfenicol, trimethoprim-sulfamethoxazole, and tulathromycin would be expected to have good efficacy, although extra-label use

of fluoroquinolones is prohibited in the USA. Treatment is frequently unrewarding unless begun very early in the disease process because of rapid progression of lung damage and endotoxin release. Parenteral fluids and anti-inflammatory agents are important adjuncts to antibiotic therapy. Although septicemic pasteurellosis has favorable antimicrobial susceptibility, response to therapy is often disappointing. Administering prophylactic antibiotics to at-risk lambs may be beneficial.

Prevention: Pasteurellosis prevention would be desirable given the economic costs of treatment, losses, and reduction of weight gains in survivors. Commercial vaccines are available for cattle but unfortunately are specific for *M. haemolytica* A1, and there is little or no cross-protection against *M. haemolytica* A2 experimentally. Commercial vaccines for *M. haemolytica* A2 are available in the UK and have been reported to be beneficial in reducing death losses and decreased weight gains from both septicemic and pneumonic forms of pasteurellosis. An intranasal recombinant vaccine has protected lambs challenged with *P. multocida*, but this vaccine is not commercially available. There are no commercial vaccines in the USA, but producers can get autogenous bacterins for their flocks; however, evidence that these are efficacious is anecdotal. Prevention of respiratory viruses by using a vaccination program would be expected to decrease respiratory pasteurellosis by preventing the initial insult that allows colonization. Inclusion of prophylactic antibiotics, mainly tetracycline, in the feed during the months of the year with the highest incidence is a common management practice. Avoidance or reduction of known stressors such as heat, overcrowding, exposure to inclement weather, poor ventilation, handling, and transportation should also be considered.

PESTE DES PETITS RUMINANTS

Peste des petits ruminants (PPR) is an acute or subacute viral disease of goats and sheep characterized by fever, necrotic stomatitis, gastroenteritis, pneumonia, and sometimes death. It was first reported in Cote d'Ivoire (the Ivory Coast) in 1942 and subsequently in other parts of West

Africa. Goats and sheep appear to be equally susceptible to the virus, but goats exhibit more severe clinical disease. The virus also affects several wild small ruminant species. Cattle, buffalo, and pigs are only subclinically infected. People are not at risk.

Etiology and Epidemiology: The causal virus, a member of the *Morbillivirus* genus in the family Paramyxoviridae, preferentially replicates in lymphoid tissues and epithelial tissue of the GI and respiratory tracts, where it produces characteristic lesions.

PPR has been reported in virtually all parts of the African continent, except for the southern tip; the Middle East; and the entire Indian subcontinent. In the last 15 yr, PPR has rapidly expanded within Africa and to large parts of Central Asia, South Asia, and East Asia (including China).

Because PPR virus and the now-eradicated rinderpest virus (see p 771) are cross-protective, it is possible that the recent rapid expansion of the PPR virus within endemic zones and into new regions may be because of disappearance of the cross-protection previously afforded by natural rinderpest infection of small ruminants and/or the hitherto use of rinderpest vaccine to prevent small ruminant infection with PPR virus in certain endemic areas. Based on this theory, PPR virus has the potential to cause severe epidemics, or even pandemics, in more small ruminant populations in an increasingly expanding area of the developing world.

At a local level, such epidemics may eliminate the entire goat or sheep population of an affected village. Between epidemics, PPR can assume an endemic profile. Mortality and morbidity rates vary within an infected country, presumably due to two factors: the varying immune status of the affected populations and varying levels of viral virulence.

Transmission: Transmission is by close contact, and confinement seems to favor outbreaks. Secretions and excretions of sick animals are the sources of infection. Transmission can occur during the incubation period. It is generally accepted that there is no carrier state. The common husbandry system whereby goats roam freely in urban areas contributes to spread and maintenance of the virus. There are also numerous instances of livestock dealers being associated with the spread of infection, especially during religious festivals when the high demand for animals increases the trade in infected stock.

Several species of gazelle, oryx, and white-tailed deer are fully susceptible; these and other wild small ruminants may play a role in the epidemiology of the disease, but few epidemiologic data are available for PPR in wild small ruminants. Cattle, buffalo,

and pigs can become naturally or experimentally infected with PPR virus, but these species are dead-end hosts, because they do not exhibit any clinical disease and do not transmit the virus to other in-contact animals of any species.

Clinical Findings: The acute form of PPR is accompanied by a sudden rise in body temperature to 40°–41.3°C (104°–106°F). Affected animals appear ill and restless and have a dull coat, dry muzzle, congested mucous membranes, and depressed appetite. Early, the nasal discharge is serous; later, it becomes mucopurulent and gives a putrid odor to the breath. The incubation period is usually 4–5 days. Small areas of necrosis may be observed on the mucous membrane on the floor of the nasal cavity. The conjunctivae are frequently congested, and the medial canthus may exhibit a small degree of crusting. Some affected animals develop a profuse catarrhal conjunctivitis with matting of the eyelids. Necrotic stomatitis affects the lower lip and gum and the gumline of the incisor teeth; in more severe cases, it may involve the dental pad, palate, cheeks and their papillae, and the tongue. Diarrhea may be profuse and accompanied by dehydration and emaciation; hypothermia and death follow, usually after 5–10 days. Bronchopneumonia, characterized by coughing, may develop at late stages of the disease. Pregnant animals may abort. Morbidity and mortality rates are higher in young animals than in adults.

Lesions: Emaciation, conjunctivitis, and stomatitis are seen; necrotic lesions are observed inside the lower lip and on the adjacent gum, the cheeks near the commissures, and on the ventral surface of the tongue. In severe cases, the lesions may extend to the hard palate and pharynx. The erosions are shallow, with a red, raw base and later become pinkish white; they are bounded by healthy epithelium that provides a sharply demarcated margin. The rumen, reticulum, and omasum are rarely involved. The abomasum exhibits regularly outlined erosions that have red, raw floors and ooze blood.

Severe lesions are less common in the small intestines than in the mouth, abomasum, or large intestines. Streaks of hemorrhages, and less frequently erosions, may be present in the first portion of the duodenum and terminal ileum. Peyer's patches are severely affected; entire patches of lymphoid tissue may be sloughed. The large intestine is usually

more severely affected, with lesions developing around the ileocecal valve and at the cecocolic junction and rectum. The latter exhibits streaks of congestion along the folds of the mucosa, resulting in the characteristic “zebra-striped” appearance.

Petechiae may appear in the turbinates, larynx, and trachea. Patches of bronchopneumonia may be present.

Diagnosis: A presumptive diagnosis is based on clinical, pathologic, and epidemiologic findings and may be confirmed by viral isolation and identification. Historically, simple techniques such as agar-gel immunodiffusion have been used in developing countries for confirmation and reporting purposes. However, PPR virus cross-reacts with rinderpest virus in these tests. Virus isolation is a definitive test but is labor intensive, cumbersome, and takes a long time to complete. Currently, antigen capture ELISA and reverse transcription-PCR are the preferred laboratory tests for confirmation of the virus. For antibody detection (such as might be needed for epidemiologic surveillance, confirmation of vaccine efficacy, or confirmation of absence of the disease in a population), competitive ELISA and virus neutralization are the OIE-recommended tests. The specimens required are lymph nodes, tonsils, spleen, and whole lung for antigen or nucleic acid

detection, and serum (from unclotted blood) for antibody detection. The virus neutralization test may also be used to confirm an infection if paired serum samples from a surviving animal yield rising titers of ≥ 4 -fold. PPR must be differentiated from other GI infections (eg, GI parasites), respiratory infections (eg, contagious caprine pleuropneumonia), and such other diseases as contagious ecthyma, heartwater, coccidiosis, and mineral poisoning.

Control: Local and federal authorities should be notified when PPR is suspected. PPR is also an OIE-reportable disease worldwide. Eradication is recommended when the disease appears in previously PPR-free countries. There is no specific treatment, but treatment for bacterial and parasitic complications decreases mortality in affected flocks or herds. An attenuated PPR vaccine prepared in Vero cell culture is available and affords protection from natural disease for >1 yr. Encouraged by the successful global eradication of rinderpest, international organizations such as OIE, Food and Agriculture Organization of the United Nations (FAO), and International Atomic Energy Agency (IAEA) are making plans (2015) for global eradication of PPR. The available homologous PPR vaccine would play an important role in that effort.

RIFT VALLEY FEVER

Rift Valley fever (RVF) is a peracute or acute, mosquito-borne, zoonotic disease of domestic and wild ruminants in Africa, Madagascar, and the Arabian Peninsula. Large outbreaks of clinical disease are usually associated with heavy rainfall and localized flooding. During epidemics, the occurrence of abortions in livestock and deaths among young animals, particularly lambs, together with an influenza-like disease in people, is characteristic. However, infections are frequently subclinical or mild.

Etiology and Epidemiology: RVF virus belongs to the genus *Phlebovirus* and is a typical Bunyavirus. An enveloped spherical particle of 80–100 nm in diameter, it has a

three-segmented, single-stranded, negative-sense RNA genome with a total length of ~ 11.9 kb. Each of the segments, L (large: 6.4 kb), M (medium: 3.9 kb), and S (small: 1.7 kb), is contained in a separate nucleocapsid within the virion. Remarkably little genetic diversity has been found between RVF virus isolates from many countries, and no significant antigenic differences have been demonstrated, but differences in pathogenicity are seen. The disease is endemic in many tropical and subtropical regions of Africa, Madagascar, and the Arabian Peninsula. Thought to have been originally confined to the Rift Valley region of eastern and southern Africa, the virus has recently expanded its range, with major outbreaks having occurred in Egypt

since 1977, West Africa since 1987, Madagascar since 1990, and the Arabian Peninsula in 2000. Particularly large epidemics with large numbers of human cases occurred in Egypt in 1977–1978 and in Kenya in 2006–2007. It is considered a threat to regions further afield, where competent mosquito vectors are present. Sporadic, large epidemics have occurred at 5–10 yr intervals in drier areas of eastern Africa, and less frequently in southern Africa.

● Outbreaks are usually associated with periods of abnormally heavy rainfall or, in some cases, with localized flooding due to dam building or flood irrigation. During interepidemic periods, the virus may remain dormant in eggs of floodwater-breeding aedine mosquitoes in the dry soil of small, ephemeral wetlands (dambos or pans). In some areas, this transovarial transmission is believed to be the most important interepidemic survival strategy of the virus; however, inapparent cycling of the virus between vectors and wild or domestic mammalian hosts has been shown to occur in many areas. RVF virus may also spread by movement of viremic animals and possibly by wind-borne mosquitoes. When emergence of infected mosquitoes, or introduction of virus to an area, coincides with abnormally wet conditions and the presence of a highly susceptible host population, a large epidemic may ensue when the virus is amplified in ruminants and spread locally by many species of mosquitoes or mechanically by other insects. The incidence of RVF peaks during the late rainy season. In areas with cold winters, both the disease and vectors may disappear after the first frost. In warmer climates where insect vectors are present continuously, seasonality is not seen.

People are readily infected through blood aerosols from infected animals during slaughter, or by exposure to infected animal tissues, aborted fetuses, mosquito bites, and laboratory procedures. Therefore, veterinarians, farm laborers, and abattoir workers are particularly at risk. People can also act as amplifying hosts and introduce the disease (via mosquitoes) to animals in uninfected areas.

Clinical Findings: Clinical signs of RVF tend to be nonspecific, rendering it difficult to recognize individual cases. The incubation period is 12–36 hr in lambs, and a biphasic fever of up to 108°F (42°C) may develop. Affected animals are listless and reluctant to move or feed and may show signs of abdominal pain. Mortality in young

lambs is high (90%–100%), and animals usually die within 2–3 days. Adult sheep are less susceptible, with 10%–30% mortality; the incubation period is 24–72 hr, and animals show a generalized febrile response, lethargy, hematemesis, hematochezia, and nasal discharge, although infection may also be inapparent. Calves are less susceptible than lambs, but mortality may still be as high as 70%; clinical signs are similar to those in sheep, but icterus is more common. Disease in adult cattle is often inapparent, but they may show anorexia, lacrimation, salivation, nasal discharge, dysgalactia, and a bloody or fetid diarrhea, with a mortality of 5%–10%. Sometimes, abortion may be the only sign of infection; the aborted fetus is usually autolyzed. In pregnant ewes, abortion rates vary from 5% to almost 100% in different outbreaks and on different farms; abortion rates in cattle are usually <10%. Vaccination of ewes with live Smithburn strain vaccine may result in early embryonic death, congenital CNS anomalies and arthrogryposis, or abortion or stillbirth. Clinical signs and abortions have also been reported in goats, and occasionally in camels, water buffalo, and some wild ungulate species. In people, RVF is usually inapparent or associated with a self-limiting febrile illness characterized by abrupt onset of malaise, myalgia, and arthralgia. A minority (1%–2%) may develop severe disease with ocular lesions, encephalitis, or severe hepatic lesions with hemorrhages; in such cases, the fatality rate may be 10%–20%.

Lesions: The hepatic lesions are similar in all species and vary mainly with the age of the affected individual. The most severe lesions, seen in aborted fetuses and newborn lambs, are moderately to greatly enlarged, soft, friable livers with irregular congested patches. Numerous grayish white necrotic foci are invariably present but may not be clearly visible. Hemorrhage and edema of the wall of the gallbladder and mucosa of the abomasum are common. Intestinal contents are dark chocolate-brown. In all animals, the spleen and peripheral lymph nodes are enlarged and edematous and may show petechiae. Histopathologically, the liver lesions are severe and extensive, with hepatic necrosis being the most striking microscopic lesion of RVF in all domestic animals and people.

Diagnosis: RVF should be suspected when abnormally heavy rains and flooding

are followed by widespread occurrence of abortions and mortality among newborn animals characterized by necrotic hepatitis, concurrent with influenza-like disease in people handling animals or their products.

The necropsy of infected animals poses considerable risk to the operator and should be performed only by trained personnel, using appropriate personal protective equipment. The virus can readily be isolated from tissues of aborted fetuses and the blood of infected animals. The viral titer in these tissues is often high enough to use organ suspensions as antigen for a rapid diagnosis in neutralization, complement fixation, ELISA, agar gel diffusion tests, or staining of organ impression smears; however, these tests should be supplemented by isolation in suckling mice or hamsters injected intracerebrally or in cell cultures such as baby hamster kidney (BHK21), monkey kidney (Vero), chicken embryo-related (CER) and mosquito cells, or primary kidney and testis cell cultures of lambs. Detection of viral nucleic acid by PCR is possible, and reverse transcriptase-PCR tests have been described. Virus can be demonstrated in organ sections using immunohistochemical stains.

All conventional serologic tests can be used to detect antibody against RVF virus and are helpful in epidemiologic studies. In some areas, however, serologic surveys may be complicated by cross-reactivity between RVF virus and other phleboviruses; virus neutralization tests are the most specific in this situation. An IgM ELISA can demonstrate recent infection using a single serum sample.

Wesselsbron disease (*see* p 775) and other insect-borne viral diseases tend to occur under the same climactic conditions. RVF mortality associated with hepatic lesions should be distinguished from hepatotoxic plant and algal intoxications; bacterial septicemias such as pasteurellosis, salmonellosis, and anthrax; and other viral infections such as Nairobi sheep disease and peste des petits ruminants. When abortion is the only finding, other important diseases such as brucellosis, leptospirosis, chlamydiosis, campylobacteriosis, *Coxiella burnetii* infection, and salmonellosis should be eliminated.

Control and Prevention: Immunization remains the only effective way to protect livestock from RVF. The mouse neuro-adapted Smithburn strain of RVF

virus can readily be produced in large quantities, is inexpensive, and induces a durable immunity 6–7 days after inoculation. It should normally not be used for protection of pregnant animals, because it may cause abortion, congenital defects, and hydrops amnii in the ewe; however, its use may be contemplated during an outbreak when possible adverse effects may be outweighed by the dangers of natural infection. Although not proved, it is theoretically possible for the attenuated virus to revert to virulence. A small-plaque variant and a mutagen-induced strain have been investigated as potential vaccine candidates but have not been accepted as replacements for the Smithburn strain. More recently, a naturally attenuated avirulent isolate of Rift Valley fever, clone 13, has been used in a commercially available vaccine. It is not advisable to use live attenuated vaccines in nonendemic countries. Possible future recombinant DNA vaccines and viral strains with deletions of the major virulence genes should offer a better alternative. Control of vectors, movement of stock to high-lying areas, and confinement of stock in insect-proof stables are usually impractical, instituted too late, and of little value.

Much work has gone into attempts to predict RVF outbreaks using meteorologic and remote-sensing data to identify high-risk areas and time periods; this has been somewhat successful in predicting outbreaks in eastern Africa but less so in southern Africa. However, outbreaks cannot yet reliably be predicted and are usually of sudden onset. Therefore, routinely immunizing lambs at 6 mo of age, which should afford lifelong protection, is advisable. The offspring of susceptible ewes can be immunized at any age. Pregnant ewes and cattle can be vaccinated with a formalin-inactivated vaccine, which elicits a better immunity in cattle and is safe in pregnancy. Revaccination after 3 mo is advisable to induce an immunity that will last >1 yr and to confer colostral immunity to the offspring.

Zoonotic Risk: Because RVF virus can cause a severe and potentially fatal disease in people, those involved in the livestock industry should be made aware of the potential dangers of exposure to RVF-infected animals and tissues. Appropriate protective measures should be taken when investigating cases of abortion, handling potentially infected animals, and collecting diagnostic samples.

RINDERPEST

(Cattle plague)

Historically, rinderpest virus was a scourge that wrought economic havoc throughout Africa, Asia, and Europe. The need to combat rinderpest provided the impetus for the establishment of the first modern veterinary school in Lyon (France) in 1762. After several decades of success in eradicating rinderpest from Europe, the disease recurred unexpectedly in Belgium in 1920, and renewed efforts to eradicate it resulted in the creation of the World Organization for Animal Health (OIE) in 1924. Shortly after the creation of the Food and Agriculture Organization (FAO) of the United Nations in 1946, the OIE and FAO signed a cooperation agreement in 1952. Since then, the two organizations (FAO and OIE) have been major participants in several global campaigns to combat rinderpest, which culminated in global eradication of the disease in 2011. In fact, the last reported rinderpest outbreak occurred in Kenya in 2001, but a 10-yr active surveillance period was necessary before global eradication could be declared. Rinderpest is only the second viral disease, after smallpox, to have been successfully eradicated worldwide.

The successful eradication of rinderpest shows that smallpox eradication in 1980 was not an unrepeatable feat and should provide a certain degree of confidence to the international community that concerted, science-based efforts can result in future successes. Rinderpest virus is biologically similar to the virus of peste des petits ruminants (*see* p 766), which has been targeted by the OIE and FAO as the next animal disease for global eradication.

Rinderpest was a disease of cloven-hoofed animals characterized by fever, necrotic stomatitis, gastroenteritis, lymphoid necrosis, and high mortality. In epidemic form, it was the most lethal plague known in cattle. All wild and domesticated species of the order Artiodactyla were variably susceptible to rinderpest, although dissemination of the virus largely depended on continual transmission among domesticated cattle, domesticated buffalo, and yaks. The virus also infected goats and sheep, leading to under-diagnosis of the clinically similar peste des petits ruminants in regions where the two diseases coexisted.

rus, closely related to the viruses causing peste des petits ruminants, canine distemper (*see* p 777), and measles. Strains of varying virulence for cattle occurred and could be differentiated genetically. However, a single serotype of the virus existed, and a vaccine prepared from any strain could protect against all strains.

Rinderpest virus is shed in nasal and ocular secretions and can be transmitted during the incubation period (1–2 days before onset of fever). Transmission required direct or close indirect contact between susceptible animals and sick animals shedding the virus. The role of fomites in transmission was negligible, because the virus is fragile, being inactivated within 12 hr of exposure to atmospheric heat and light. There was no carrier state, and recovered animals acquired lifelong immunity. In endemic areas, young cattle became infected after maternal immunity disappeared and before vaccinal immunity began, with possible auxiliary cycles in wild ungulates.

Clinical Findings: After an incubation period of 3–15 days, fever, anorexia, depression, and oculonasal discharges developed, followed by necrotic lesions on the gums, buccal mucosa, and tongue. The hard and soft palates were often affected. The oculonasal discharge became mucopurulent, and the muzzle appeared dry and cracked. **Diarrhea**, the final clinical sign, could be watery and bloody. Convalescence was prolonged and could be complicated by concurrent infections due to immunosuppression. Morbidity was often 100% and mortality was up to 90% in epidemic areas, but in endemic areas morbidity was low and clinical signs were often mild.

Lesions: Gross pathologic lesions occurred throughout the GI and upper respiratory tracts, either as areas of necrosis and erosion, or congestion and hemorrhage, the latter creating classic “zebra-striping” in the rectum. Lymph nodes could be enlarged and edematous, with white necrotic foci in the Peyer’s patches. Histologic lesions included lymphoid and epithelial necrosis with viral-induced syncytia, and intracytoplasmic and intranuclear inclusions were often seen.

Etiology, Epidemiology, and Transmission: Rinderpest virus is a *Morbillivi-*

Diagnosis: Clinical and pathologic findings were sufficient for diagnosis in endemic areas and after initial laboratory confirmation of an outbreak. In areas where rinderpest was uncommon or absent, laboratory tests had to be used to differentiate it from bovine viral diarrhea in particular, as well as East Coast fever, foot-and-mouth disease, infectious bovine rhinotracheitis, and malignant catarrhal fever. Viral isolation and detection of specific viral antigens in affected tissues using an immunodiffusion test was the standard, but simpler, more rapid and more discriminating tests, such as immune capture ELISA and reverse transcription-PCR (RT-PCR), were favored toward the end of the eradication campaign. The RT-PCR technique allowed phylogenetic characterization of the virus and helped trace the origin of strains in new outbreaks. A simple lateral flow penicillin test for field use also proved useful in the final stages of the eradication campaign. In the 10-yr

period between occurrence of the last outbreak and the official declaration of eradication, active rinderpest surveillance in recent endemic areas included the testing of all susceptible cloven-hoofed animals presenting with erosive stomatitis.

Control: Active immunity was lifelong, whereas maternal immunity lasted 6–11 mo. Control in endemic areas was by immunization of all cattle and domestic buffalo >1 yr old with an attenuated cell culture vaccine. In these areas, outbreaks were controlled by quarantine and “ring vaccination” and sometimes by slaughtering. In epidemics, the disease was best eliminated by imposing quarantine and by slaughtering affected and exposed animals. Control of animal movements was paramount to control rinderpest; many outbreaks were due to the introduction of infected cattle to hitherto uninfected herds. The lessons learned from this huge success will be instrumental in the fight against peste des petits ruminants.

TICKBORNE FEVER

(Pasture fever)

Tickborne fever is a febrile disease of domestic and free-living ruminants in the temperate regions of Europe. It is prevalent in sheep and cattle in the UK, Ireland, Norway, Finland, The Netherlands, Austria, and Spain. Disease is transmitted by the hard tick *Ixodes ricinus*. A similar disease transmitted by other ticks has been described in India and South Africa. The main hosts are sheep and cattle, but goats and deer are also susceptible.

Etiology: The causative agent is now classified as a member of the order Rickettsiales, family Anaplasmataceae, as *Anaplasma phagocytophilum*, which includes the granulocytic agents formerly known as *Ehrlichia phagocytophila*, *Ehrlichia equi*, and the agent of human granulocytic ehrlichiosis.

The organism infects eosinophils, neutrophils, and monocytes, in that order. Cytoplasmic inclusions are visible as grayish blue bodies in Giemsa-stained blood smears and may contain one or more rickettsial particles of variable size and shape. The varied morphologic types in the cytoplasmic inclusions do not represent

stages of development, as in chlamydiae, but rather are rickettsial colonies within cytoplasmic vacuoles.

The disease is transmitted by the hard tick *I. ricinus*. Adult ticks infected as larvae or nymphs can transmit the disease as can nymphs infected as larvae, but infections do not appear to pass from the adult female to the larva via the egg. The rickettsiae can survive in infected ticks for long periods and, because *I. ricinus* can survive unfed for >1 yr awaiting a new host, ticks infected in their previous instar can still be infective after long periods of hibernation. The ready transmission of infection by injecting infected blood suggests that the organism could be transmitted mechanically by biting insects. In addition, if the organisms reported to cause a similar disease in ruminants in India and South Africa are indeed *A. phagocytophilum*, it is most likely that ticks other than *I. ricinus* are involved.

Clinical Findings: After infestation with infected ticks, the incubation period may be 5–14 days, but after injection with infected blood, the incubation period is 2–6 days. In sheep, the main clinical sign is a sudden

fever (105°–108°F [40.5°–42.0°C]) for 4–10 days. Other signs are either absent or mild, but the animals generally appear dull and may lose weight. Respiratory and pulse rates are usually increased, and a cough often develops.

In cattle, the disease is known as pasture fever in many parts of Europe, including Finland, Norway, Austria, Spain, and Switzerland. The disease occurs as an annual minor epidemic when dairy heifers and cows are turned out to pasture in the spring and early summer. Within days, the cows are dull and depressed, with a marked loss of appetite and milk yield. Affected cows usually suffer from respiratory distress and coughing. Clinical signs are more obvious and last longer in newly purchased animals than in home-bred animals. Often, veterinary advice is sought after a sudden drop in milk yield.

Abortions affect susceptible ewes and cows newly introduced onto tick-infested pastures during the last stages of gestation, with abortions occurring 2–8 days after the onset of fever. Except for aborting ewes, death due to tickborne fever is rare. The semen quality of infected rams and bulls may be greatly reduced. Variations in severity of the clinical effects may be related to differences between strains of *A. phagocytophilum* or in host susceptibility.

Perhaps the most significant effect of infection is its serious impairment of humoral and cellular defense mechanisms, which results in increased susceptibility to secondary infections such as tick pyemia, pneumonic pasteurellosis, louping ill, and listeriosis.

Lesions: Tickborne fever is characterized by transient but distinct hematologic changes. A modest neutrophilia develops 2–4 days after natural or experimental infection and is followed by a severe leukopenia due to lymphocytopenia and neutropenia. The lymphocytopenia lasts 4–6 days, whereas the neutropenia develops progressively and becomes more marked ~10 days after infection. Studies with monoclonal antibodies that recognize surface markers for lymphocyte subsets have shown that both T and B lymphocytes are reduced. The number of circulating eosinophils is also depressed for as long as 2 wk. After the febrile period has subsided, the number of monocytes may increase. At the peak of reaction, >90% of circulating neutrophils and eosinophils may be infected. The monocytes are predominantly infected during the later stages of bacteremia, whereas the granulocytes are usually

infected throughout the period of bacteremia. The number of circulating thrombocytes is also reported to be depressed during the febrile period, and the occasional hemorrhagic syndromes associated with tickborne fever are probably related to the reduction in circulating thrombocytes.

Diagnosis: In sheep, the onset of high fever in tick-infested areas during the spring and summer in association with hematologic changes and the presence of inclusions within granulocytes or the detection of specific DNA by PCR is diagnostic. PCR and other molecular methods are particularly useful during the late stages of primary bacteremia and during persistent infection when it is difficult to detect inclusion bodies in blood smears. Clinical disease usually is seen only in young lambs born in tick-infested areas or in older animals newly introduced to such areas. Demonstration of typical inclusion bodies in blood smears or specific DNA by PCR should indicate the association of tickborne fever and cases of tick pyemias and abortions, particularly when abortions occur after pregnant animals are moved from tick-free to tick-infested pastures. Infection could be established retrospectively by demonstrating a rise in antibody titers by indirect immunofluorescence or ELISA.

In affected dairy cattle, the main signs are abortions and a sudden drop in milk yield. The other common clinical sign in infected cattle is respiratory illness after a herd is introduced to tick-infested pastures. Tickborne fever must also be considered when abortions and stillbirths, particularly in heifers, occur soon after their introduction to tick-infested pastures. Therefore, in areas where the disease is enzootic, blood smears must be examined for the presence of organisms in all cases of abortion in sheep and cattle and when milk yield drops suddenly soon after the animals have returned to pasture.

Treatment and Control: The short-acting oxytetracyclines are regarded as the most effective treatment, because other antibiotics such as penicillin, streptomycin, and ampicillin do not prevent relapses. Sulfamethazine has also proved useful. If dairy cattle are treated with oxytetracyclines within a few days of infection, the pyrexia is reduced quickly and milk yield restored.

There are three important aspects of control: vector control, chemotherapy, and immunity. Effective control can be achieved by eliminating or markedly reducing

contact with the tick vector either by grazing sheep and cattle on tick-free pastures in lowland areas or by use of acaricides. In sheep practice, this commonly involves keeping ewes and lambs in a fenced, relatively tick-free pasture until the lambs are ~6 wk old. Lambs also benefit from improved nutrition of the ewes. Dipping lambs within 1–2 wk of birth is not commonly practiced because of difficulties of gathering the lambs on widely dispersed hill farms, the risks of mismothering, and the relatively short duration of protection provided by acaricides, possibly because of the short fleece and rapid growth rate of lambs. However, dipping twice with a 2- to 3-wk interval or use of pour-on preparations or smears applied before lambs are moved from lambing fields to hill pastures reportedly controls ticks effectively. Pregnant animals should not be moved from tick-free to tick-infested pastures.

In enzootic areas, treatment with long-acting tetracyclines may be used as a prophylactic measure. When susceptible animals, particularly pregnant ewes and cows and newborn lambs, are to be moved from tick-free to tick-infested areas, it may be necessary to combine dipping with prophylactic use of long-acting tetracyclines. Such treatment of lambs in the first 2–3 wk of life can be protective for as long

as 3 wk and helps reduce secondary infections such as tick pyemia, pasteurellosis, and colibacillosis. It may also improve growth rate.

Several aspects of immunity remain controversial, but it is generally accepted that sheep and cattle are immune to challenge after recovery from one or two bouts of clinical disease caused by tickborne fever. The immunity may last for several months but wanes rapidly if the animals are removed from tick-infested areas. Secondary infections are usually milder as residual immunity persists. There is a variable degree of cross-protection among strains of *A phagocytophilum*. No effective vaccines are available to protect ruminants from clinical tickborne fever. However, if susceptible animals are being brought into tick-infested pastures, it may be sensible to deliberately infect them before introduction and treat them with oxytetracyclines before or immediately after the onset of fever. This allows multiplication of the organism and therefore stimulation of immune responses without uncontrolled clinical disease; a minimum duration of bacteremia may be required for protective immunity to develop. Because not all strains of *A phagocytophilum* are cross-protective, strains specific to the area must be used.

TICK PYEMIA

Tick pyemia affects lambs 2–12 wk old and is characterized by debility, crippling lameness, and paralysis. Pyemic abscesses are common in joints but may be found in virtually any organ. The disease causes significant economic loss through debilitation and death. The disease is enzootic in many regions of the UK and Ireland where the tick *Ixodes ricinus* is common, and it is likely to be present in other parts of Europe where the same tick is found.

Etiology: *Staphylococcus aureus* is regarded as the main cause of the pyemic abscesses, because it has been isolated consistently from superficial and deep-seated lesions and it is rare to find other bacteria. The bacteria are believed to gain entry into the bloodstream either by direct inoculation during tick feeding, from local

superficial wounds, or through the infected umbilicus. However, there is clinical and experimental evidence that *I ricinus* does not simply act as a vector directly injecting staphylococci into the bloodstream. The main role of *I ricinus* is as a vector of the rickettsial agent *Anaplasma phagocytophilum*, which causes tickborne fever (see p 772), which in turn creates factors favorable to development of pyemia. Lambs affected with tickborne fever have severe leukopenia, and their peripheral blood neutrophils are less capable of phagocytizing and killing *S aureus*. Experimental studies have shown that lambs with tickborne fever were more susceptible to experimental infections with *S aureus* during the period of neutropenia and that as many as 30% of lambs with tickborne fever may develop staphylococcal infections.

The epidemiology of the disease is closely related to the biology of *I ricinus*. The disease is limited to areas populated by *I ricinus* and to seasons of the year climatically favoring high tick population and activity.

Clinical Findings: Abscesses form in various parts of the body, mainly in the joints, tendon sheaths, and muscles, resulting in lameness—hence the common use of the term “crippled lambs.” In some outbreaks, >30% of lambs may be affected; they are usually dull and lame and often suffer from loss of body condition. Internal abscesses without joint lesions may result in no clinical signs other than the loss of condition, but when lesions are present in the CNS, there may be ataxia, paraplegia, or other nervous signs. The crippling disease lasts for days or weeks, but the disease may also appear as an acute septicemia. On occasion, there may be sudden deaths resulting from multiple internal abscesses without other visible signs. As many as 50% of affected lambs may die, and the survivors recover slowly.

Lesions: Apart from the joints and other superficial structures, abscesses are commonly found in the liver, lungs, and kidneys. They may also be present in the meninges of the spinal cord and in the pericardium and myocardium. The diaphragm, thymus, and adrenal glands are less commonly affected. Ticks are often found attached to an inflamed area.

Diagnosis: History and clinical signs are valuable indicators. The restriction of the disease to tick-infested areas, its occurrence during seasons of tick activity, and demonstration of *A phagocytophilum* or specific DNA by PCR in the blood of affected lambs or other sheep in the flock are diagnostic features. Isolation of *S aureus* from lesions and the absence of other bacteria will help to confirm tick pyemia. The loss of condition and ill-thrift without lameness may be difficult to recognize as tick pyemia, and the acute condition can be confused with other

septicemic diseases. Tick pyemia may also resemble other suppurative infections of the newborn, including navel ill and joint ill due to infections by other bacteria such as streptococci and *Trueperella pyogenes*.

Treatment and Control: Treatment of clinical cases of tick pyemia with penicillin or tetracycline can be effective, provided the lesions are not too advanced.

Control of tick infestation is the most effective prevention. This can be achieved either by restricting lambs and ewes to low-ground, tick-free pastures for the first few weeks of life or by dipping ewes before lambing and administering acaricides as dips or smears on lambs. In young lambs, pour-on preparations of cypermethrin or smears applied before lambs are moved from lambing fields to hill pastures reportedly control ticks effectively.

Administration of long-acting oxytetracycline at the time of risk can help prevent both tickborne fever and tick pyemia during the first weeks of life. A single injection at double the standard dose given at 3 wk of age can significantly reduce mortality and morbidity in young hill lambs on tick-infested pasture and improve weight gains and condition in the remainder. Prophylactic treatment with a long-acting antibiotic may prevent development of tickborne fever for as long as 3 wk, without pyrexia and immunosuppression, so that the incidence of tick pyemia and other infections such as pasteurellosis and colibacillosis are reduced. Although treatment with oxytetracycline may inhibit the development of immunity, if the lambs eventually develop tickborne fever, they are several weeks older and apparently less susceptible to tick pyemia. Deliberate exposure of lambs by injections, followed by treatment with oxytetracycline, could provide some immunity before the lambs enter tick-infested areas; however, strains specific to the area must be used because some strains of *A phagocytophilum* have no cross-immunity.

WESSELSBRON DISEASE

Wesselsbron disease is an acute, arthropod-borne flavivirus infection of mainly sheep, cattle, and goats in sub-Saharan Africa. Infection is common, but clinical disease is

infrequent although likely under-reported. Newborn lambs and goat kids are most susceptible, and mortality may occur. Infection in adult sheep, cattle, and goats

is usually subclinical, but disease may be severe in sheep with preexisting liver pathology. Occasional abortion in ewes, together with congenital malformation of the CNS with arthrogryposis of the ovine (and also the bovine) fetus and hydrops amnii in ewes, is seen. Incidental spillover occurs to people, causing a nonfatal, influenza-like disease.

Etiology and Epidemiology: Wesselsbron disease is caused by a flavivirus, which is an enveloped, positive-sense RNA virus. It has not been well characterized but has properties typical of a hemagglutinating flavivirus. It has been isolated from vertebrates and arthropods from many sub-Saharan African countries, and serologic surveys provide evidence of its occurrence in other countries. Evidence of infection has been reported in cattle, sheep, goats, camels, pigs, donkeys, horses, ostriches, and wild ruminants. Based on the distribution of aedine mosquitoes associated with Wesselsbron disease, the incidence of infection is likely greater than is generally realized. The high prevalence of antibodies in warmer and moister coastal areas of southern and eastern Africa suggests that domestic herbivores may play a significant role in maintenance of the virus, and activity appears to occur year round. In drier areas, however, seroprevalence is generally lower, with irregular disease outbreaks occurring, usually in conjunction with Rift Valley fever (see p 768) when abnormally heavy rains lead to an abundance of floodwater-breeding mosquitoes. People may become infected by mosquitoes or by handling organs from infected animals.

Clinical Findings: After an incubation period of 1–3 days in newborn lambs, nonspecific signs of illness, including fever, anorexia, listlessness, weakness, and increased respiration, become evident. Death may occur within 72 hr. In calves and adult sheep, goats, and cattle, nonfatal febrile or inapparent infection occurs. Occasional abortion, congenital CNS malformations with arthrogryposis, and hydrops amnii are seen in ewes. Wesselsbron disease and Rift Valley fever share many clinical and pathologic features. However, Wesselsbron disease is usually milder, producing much lower mortality, fewer abortions, and less destructive liver lesions. The virus appears to be more neurotropic than that

of Rift Valley fever, and severe fetal teratology of the CNS is seen after experimental infection. Use of the attenuated vaccine in pregnant ewes may result in early embryonic death, severe teratology of the CNS, arthrogryposis, hydrops amnii, abortion, or fetal mummification. In people, mild to severe, nonfatal influenza-like symptoms are seen.

Lesions: In newborn and young animals, a moderate to severe icterus and hepatomegaly are seen with Wesselsbron disease; the liver is yellowish to orange brown. Petechiae and ecchymoses are commonly found in the mucosa of the abomasum, the contents of which are chocolate-brown in color. Histopathology reveals mild to extensive necrosis of the parenchyma as well as individual or small, scattered groups of necrotic hepatocytes. Lesions in adult animals are usually much milder.

Diagnosis: The clinical signs and epidemiology, together with a relatively high mortality in lambs, are an indication of Wesselsbron disease. It should, however, be distinguished from Rift Valley fever, and the two diseases may occur together. The virus can be isolated from almost all organs of lambs that have died during the clinical stage of the disease. Intracerebral inoculation of newborn mice is the best method of isolation. The virus can be distinguished from that of Rift Valley fever by intraperitoneal inoculation of weaned mice; Wesselsbron disease virus will not kill such mice, whereas Rift Valley fever virus will. Confirmation of the viral identity can be accomplished by virus neutralization.

Serodiagnosis has been based on hemagglutination-inhibition, complement fixation, and virus neutralization. Flavivirus cross-reactivity is marked in hemagglutination-inhibition tests but less so in complement fixation, a test that is specific in cattle sera. Nevertheless, homologous Wesselsbron titers greatly exceed heterologous flavivirus titers.

Control: Production of an attenuated vaccine was discontinued shortly before 2000. Incidence of disease is low in sheep, but injudicious use of the vaccine in pregnant ewes resulted in severe economic losses in the past due to abortion and fetal malformations. Attempts to control mosquito vectors are of little value as a preventive measure.

CANINE DISTEMPER

Canine distemper is a highly contagious, systemic, viral disease of dogs seen worldwide. Clinically, it is characterized by a diphasic fever, leukopenia, GI and respiratory catarrh, and frequently pneumonic and neurologic complications. Its epidemiology is complicated by the large number of species susceptible to infection. The disease is seen in Canidae (dog, fox, wolf, raccoon dog), Mustelidae (ferret, mink, skunk, wolverine, marten, badger, otter), most Procyonidae (raccoon, coati mundi), some Viveridae (binturong, palm civet), Ailuridae (red panda), Ursidae (bear), Elephantidae (Asian elephant), primates (Japanese monkey), and large Felidae. Domestic dogs (including feral populations) are considered to be the reservoir species in most, if not all, locations. Antigenic drift and strain diversity is increasingly documented in association with outbreaks in wild species, domestic dogs, and exotic animals held in zoos and parks.

Etiology and Pathogenesis: Canine distemper is caused by a parainfluenza virus closely related to the viruses of measles and rinderpest. The fragile, enveloped, single-strand RNA virus is sensitive to lipid solvents, such as ether, and most disinfectants, including phenols and quaternary ammonium compounds. It is relatively unstable outside the host. The main route of infection is via aerosol droplet secretions from infected animals. Some infected dogs may shed virus for several months.

Virus initially replicates in the lymphatic tissue of the respiratory tract. A cell-associated viremia results in infection of all lymphatic tissues, which is followed by infection of respiratory, GI, and urogenital epithelium, as well as the CNS and optic nerves. Disease follows virus replication in these tissues. The degree of viremia and extent of viral spread to various tissues is moderated by the level of specific humoral immunity in the host during the viremic period.

Clinical Findings: A transient fever usually occurs 3–6 days after infection, and there may be a leukopenia (especially lymphopenia) at this time; these signs may go unnoticed or be accompanied by anorexia. The fever subsides for several days before a second fever occurs, which

may be accompanied by serous nasal discharge, mucopurulent ocular discharge, lethargy, and anorexia. GI and respiratory signs, typically complicated by secondary bacterial infections, may follow; rarely, pustular dermatitis may be seen. Encephalomyelitis may occur in association with these signs, follow the systemic disease, or occur in the absence of systemic manifestations. Dogs surviving the acute phase may have hyperkeratosis of the footpads and epithelium of the nasal planum, as well as enamel hypoplasia in incompletely erupted teeth.

Overall, a longer course of illness is associated with the presence of neurologic signs; however, there is no way to anticipate whether an infected dog will develop neurologic manifestations. CNS signs include circling, head tilt, nystagmus, paresis to paralysis, and focal to generalized seizures. Localized involuntary twitching of a muscle or group of muscles (myoclonus, chorea, flexor spasm, hyperkinesia) and convulsions characterized by salivation and, often, chewing movements of the jaw ("chewing-gum fits") are considered classic neurologic signs. Emerging viral strains may be associated with greater neurotropism; increased morbidity and mortality from neurologic complications has been observed.

A dog may exhibit any or all of these multisystemic signs during the course of the disease. Infection may be mild and inapparent or lead to severe disease with most of the described signs. The course of the systemic disease may be as short as 10 days, but the onset of neurologic signs may be delayed for several weeks or months as a result of chronic progressive demyelination within the CNS.

Clinicopathologic findings are nonspecific and include lymphopenia, with the possible finding of viral inclusion bodies in circulating leukocytes very early in the course of the disease. Thoracic radiographs may reveal an interstitial pattern typical of viral pneumonia.

Chronic distemper encephalitis (old dog encephalitis, [ODE]), a condition often marked by ataxia, compulsive movements such as head pressing or continual pacing, and incoordinated hypermetria, may be seen in fully vaccinated adult dogs without a history suggestive of systemic canine distemper infection. Although canine

distemper antigen has been detected in the brains of some dogs with ODE by fluorescent antibody staining or genetic methods, dogs with ODE are not infectious, and replication-competent virus has not been isolated. The disease is caused by an inflammatory reaction associated with persistent canine distemper virus infection in the CNS, but mechanisms that trigger this syndrome are unknown.

Lesions: Thymic atrophy is a consistent postmortem finding in infected young puppies. Hyperkeratosis of the nose and footpads is often found in dogs with neurologic manifestations. Depending on the degree of secondary bacterial infection, bronchopneumonia, enteritis, and skin pustules also may be present. In cases of acute to peracute death, exclusively respiratory abnormalities may be found. Histologically, canine distemper virus produces necrosis of lymphatic tissues, interstitial pneumonia, and cytoplasmic and intranuclear inclusion bodies in respiratory, urinary, and GI epithelium. Lesions found in the brains of dogs with neurologic complications include neuronal degeneration, gliosis, noninflammatory demyelination, perivascular cuffing, nonsuppurative leptomeningitis, and intranuclear inclusion bodies predominately within glial cells.

Diagnosis: Distemper should be considered in the diagnosis of any febrile condition in dogs with multisystemic manifestations. Characteristic signs sometimes do not appear until late in the disease, and the clinical picture may be modified by concurrent parasitism and numerous viral or bacterial infections. Distemper is sometimes confused with other systemic infections such as leptospirosis (see p 650), infectious canine hepatitis (see p 798), or Rocky Mountain spotted fever (see p 806). Intoxicants such as lead or organophosphates can cause simultaneous GI and neurologic signs. A febrile catarrhal illness with neurologic sequelae justifies a clinical diagnosis of distemper.

In dogs with multisystemic signs, the following can be examined by immunofluorescent assay or reverse transcriptase (RT) PCR: smears of conjunctival, tracheal, vaginal, or other epithelium; the buffy coat of the blood; urine sediment; or bone marrow aspirates. Commercially available quantitative RTPCR can usually distinguish natural infection from vaccinal virus. A combined two-step RT-PCR to distinguish vaccinal strains from emerging wild-type

strains has also been described; this assay would be of particular value in epidemiologic investigations or in outbreaks in non-canine species. Antibody titers or ELISA can be performed on CSF and compared with peripheral blood; a relatively higher level in the CSF is typical of natural infection versus vaccination. Viral antigen immunofluorescent assay (IFA) or fluorescent in situ hybridization for viral DNA can be performed on biopsies from the footpads or from the haired skin of the dorsal neck.

At necropsy, diagnosis is usually confirmed by histologic lesions, IFA, or both. These samples are often negative when the dog is showing only neurologic manifestations or when circulating antibody is present (or both), requiring that the diagnosis be made by CSF evaluation or RT-PCR as described above.

Treatment: Treatments are symptomatic and supportive, aimed at limiting secondary bacterial invasion, supporting fluid balance, and controlling neurologic manifestations. Broad-spectrum antibiotics, balanced electrolyte solutions, parenteral nutrition, antipyretics, analgesics, and anticonvulsants are used, and good nursing care is essential. No single treatment is specific or uniformly successful. Experimental in vitro work with antiviral agents shows promise, but these agents have not yet been widely used.

Unfortunately, treatment for acute neurologic manifestations of distemper is frequently unsuccessful. If the neurologic signs are progressive or severe, the owner should be appropriately advised. With prompt, aggressive care, dogs may recover completely from multisystemic manifestations, but in other cases, neurologic signs may persist after GI and respiratory signs have resolved. Some dogs with chronic progressive or vaccine-induced forms of neurologic disease may respond to immunosuppressive therapy with anti-inflammatory or greater dosages of glucocorticoids.

Prevention: With the potential increasing virulence of emerging strains and the wide host range of canine distemper virus, widespread vaccination of domestic dogs is essential. Successful immunization of pups with canine distemper modified-live virus (MLV) vaccines depends on the lack of interference by maternal antibody. To overcome this barrier, pups are vaccinated with MLV vaccine when 6 wk old and at 3- to 4-wk

intervals until 16 wk old. Alternatively, measles virus vaccine induces immunity to canine distemper virus in the presence of relatively greater levels of maternal distemper antibody. MLV measles vaccine is administered IM to pups 6–7 wk old and is followed with at least two more doses of MLV distemper vaccine when 12–16 wk old.

Many varieties of attenuated distemper vaccine are available and should be used according to manufacturers' directions. MLV vaccines should not be used in late-pregnant or early-lactation bitches. MLV vaccines can produce postvaccinal illness in some immunosuppressed dogs. A recombinant canarypox vector vaccine expressing distemper virus proteins is licensed for use in ferrets; the American

Association of Zoo Veterinarians recommends its extra-label use in many at-risk species held in zoos and parks. Historically, annual revaccination has been standard because of the breaks in protection that can occur in stressed, diseased, or immunosuppressed dogs, and because vaccines have been labeled for annual use. Substantial evidence supports the finding that immunity induced by MLV distemper vaccines lasts ≥ 3 yr. However, in most cases, this remains an extra-label use of the vaccine; thus, decisions to revaccinate less often than annually should be considered in light of local prevalence of the disease and other potential risk factors, as well as industry and professional organization recommendations.

CANINE HERPESVIRAL INFECTION

Canine herpesvirus is best known as a severe viral infection of puppies worldwide, which often has a 100% mortality rate in affected litters. Increasingly sensitive molecular diagnostics have enabled its recognition in adult dogs with upper respiratory infection, ocular disease, vesicular vaginitis or posthitis, and in dogs with no clinical signs. As is typical of herpesviruses, recovery from clinical disease is associated with lifelong latent infection. Only canids (dogs, wolves, coyotes) are known to be susceptible. The seroprevalence in dog populations worldwide ranges from 20% to 98% depending on the region. Because latently infected animals may transiently convert to seronegative status, any seroprevalence study likely underestimates the true rate of exposure and carriage.

Etiology and Pathogenesis: The disease is caused by an enveloped DNA canine herpesvirus (CHV) that is sensitive to lipid solvents (such as ether and chloroform) and most disinfectants. CHV is relatively unstable outside the host, so close contact is required for transmission.

Transmission usually occurs by contact between susceptible individuals and the infected oral, nasal, or vaginal secretions of shedding dogs. Many dogs shedding virus exhibit no clinical signs. Immunologically naive pregnant bitches are at risk of acute infection, which may be transmitted to fetuses or neonatal pups; previously infected bitches are unlikely to transmit infection. The most significant systemic disease

occurs in fetal or neonatal puppies from in utero infection, or infection in the first 3 wk of life. After this time, natural resistance to infection improves as puppies mature and maintain a higher body temperature.

Infection of susceptible animals results in replication of CHV in the surface cells of the nasal mucosa, pharynx, and tonsils. In the case of newborn susceptible pups or other dogs with compromised immune response, viremia and invasion of diverse visceral organs occur. Primary systemic infection is associated with a high degree of viral shedding; shedding by latently infected animals after clinical or subclinical recrudescence is of lesser severity and duration.

Clinical Findings: Deaths due to CHV infection usually occur in puppies 1–3 wk old, occasionally in puppies up to 1 mo old, and rarely in pups as old as 6 mo. Typically, onset is sudden, and death occurs after an illness of ≤ 24 hr. If clinical signs are observed, they may include lethargy, decreased suckling, diarrhea, nasal discharge, conjunctivitis, corneal edema, erythematous rash, rarely oral or genital vesicles, and the notable absence of fever. Thoracic radiographs show a diffuse unstructured interstitial pattern that is typical of viral pneumonia, but, in contrast to other viral diseases of puppies, leukocytosis may be present.

Older dogs exposed to or experimentally inoculated with CHV may develop a mild rhinitis, which may be part of the "kennel cough" syndrome (infectious tracheobron-

chitis, *see* p 1490) or a vesicular vaginitis or posthitis. There are also reports of conjunctivitis and dendritic corneal ulcers in the absence of other upper respiratory signs. Acutely infected pregnant bitches may abort a litter, or deliver a partially stillborn litter; however, they seldom exhibit other clinical signs, and future breedings are likely to be successful.

Lesions: The characteristic gross lesions at necropsy consist of disseminated focal necrosis and hemorrhages. The most pronounced lesions are seen in the lungs, cortical portion of the kidneys, adrenal glands, liver, and GI tract. All lymph nodes are enlarged and hyperemic, and the spleen is swollen. Lesions may also be found in the eyes and CNS. The basic histologic lesion is necrosis with hemorrhage in the adjacent parenchyma. The inflammatory reaction in many organs may be limited, but marked neutrophilic and mononuclear infiltration is seen in ocular lesions. Single, small, basophilic, intranuclear inclusion bodies are most common in areas of necrosis in the lung, liver, and kidneys; occasionally, they are seen as faintly acidophilic bodies located within the nuclear space.

Diagnosis: In systemically affected puppies, CHV infection may be confused with infectious canine hepatitis (*see* p 798), but it is not accompanied by the thickened, edematous gallbladder often associated with the latter. The focal areas of necrosis and hemorrhage, especially those that are seen in the kidneys, distinguish it from hepatitis and neosporosis (*see* p 663). CHV causes serious disease only in very young puppies. The rapid death and characteristic lesions distinguish it from canine distemper (*see* p 777).

Hemagglutination, ELISA, and immunofluorescence antibody tests are available, and PCR is highly sensitive and specific when used on fresh tissue and fluid samples. In cases of neonatal mortality, the diagnosis typically is made postmortem with virus isolation from fresh lung, liver, kidney, and

spleen by cell culture techniques and subsequent identification by PCR and sequencing, transmission electron microscopy, immunofluorescence, or fluorescence in situ hybridization. The tissues should be submitted to the laboratory refrigerated but not frozen.

Treatment: Therapy is typically unrewarding in systemically affected puppies, and the prognosis for puppies that do survive is guarded because damage to lymphoid organs, brain, kidneys, and liver may be irreparable. Before onset of clinical signs in littermates or other nearby puppies, rearing in incubators at an increased temperature (95°F [35°C], 50% relative humidity), and/or passive immunization with intraperitoneal serum may reduce losses within an exposed litter. Limited studies with antiviral agents such as vidarabine are inconclusive, but immediate recognition and treatment would be needed to have any possibility of success.

Adult dogs with ocular, respiratory, or genital disease often experience mild and self-limiting signs. Ophthalmic antiviral cidofovir (0.5% bid) has been used successfully in one reported case of primary ocular infection in an adult dog and may be useful for persistent or painful ocular lesions.

Prevention: No vaccine is available in the USA. Infected bitches develop antibodies, and litters subsequent to the first infected litter receive maternal antibodies in the colostrum. Puppies that receive maternal antibodies may be infected with the virus, but disease does not result. Isolation of pregnant bitches from other dogs during the last 3 wk of gestation and first 3 wk postpartum, with excellent hygiene by human handlers, is the most effective way to minimize risk to puppies. Because of the high seroprevalence among adult dogs and because virus may be shed by asymptomatic individuals, complete avoidance of exposure is not a reasonable management strategy for most dogs.

FELINE INFECTIOUS PERITONITIS

Feline infectious peritonitis (FIP) is an immune-mediated disease triggered by infection with a feline coronavirus (FCoV). FCoV belongs to the family Coronaviridae, a group of enveloped, positive-stranded RNA viruses frequently found in cats.

Coronavirus-specific antibodies are present in as many as 90% of cats in catteries and in as many as 50% of those in single-cat households. However, <5% of FCoV-infected cats develop FIP in multicat households.

Geographic Distribution: FCoV infection and FIP occur worldwide with similar prevalence and are found in domestic and wild cats. FCoV strains can be classified into serotypes I and II, depending on their antigenic relationship to canine coronavirus (CCV), and these subtypes vary in proportion among different countries. Among FCoV strains isolated in the field in the USA and Europe, 70%–95% are serotype I. In contrast, in Japan serotype II predominates. Most cats with FIP are infected with FCoV serotype I. However, both serotypes can cause FIP and both can cause clinically inapparent FCoV infections.

FCoV belongs to the same taxonomic cluster of coronaviruses as transmissible gastroenteritis virus, porcine respiratory coronavirus, CCV, and some human coronaviruses. In many species, coronaviruses have a relatively restricted organ tropism, mainly infecting the respiratory and/or GI tracts. In cats and mice, however, coronavirus infections can, in certain circumstances, involve multiple organs.

In addition to cats, other felid species are susceptible, and FCoV is also an important pathogen in nondomestic felids. There was evidence of FCoV infection in 195 of 342 nondomestic felids in southern Africa, which included both wild and captive animals. There is also a high incidence of FIP in nondomestic felids in captivity in the USA and Europe. Cheetahs in captivity seem to be highly prone to developing FIP; loss of genetic diversity and a genetic deficiency in their cellular immunity is thought to predispose them to the disease. Although FIP can only occur in felids, a clinically similar condition in ferrets is associated with ferret systemic coronavirus.

Etiology and Pathogenesis: FIP is a sporadic disease thought to be caused by viral variants that develop within each specific cat. The pathogenesis of FIP is unclear, but there are two main hypotheses. The “internal mutation theory” states that cats are infected with the primarily avirulent FCoV that replicates in enterocytes; in some cats, a mutation occurs in a certain region of the FCoV genome that creates a new phenotype with the ability to replicate within macrophages. The presence of highly virulent strains of FCoV capable of consistently inducing FIP support this theory, albeit under experimental conditions. Several researchers speculate that some circulating feline enteric coronaviruses are closer to making critical mutations necessary for development of FIP, possibly explaining FIP

outbreaks. No consistent mutation has yet been identified, although studies have suggested sequence differences in the spike protein, membrane protein, or NSP3c correlate with disease manifestation. Recent studies have found feline coronaviruses to have intact NSP3c genes, whereas most isolates from diseased tissues of FIP cases had disrupted NSP3c genes. Findings suggested that 3c-inactivated viruses only rarely replicate in the intestine, which possibly explains the rare incidence of FIP outbreaks. In additional work, it was concluded that mutation of the S1/S2 locus and modulation of a furin recognition site normally present in the S gene of enteric coronaviruses is a critical contributing factor for development of FIP.

The second hypothesis for the development of FIP is the existence of distinct circulating virulent and avirulent strains in a population, and exposure to the pathogenic strain, the viral load, and the cat's immune response determine whether FIP will develop. It is likely both viral genetics and host immunity play a role. In both hypotheses, the key pathogenic event in the development of FIP is the massive replication of FCoV in macrophages. If the cat does not eliminate macrophages infected with replication-competent virus early in infection, the presence of the virus within circulating macrophages initiates an ultimately fatal arthus-type immune-mediated reaction, which defines FIP.

Factors that increase FCoV replication in the intestines (and increase the probability of the mutation) include young age, breed predisposition, immune status, stress, corticosteroid treatment, and surgery, as well as dosage and virulence of the virus and reinfection rate in multicat households. Crowded environments, such as catteries or shelters, also may increase stress and exposure to FCoV. Whenever FCoV infection exists, so does the potential for development of FIP.

After a cat becomes infected with FCoV via fecal-oral transmission (or less commonly, inhalation), the main site of viral replication is the intestinal epithelium. Replication of FCoV in the cytoplasm can destroy intestinal epithelial cells, leading to diarrhea in some cats. In many cats, infection persists for weeks to months in the absence of clinical signs. These cats shed FCoV either intermittently or continually and act as a source of infection for other cats. Previously, it was believed that avirulent FCoV remained confined to the digestive tract, did not cross the gut mucosa, and did not spread beyond the

intestinal epithelium and regional lymph nodes. However, PCR can detect FCoV in the circulating macrophages of healthy cats from households with endemic FCoV, indicating that avirulent FCoV may also cause viremia.

FIP is an immune complex disease involving viral antigen, antiviral antibodies, and complement. Within weeks after macrophage invasion and replication, virions are found in the cecum, colon, intestinal lymph nodes, spleen, and liver after distribution by macrophages in the whole body, including the CNS. There are two possible explanations for the events that follow viral dissemination from the intestines. The first proposed mechanism is that FCoV-infected macrophages leave the bloodstream and carry virus into the tissues. The virus attracts antibodies, complement is fixed, and more macrophages and neutrophils are attracted to the lesion; as a consequence, typical pyogranulomatous changes develop. The alternative explanation is that FIP occurs as a result of circulating immune complexes lodging in blood vessel walls, fixing complement, and leading to development of the pyogranulomatous changes. It is assumed that these antigen-antibody complexes are recognized by macrophages but are not, as they should be, presented to killer cells, and thus are not destroyed.

In addition to virus, chemotactic substances, including complement and inflammatory mediators, are released from infected macrophages. Complement fixation leads to the release of vasoactive amines, which cause endothelial cell retraction and thus increased vascular permeability. Retraction of capillary endothelial cells allows exudation of plasma proteins and, hence, development of characteristic protein-rich exudates. Inflammatory mediators activate proteolytic enzymes that cause tissue damage.

Epidemiology and Transmission:

FCoV and FIP are a major problem in multicat households. The virus is endemic in environments in which many cats are kept together in a confined space (eg, catteries, shelters, pet stores). FCoV is found less commonly in free-roaming community cats, because they do not typically use the same locations to bury their feces; shared litter boxes are a major source of transmission in multicat households.

Although the prevalence of FCoV infection is very high in multicat households, <5% of cats in these situations

develop FIP; the number is even lower in a single cat environment. The risk of developing FIP is higher for young and immunocompromised cats because the replication of FCoV in these animals is less controlled and, thus, the critical mutation is more likely to occur. More than half of the cats with FIP are <12 mo old. Sexually intact cats, males, and purebred cats have a higher incidence of FIP. Epidemiologic data suggest that the cat's genetic background contributes to the manifestation of FIP. Investigators have described variation in breed resistance and susceptibility to FIP. Susceptibility to FIP is a polygenic inherited trait in Persians and Birmans. Breeds with higher prevalence of FIP include Abyssinian, Bengal, Birman, Himalayan, Ragdoll, and Rex.

FCoV is shed mainly in the feces. Infection is generally via the oronasal route. After natural infection, cats begin to shed virus in feces within 1 wk. In very early infection, it may be found in saliva, respiratory secretions, and urine. When naive cats in multicat households first encounter FCoV, it is likely that all will become infected (and develop antibodies); most will shed virus intermittently for a period of weeks or months. Some cats become chronic FCoV shedders, providing a continual source for reinfection of other cats. Cats that are antibody-negative are very unlikely to shed, whereas approximately one-third of all FCoV antibody-positive cats shed virus. Cats with high antibody titers are more likely to shed FCoV. They also are more likely to shed consistently and higher amounts of the virus. Most cats with FIP also shed non-mutated FCoV; however, the virus load in feces seems to decrease after a cat has developed FIP.

The major sources of FCoV for naive cats are litter boxes shared with shedding cats. Also, continuous reinfection through the contaminated litter box of a cat already infected seems to play an important role in the endemic survival of the virus. Rarely, virus can be transmitted through saliva, by mutual grooming, sharing the same food bowl, and through close contact. Sneezed droplet transmission is also rare but possible. It is uncertain whether FCoV transmission occurs to a significant degree at cat shows. Transmission by lice or fleas is considered unlikely. Transplacental transmission can occur but is very uncommon under natural circumstances. Most kittens that are removed from contact with virus-shedding adult cats at 5–6 wk of age do not become infected. Most commonly, kittens are infected at the age of

6–8 wk at a time when their maternal antibodies wane, mostly through contact with feces from their mothers or other FCoV-excreting cats.

FCoV is a relatively fragile virus that is destroyed by most household disinfectants and detergents. However, it may survive in cold or dry conditions (eg, in carpet) for as long as 7 wk outside the cat. Indirect fomite transmission is possible, and the virus can be transmitted for a short time via clothes, toys, and grooming tools.

Clinical Findings:

Feline Coronavirus Infection: FCoV infection can cause a transient and clinically mild diarrhea and/or vomiting due to replication of FCoV in enterocytes. Kittens infected with FCoV may have a history of stunted growth or upper respiratory tract signs. Occasionally, the virus may cause severe diarrhea with weight loss, which may be unresponsive to treatment and continue for months. However, most FCoV-infected cats do not show clinical signs.

Feline Infectious Peritonitis: Clinical signs of FIP vary depending on organ involvement. Many organs, including the liver, kidneys, pancreas, CNS, and eyes, can be involved. The clinical signs and pathologic findings are a consequence of the vasculitis and, less commonly, organ failure resultant from damage to the blood vessels that supply them. In all cats with nonspecific clinical signs, such as chronic weight loss or fever of unknown origin resistant to antibiotic treatment or recurrent in nature, FIP should be on the list of differential diagnoses.

The length of time between infection and development of clinical signs is unknown and depends on the immune response of the individual cat. Disease generally becomes apparent from a few weeks to 2 yr after the mutation has occurred. Cats are at greatest risk of developing FIP in the first 6–18 mo after infection with FCoV; the risk decreases to ~4% at 36 mo after infection.

Previously, three different forms of FIP were distinguished: 1) an effusive, exudative, “wet form”; 2) a noneffusive, nonexudative, granulomatous, parenchymatous “dry form”; and 3) a mixed form. The first form was characterized by a fibrinous peritonitis, pleuritis, and/or pericarditis with effusion in the abdomen, thorax, and/or pericardium, respectively. The second form was characterized by granulomatous changes in different organs that may include the eyes and CNS. Differentiation between these forms is not useful and is of value only

for the diagnostic approach, because there is nearly always effusion to a greater or lesser degree in combination with more or less granulomatous changes present in cats with FIP. In addition, the forms can transform into each other. Cats with FIP may be alert or depressed. Some eat with a normal or even increased appetite; others are anorectic. Fever, weight loss, and/or icterus may be noted.

In cats with ascites, an abdominal swelling is commonly noticed. Fluctuation and a fluid wave may be present; in less severe cases, fluid can be palpated between the intestinal loops. Abdominal masses can sometimes be palpated, reflecting omental and visceral adhesions or enlarged mesenteric lymph nodes. Thoracic effusions may cause dyspnea, tachypnea, open-mouth breathing, or cyanotic mucous membranes. Auscultation reveals muffled heart sounds. In cats with pericardial effusions, heart sounds are muffled and typical changes can be seen on ECG and echocardiography. Effusions can be visualized by diagnostic imaging (eg, radiographs, ultrasound) and verified by a fluid centesis.

In cats without obvious effusion, in which mainly granulomatous changes are present, signs are often vague and include fever, weight loss, lethargy, and decreased appetite. If the lungs are involved, cats can be dyspneic, and thoracic radiographs may reveal patchy densities in the lungs. Abdominal palpation may reveal enlarged mesenteric lymph nodes and irregular kidneys or nodular irregularities in other viscera. Presenting clinical signs sometimes can be unusual. In some cats, abdominal tumors are suspected, but FIP is finally diagnosed at surgery or necropsy.

Cats with FIP frequently have ocular lesions. The most common ocular lesions are retinal changes, and a retinal examination should be performed in all cats with suspected FIP. FIP can cause cuffing of the retinal vasculature, which appears as fuzzy grayish lines on either side of the blood vessels. Occasionally, granulomatous changes are seen on the retina. Retinal hemorrhage or detachment may also occur. These changes, however, are not pathognomonic; similar changes can be seen in other systemic infectious diseases, including toxoplasmosis, systemic fungal infections, and feline immunodeficiency virus or feline leukemia virus infection. Uveitis is another common manifestation. Mild uveitis can manifest by color change of the iris. Uveitis may also manifest as aqueous flare, with cloudiness of the anterior chamber, which can be detected in a darkened room using

focal illumination. Large numbers of inflammatory cells in the anterior chamber settle on the back of the cornea and cause keratic precipitates, which may be hidden by the nictitating membrane. Hemorrhage into the anterior chamber can occur. If aqueous humor is sampled, it may reveal increased protein and pleocytosis.

Neurologic signs are common in cats with FIP. These are variable and reflect the area of CNS involvement. The lesions are usually multifocal. The most common clinical sign is ataxia followed by nystagmus and seizures. In addition, incoordination, intention tremors, hyperesthesia, behavioral changes, and cranial nerve involvement can be seen. If cranial nerves are involved, neurologic signs such as visual deficits and loss of menace reflex may be present. When FIP lesions are located on a peripheral nerve or the spinal column, lameness, progressive ataxia, or paresis may be seen. Finding hydrocephalus on a CT scan is suggestive of neurologic FIP. In a study of 24 cats with FIP with neurologic involvement, 75% were found to have hydrocephalus on postmortem examination.

Solitary mural intestinal lesions have been described in cats with a histologic diagnosis of FIP. Diarrhea, vomiting, or obstruction can occur, and a suspected neoplastic mass can be found in the colon or ileoceocolic junction, with associated lymphadenopathy, and a markedly thickened and firm segment of bowel with multifocal pyogranulomas extending through the intestinal wall on histology.

Skin fragility syndrome was described in a cat with FIP, and other skin lesions (eg, nodular skin lesions, papular skin lesions, pododermatitis) may be present as well. Reproductive disorders, neonatal deaths, and fading kittens are not usually associated with FIP.

Lesions: Histology of lesions is usually pathognomonic and is traditionally considered the gold standard for diagnosis of FIP. H&E-stained samples typically contain localized perivascular mixed inflammation with macrophages, neutrophils, lymphocytes, and plasma cells. FCoV can be identified by immunohistochemistry in the macrophages within the lesions. Pyogranulomas may be large and consolidated, sometimes with focal tissue necrosis, or numerous and small. Lymphoid tissues in cats with FIP often show lymphoid depletion caused by apoptosis.

Diagnosis: Reliable and rapid diagnosis of FIP is important but can be challenging.

Difficulties arise from the lack of noninvasive confirmatory tests in cats without obvious effusion. Obtaining and analyzing effusion is minimally invasive and much more sensitive than diagnostic tests in blood. In cats with no effusion, several parameters including history, clinical signs, laboratory changes, and level of antibody titers should be considered to determine whether to use invasive confirmative diagnostic methods.

Hematology and Serum Biochemistry: WBC counts can be decreased or increased. Lymphopenia is commonly present, mainly caused by apoptosis of uninfected T cells, primarily CD8⁺ T cells, as a result of high TNF- α concentrations produced by virus-infected macrophages. However, lymphopenia in combination with neutrophilia can occur in many severe diseases in cats. A mild to moderate nonregenerative anemia is another nonspecific finding that may be seen in almost any chronic disease in cats.

The most common laboratory abnormality in cats with FIP is an increase in total serum protein concentration caused by increased globulins, mainly γ -globulins, which occurs in >70% of cats with FIP. Total protein in cats with FIP can reach very high concentrations of ≥ 12 g/dL. The albumin to globulin ratio, however, has a significantly higher diagnostic value to distinguish FIP from other diseases than total serum protein or γ -globulin concentrations, because serum albumin also may decrease. Albumin loss in cats with FIP may be caused by glomerulonephritis secondary to immune complex deposition, by loss of protein due to exudative enteropathy in cases of granulomatous changes in the intestines, or by extravasation of protein-rich fluid during vasculitis. An optimal cut-off value of 0.8 was determined for the albumin to globulin ratio (specificity 82%, sensitivity 80%). If the serum albumin to globulin ratio is <0.8, the probability that the cat has FIP is high (92% positive predictive value [PPV]); if the albumin to globulin ratio is >0.8, the cat likely does not have FIP (61% negative predictive value [NPV]). Reference laboratories have variation in techniques for measurement of serum proteins. Serum protein electrophoresis may be performed in cats with suspected FIP to distinguish a polyclonal from a monoclonal hypergammaglobulinemia to differentiate FIP (and other chronic infection) from tumors such as multiple myelomas or other plasma cell tumors. However, hyperglobulinemia is generally nonspecific and reflects active inflammation.

Other laboratory parameters, including liver enzymes, bilirubin, urea (or BUN), and creatinine, can be variably increased depending on the degree and localization of organ damage but are not helpful in establishing an etiologic diagnosis. Hyperbilirubinemia and icterus are often seen in cats with FIP. High bilirubin (in the absence of hemolysis) and increased liver enzyme activity should raise the suspicion of FIP.

High serum levels (>3 mg/mL) of α -1-acid glycoprotein (AGP), a serum acute phase protein that is increased in cats with FIP, can support diagnosis, but levels also are increased in other inflammatory conditions; thus, these changes are not specific. Additionally, AGP may also be high in asymptomatic cats infected with FCoV, especially in households where FCoV is endemic. However, the most prominent increases in serum AGP concentration have been recorded in cats with FIP. Levels of AGP in serum and effusions increased 2- to 5-fold in cats with FIP, more than in diseases such as neoplasia and cardiomyopathy. In a study with a small number of cases, measurement of serum AGP concentrations was demonstrated to be most helpful, because it was the only diagnostic test in complete concordance with immunohistochemistry. Two factors must be considered when evaluating AGP concentration to support a clinical diagnosis of FIP: the magnitude of the increase in concentration and the pretest probability of FIP (compatible history and clinical findings). Serum amyloid A (SAA), another acute phase protein, increases 10-fold in the serum of cats with FIP compared with asymptomatic cats exposed to feline enteric coronaviruses. SAA may be a useful biomarker in the future.

Diagnostic Imaging: A recent study highlighted specific concurrent ultrasonographic findings that should increase the index of suspicion for FIP, including abdominal lymphadenopathy, peritoneal or retroperitoneal effusion, renomegaly, irregular renal contour, hypoechoic subcapsular echogenicity, and diffuse changes within the intestines. In most cats in the study population, the liver and spleen were normal in echogenicity. A normal abdominal ultrasound does not exclude the possibility of FIP infection.

Effusion Fluid: Tests on effusion have a much higher diagnostic value than tests performed on blood. Fluid can be obtained through ultrasound-guided fine-needle aspiration or by using the "flying cat technique" in case of ascites. Although clear

yellow effusions of sticky consistency are considered typical, the presence of this type of fluid in body cavities alone is not diagnostic. Cases with pure chylous effusion have been reported. Usually, the protein content is very high (>3.5 g/dL), consistent with an exudate, whereas the cellular content is low ($<5,000$ nucleated cells/mL), resembling a modified transudate or even pure transudate. Major differential diagnoses for these effusions include inflammatory liver disease, lymphoma, heart failure, and bacterial peritonitis or pleuritis. LDH activity typically is high (>300 IU/L). Cytology is variable but often consists predominantly of macrophages and nondegenerate neutrophils (in much lower numbers than seen with bacterial infection). These effusions can usually be differentiated from bacterial infection or lymphoma by the presence of malignant cells, degenerate neutrophils, or intracellular bacteria on cytology and bacterial growth on culture, respectively. The albumin to globulin ratio of the effusion can be measured: a ratio of <0.5 is strongly correlated with FIP, with a PPV between 66% and 95%, depending on the prevalence of FIP in the cat's environment. An albumin to globulin ratio >0.81 has a 100% NPV, essentially excluding FIP.

Rivalta's test is a simple, inexpensive method that does not require special laboratory equipment and can be performed easily in private practice. It is very useful in cats to differentiate between effusions caused by FIP and effusions caused by other diseases. The high protein content and high concentrations of fibrin and inflammatory mediators lead to a positive reaction. To perform the test, a transparent reagent tube (10 mL) is filled with ~ 8 mL distilled water, to which 1 drop of acetic acid (highly concentrated vinegar, 98%) is added and mixed thoroughly. On the surface of this solution, 1 drop of the effusion fluid is carefully layered. If the drop disappears and the solution remains clear, the Rivalta's test is defined as negative. If the drop retains its shape, stays attached to the surface, or slowly floats down to the bottom of the tube (drop- or jelly-fish-like), the test is defined as positive. Rivalta's test has a high PPV (86%) and a very high NPV (96%) for FIP. Positive results can sometimes be seen in cats with bacterial peritonitis or lymphoma. Those effusions, however, are usually easy to differentiate through macroscopic examination, cytology, and bacterial culture.

Cerebrospinal Fluid: Analysis of cerebrospinal fluid (CSF) from cats with neurologic signs due to FIP lesions may

reveal increased protein (50–350 mg/dL with a normal value of <25 mg/dL) and pleocytosis (100–10,000 nucleated cells/mL) containing mainly neutrophils, lymphocytes, and macrophages (a relatively nonspecific finding). Many cats with neurologic signs caused by FIP have normal CSF. In one study, typical CSF findings in cats with FIP were a protein concentration >200 mg/dL and a WBC count of >100 cells/ μ L, which consisted predominantly of neutrophils.

Measurement of Antibodies: There is no FIP-specific antibody test; all that can be measured is antibodies against FCoV. Antibody titers measured in serum are extensively used as a diagnostic tool. However, most FCoV antibody-positive cats never develop FIP. Thus, antibody titers must be interpreted extremely cautiously and should never be used as the sole test to diagnose FIP. Antibody testing still has a certain role in the diagnosis and, more importantly, in the management of multicat households, when done by appropriate methodologies and when results are properly interpreted. However, antibody testing can only be useful if the laboratory is reliable and consistent. Low or medium titers have no diagnostic value. If interpreted carefully, however, very high titers can be of certain diagnostic value. A very high titer in a cat with compatible clinical signs (1:1,600) has a 94% PPV for FIP; a negative titer has a 90% NPV for FIP. Cats with high antibody titers are more likely to shed FCoV and to shed more consistently higher amounts of the virus. Thus, the titer is directly correlated with virus replication rate and the amount of virus in the intestines. Screening a cattery for the presence of FCoV or screening a cat before introduction into an FCoV-free cattery are additional indications.

Measuring antibodies in fluids (eg, effusion, CSF) other than blood has been investigated. Detection of anticoronavirus antibodies in effusion fluid has a PPV of 90% and a NPV of 29% for diagnosis of FIP. Presence of antibodies in effusion is correlated with the presence of antibodies in blood; thus, antibody titers in effusions are not very helpful. One study investigating the diagnostic value of antibody detection in CSF reported a very good correlation to the presence of FIP when compared with histopathology; however, two studies investigating a large number of cats presented to veterinary teaching hospitals revealed no significant difference in antibody titers in CSF from cats with neurologic signs due to FIP compared with cats with other neurologic diseases confirmed by histopathology.

Feline Coronavirus Reverse Transcriptase PCR: FCoV reverse transcriptase PCR in blood is used with increasing frequency as a diagnostic tool for FIP. However, so far, no PCR has been developed that can definitively diagnose FIP. PCR can be false-negative (eg, because the assay requires reverse transcription of viral RNA to DNA before amplification of DNA, and degradation of RNA can occur due to contamination with ubiquitous RNAses) or false-positive (eg, the assay does not distinguish between virulent and avirulent FCoV strains and will not discriminate FCoV from coronaviruses of other species). Furthermore, viremia appears to occur not only in cats with FIP but also in healthy carriers. FCoV RNA has been detected in the blood of cats with FIP but also in healthy cats that did not develop FIP for as long as 70 mo. Therefore, the results of PCR tests in general must be interpreted carefully, and PCR cannot be used as a tool to definitively diagnose FIP.

PCR has been used to detect FCoV in fecal samples, and it is sensitive and useful to document that a cat is shedding FCoV in feces. The strength of the PCR signal in feces correlates with the amount of virus present in the intestines. These results can be useful to detect cats that chronically shed high virus loads and that pose a high risk in multicat households.

Immunostaining of Feline Coronavirus Antigen: Direct staining of FCOVs within macrophages by immunofluorescence in cytocentrifuged effusions or immunohistochemistry in tissue is considered the most specific test to confirm FIP. Immunostaining cannot differentiate between the “harmless” FCoV and FIP-causing FCoV, but finding infected macrophages in characteristic pyogranulomatous lesions or in inflammatory effusions is highly associated with FIP. In a recent study in which a large number of cats with confirmed FIP and controls with other confirmed diseases were investigated, positive immunofluorescence staining of intracellular FCoV antigen in macrophages of the effusion was 100% predictive of FIP. Unfortunately, the NPV of the test is not very high (57%), which can be explained by low numbers of macrophages on effusion smears resulting in negative staining. Immunohistochemistry can be used to detect the expression of FCoV antigen in tissue and is also 100% predictive of FIP if positive. However, invasive methods (eg, laparotomy or laparoscopy) are usually necessary to obtain appropriate tissue samples. Either histology itself is confirmative, or immunohistochemistry staining of

FCoV antigen in tissue macrophages can be used to diagnose FIP.

Treatment, Control, and Prevention:

Because of the high prevalence of FCoV antibodies in healthy cats, widespread antibody testing of healthy cats is not an appropriate screening test for FIP in pet cats. Nor should cats in shelters be screened for antibodies before adoption. No treatment of healthy antibody-positive cats has been shown to prevent development of FIP.

Treatment of cats with FIP remains frustrating and is limited to the cases that respond favorably within the first few days. The prognosis for a cat with FIP is very poor. In a prospective study including 43 cats with confirmed FIP, the median survival after the definitive diagnosis was 9 days. Some cats, however, may live for several months. Factors that indicate a poor prognosis and a short survival time are low Karnofsky score (index for quality of life), low platelet count, low lymphocyte count, high bilirubin concentration, and a large amount of effusion. Seizures are an unfavorable prognostic sign; they are significantly more frequent in cats with marked extension of the inflammatory lesions to the forebrain. Cats that show no improvement within 3 days after treatment initiation are unlikely to show any benefit from therapy, and euthanasia should be considered. Longer survival or remission from clinical signs is rare.

Supportive treatment is aimed at suppressing the immune overreaction, usually using corticosteroids. However, there are no controlled studies that indicate whether corticosteroids have any beneficial effect. Cats treated with corticosteroids have shown anecdotal improvement for as long as several months. Immunosuppressive drugs such as prednisolone (2–4 mg/kg/day, PO) are commonly used. More potent cytotoxic drugs such as cyclophosphamide (4 mg/kg/day) have also been suggested. Cats with large effusions benefit from removal of the fluid; injection of dexamethasone into the abdominal or thoracic cavity may follow (1 mg/kg/day until no effusion is present).

Cats with FIP should receive supportive therapy, including fluids and nutritional support, and their quality of life should be monitored. Anecdotal reports suggest that ozagrel hydrochloride, a thromboxane synthetase inhibitor that inhibits platelet aggregation, and pentoxifylline, a drug that decreases vasculitis and inhibits several cytokines (such as interleukins and TNF α), may be beneficial in some cats.

Immune modulators (eg, *Propionibacterium acnes*, acemannan, tylosin, promodulin, interferon- α) have been used to treat cats with FIP. However, controlled trials are lacking, and anecdotal reports often lack definitive diagnosis. It has been suggested that these agents may benefit infected animals by restoring compromised immune function. However, a nonspecific stimulation of the immune system would seem to be contraindicated in FIP, because clinical signs develop and progress as a result of an immune-mediated response.

A number of studies have investigated effectiveness of various antiviral treatments in cats with FIP, including interferons and ribavirin. To date, none have proved to be very successful. See TABLE 7.

Interferons have been used frequently in cats with FIP. Human interferon- α has a direct antiviral effect, and in vitro antiviral efficacy against an FIP-causing FCoV strain has been demonstrated. In a controlled study, cats with confirmed FIP treated with interferon- α at 106 IU/kg in combination with *Propionibacterium acnes* survived for ~3 wk. Feline interferon- ω is available in some European countries and Japan. FCoV replication is inhibited by feline interferon- ω in vitro, but there was no statistically significant difference in the mean survival time of cats enrolled in a randomized placebo-controlled double-blind treatment trial. Cats survived for 3–200 days, regardless of whether they received the drug or placebo.

Management of Exposed Cats:

When a cat in a household develops FIP, all in-contact cats will have already been exposed to the same FCoV. Under natural circumstances, it appears that the FIP-causing virus strain is not excreted in such cases, and FIP is not transmitted from cat to cat. However, under experimental conditions it has been possible to transmit FIP-causing virus from a cat with FIP to in-contact cats. Still, it appears to be relatively safe for a cat with FIP to remain in the same household with cats that have already been in contact to the FCoV strain. However, it is not recommended to allow contact between a cat with FIP and any new “naïve” cat. Kittens, which are more susceptible to FIP than adults, should not be introduced to households with a recent history of FIP.

If a cat has been euthanized or has died due to FIP, the owner should wait 2 mo before obtaining another cat. FCoV can remain infectious for at least 7 wk in the environment, particularly where litter boxes are in use. Other cats currently in the

household are most likely infected with and shedding FCoV. Cats are commonly presented to the veterinarian for evaluation after contact with a cat with FIP or a suspected or known virus excretor. The owner may want to know the prognosis for the exposed cat or whether it is shedding FCoV. Such cats will likely be antibody positive, because 95%–100% of cats exposed to FCoV become infected and develop antibodies ~2–3 wk after exposure. A few cats may be resistant to FCoV infection. Some cats in FCoV-endemic multicat households continuously remain antibody negative. The mechanism of action for this resistance is unknown.

Although exposed cats will most likely have antibodies, this is not necessarily associated with a poor prognosis. Most cats infected with FCoV will not develop FIP, and many cats in single- or two-cat households will eventually clear the infection and become antibody negative in a few months to years (usually ~6 mo). If titers are monitored, cats should be retested (using the same laboratory) every 6–12 mo until the antibody test is negative. Some cats will remain antibody positive for years. The value of serial antibody or PCR testing is mostly limited to protocols aimed at creating FCoV-free closed catteries.

Management of Multicat Households:

In most multicat households with unusually high cat numbers, FCoV is endemic and FIP is almost inevitable. Households of <5 cats may spontaneously and naturally become FCoV-free, but in households of >10 cats per group, this is almost impossible because the virus passes from one cat to another, maintaining the infection. In these FCoV-endemic environments, such as breeding catteries, shelters, foster homes,

and other multicat homes, there is virtually nothing to prevent FIP.

Various tactics have been used to eliminate FCoV from an endemic cattery. Reducing the number of cats (especially of kittens <12 mo old) and keeping suspected FCoV-contaminated surfaces clean can minimize population loads of the virus. Antibody or fecal PCR testing and removal of positive cats should be performed to stop exposure and reinfection of recovered cats. Approximately 1/3 of antibody-positive cats excrete virus; thus, every antibody-positive cat should be considered infectious. After 3–6 mo, antibody titers can be retested. Alternatively, PCR testing of (several) fecal samples can be performed to detect chronic FCoV carriers; these cats should be removed. In large, multicat environments, 40%–60% of cats shed virus in their feces at any given time. Approximately 20% will shed virus persistently. If a cat remains persistently PCR-positive for >6 wk, it should be placed in a single-cat environment or with other chronic shedders.

Kittens of FCoV-shedding queens are often protected from infection by maternally derived antibodies until they are 5–6 wk old. An early weaning protocol for prevention of FCoV infection in kittens has been proposed and consists of isolation of queens 2 wk before parturition, strict quarantine of queen and kittens, and early weaning at 5 wk of age. Early removal of kittens from the queen and prevention of infection from other cats may succeed in keeping kittens free of infection. Kittens should be taken to a new home (with no FCoV-infected cats) at 5 wk of age. Although straightforward in concept, the protocol requires quarantine rooms and procedures to ensure that new virus does not enter. Special care must be taken during this

TABLE 7

DRUGS THAT HAVE BEEN SUGGESTED FOR USE IN FELINE INFECTIOUS PERITONITIS CASES

Drug ^a	Comment	ABCD Recommendation (EBM Level ^b)
ANTIVIRALS		
Ribavirin	Active in vitro but toxic in cats	Not recommended (2)
Vidarabin	Active in vitro but toxic in cats	Likely ineffective (4)
Human interferon- α , SC, high dose	Although effective in vitro against FCoV, SC treatment did not work in an experimental trial	Ineffective (2)

TABLE 7

**DRUGS THAT HAVE BEEN SUGGESTED FOR USE IN FELINE
INFECTIOUS PERITONITIS CASES** (*continued*)

Drug ^a	Comment	ABCD Recommendation (EBM Level ^b)
Human interferon- α , PO, low dose	No trials. Only acts as immunostimulant if given orally; immune stimulation should be avoided in cats with FIP	Contraindicated (4)
Feline interferon- ω	Single placebo-controlled study of naturally occurring cases and one uncontrolled study	No benefit was observed (level 1 study); may require further studies in view of anecdotal clinical evidence (4)
Polyprenyl immunostimulant (investigational drug)	Upregulation biosynthesis of mRNA of TH1 cytokines, uncontrolled study treating three noneffusive cases, long survival	May have some beneficial effect in noneffusive FIP (3); controlled studies required
IMMUNOSUPPRESSANTS		
Prednisolone/dexamethasone (immunosuppressive doses)	No controlled studies; some cats improved during treatment and survived for several months; does not cure FIP	Currently supportive treatment of choice (3); if effusion is present, dexamethasone intrathoracic or intraperitoneal may be helpful
Pentoxyfylline	Aimed at treating vasculitis	Ineffective in one case study (4)
Ozagrel hydrochloride	Thromboxane synthesis inhibitor aimed at treating inflammatory response; only used in two cases with beneficial effect	Controlled studies needed (3)
Cyclosporin A	Immunosuppressive; no published studies	Not recommended; more directed against cellular immunity than humoral (lack of data) (4)
Cyclophosphamide	Immunosuppressive; no published studies	Might be considered in combination with glucocorticoids (4)
Chlorambucil	Immunosuppressive; no published studies	Might be considered in combination with glucocorticoids (4)
Azathioprine	Toxic in cats; immunosuppressive; no published studies	Not recommended (4)
Acetylsalicylic acid (aspirin), platelet inhibitory dosage	To treat inflammatory response as well as vasculitis; no published studies	May have some beneficial effect, but adverse effects possible if used in combination with high-dose glucocorticoids

^a Many of the treatments listed represent extra-label use for treatment of FIP.

^b Evidence-based medicine (EBM) level 1 = confirmed by randomized controlled clinical trials in target species; EBM level 2 = confirmed by randomized controlled experimental studies in target species; EBM level 3 = supported by case series, other experimental studies, nonrandomized clinical trials; EBM level 4 = based on expert opinion, case reports, studies in other species. Modified, with permission, from Feline infectious peritonitis. Guidelines of The European Advisory Board on Cat Diseases (ABCD), © 2012 Advisory Board on Cat Diseases.

period to socialize the kittens. The success of early weaning and isolation depends on effective quarantine and low numbers of cats (<5) in the household.

Another possible approach is to maximize heritable resistance to FIP in breeding catteries. Genetic predisposition plays a role in the disease but is not completely understood. Full-sibling littermates of kittens with FIP have a higher likelihood of developing FIP than other cats in the same environment. A cat that has two or more litters in which kittens develop FIP should not be bred again. Particular attention should be paid to pedigrees of toms in which FIP is overrepresented. Because line breeding often uses valuable tomcats extensively, eliminating such animals may have an effect on improving overall resistance.

In shelters, prevention of FIP is virtually impossible unless cats are strictly separated and handled only through sterile handling devices (comparable to isolation units). Isolation is often not effective because FCoV is easily transported on clothes, shoes, dust, and cats. There appears to be significant correlation between the number of handling events outside the cages and stress and the percentage of antibody-positive cats. Studies have shown dramatic increases in fecal shedding of FCoV in infected cats after entering an animal shelter. Half of the cats that were originally FCoV-negative were shedding FCoV within 1 wk of entering the shelter environment. Shelters should have written information sheets or contracts informing adopters about FCoV and FIP. Personnel should

understand that FCoV is an unavoidable consequence of endemic FCoV in multicat environments. Good husbandry practices and facilities that can be cleaned easily may minimize virus spread.

Vaccination: A vaccine developed with a temperature-sensitive mutant of the FCoV strain DF2-FIPV, which is reported to replicate in the cool lining of the upper respiratory tract but not at higher internal body temperature, is available in the USA, Canada, and Europe. This vaccine is administered intranasally and produces local immunity (IgA antibodies) at the site where FCoV first enters the body (the oropharynx), as well as cell-mediated immunity. Vaccination in an FCoV-endemic environment or in a household with known cases of FIP is not effective, probably because most cats are already seropositive for FCoV. The vaccine is labeled for use beginning at 16 wk of age, which may be too late to protect kittens against FCoV in endemic populations. Most cats develop systemic antibodies after vaccination, thus making the establishment and control of an FCoV-free household difficult. The American Association of Feline Practitioners lists the FIP vaccine as “not recommended.”

Zoonotic Risk: Although coronaviruses shared with animals, such as severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS), are responsible for severe respiratory disease outbreaks in people, there is no indication that FCoV is infectious to people.

FELINE LEUKEMIA VIRUS AND RELATED DISEASES

(Feline lymphoma and leukemia, Lymphosarcoma)

Feline leukemia virus (FeLV) remains one of the most important infectious diseases of cats globally. It manifests primarily through profound anemia, malignancies, and immunosuppression and infects domestic cats and other species of Felidae. In the laboratory, cells from a much wider range of species can be infected by some strains of the virus.

The Feline Retrovirus Management Guidelines published by the American Association of Feline Practitioners is a key resource for expert consensus on preven-

tion, diagnosis, and management of FeLV for veterinary practitioners in private practice, animal shelters, and catteries (see TABLE 8).

Etiology and Epidemiology: FeLV is a retrovirus in the family Oncovirinae. Other oncoviruses include feline sarcoma virus, mouse leukemia viruses, and two human T-lymphotropic viruses. Although oncogenesis is one of their more dramatic effects, oncoviruses cause many other conditions, including degenerative, proliferative, and immunologic disorders.

TABLE 8 SUMMARY OF CLINICAL MANAGEMENT OF FELINE RETROVIRUS

Test cats that are:	Sick regardless of age and previous test status Entering a new household 30 days since last high potential for exposure At risk with unknown infection status Receiving routine veterinary care and have outdoor access or live in a home with FeLV-positive cats Candidates for blood donation
Vaccinate cats that are:	Kittens, as part of the initial vaccination series Often outdoors In transient group situations such as foster homes or temporary colony housing Living with known FeLV-positive cats <i>Note:</i> All cats should be tested for FeLV before vaccination.
Diagnostic considerations	Antigen tests do not detect previous vaccination. Positive results on immunofluorescent assay or PCR confirm positive infection status, but a negative result creates a discordant situation that clouds confirmation of true infection status. Current test modalities cannot exclude the potential of a regressive infection with subsequent negative tests after any initial positive result.
Management of infected cats	Infected cats may have a good quality of life. Although many cats succumb within 3 yr of diagnosis, others remain clinically healthy for multiple years. Preventive veterinary care, including frequent physical examination, laboratory monitoring, core vaccination, spay/neuter surgery, dental prophylaxis, and parasite control, is essential. Avoid transmission to other cats by preventing access to outdoors and other uninfected cats in household. Many antiviral and immunotherapeutic treatments are described in early trials or anecdotal use, but none has both wide availability and demonstrated clinical efficacy in controlled field studies.

Adapted from the Feline Retrovirus Management Guidelines, American Association of Feline Practitioners, 2008.

There are four FeLV subgroups of clinical importance. Almost all naturally infected cats are originally infected by FeLV-A, the original, archetypical form of the virus. Additional mutated forms of the original FeLV-A subtype as well as FeLV-B, FeLV-C, or FeLV-T may develop in infected cats. FeLV-B increases the frequency of neoplastic diseases; FeLV-C is strongly associated with development of erythroid hypoplasia and consequent severe anemia; and FeLV-T has the propensity to infect and destroy T lymphocytes, leading to lymphoid depletion and immunodeficiency. Viruses of all four subgroups are detected (but cannot be distinguished) by commonly used FeLV diagnostic test kits.

The prevalence of FeLV infection documented in cross-sectional surveys in North America has been declining throughout the past three decades and is

attributed to testing and vaccination efforts. In the USA, 3.1% of cats in a large, nationwide data set tested positive for FeLV in 2010, with increased risk among outdoor cats, unneutered males, and cats with other disease conditions (particularly respiratory disease, oral disease, and abscessation). Prevalence was highest in the midwestern and western regions of the USA and lowest in the northeast. Seroprevalence surveys of varying statistical power have found rates of positive test results to range from 3.6% in Germany and Canada to 4.6% in Egypt and 24.5% in Thailand.

Persistently infected, healthy cats serve as reservoirs of FeLV for both vertical and horizontal viral transmission. Oronasal contact with infectious saliva or urine represents the most likely mode of horizontal transmission; vertical transmission in utero or through nursing is also

common. Tears and feces may contain virus but are not considered to be clinically significant in disease transmission or diagnostic detection. Although direct contact, mutual grooming, and shared litter trays and food dishes are the primary methods of horizontal transmission, infection through bite wounds is possible. In a national (USA) study, FeLV infection was diagnosed in 9% of cats undergoing treatment for bite wounds, approximately three times the rate for cats in general. Because FeLV is a fragile, enveloped virus, horizontal transmission between adults usually requires prolonged, intimate contact. In addition, the dose required for oronasal transmission of the virus is relatively high.

FeLV is considered to be an age-dependent disease; young kittens are at higher risk of progressive infection and more rapid disease progression, whereas adults display some degree of age resistance. However, transmission can occur at any age, and factors affecting clinical course of disease are complex and incompletely understood.

Pathogenesis: After oronasal inoculation, the virus first replicates in oropharyngeal lymphoid tissue. From there, virus is carried in blood mononuclear cells to spleen, lymph nodes, epithelial cells of the intestine and bladder, salivary glands, and bone marrow. Virus also appears in secretions and excretions of these tissues and in peripheral blood leukocytes and platelets. Viremia is usually evident 2–4 wk after infection. The acute stage of FeLV infection occurring 2–6 wk after infection is rarely detected but typically characterized by mild fever, malaise, lymphadenopathy, and blood cytopenias. Cats unable to mount an adequate immune response become persistently viremic and develop a progressive infection, often leading to fatal disease. Oncogenesis occurs when FeLV virus inserts into the host cellular genome, either in proximity to an oncogene resulting in activation or directly into the oncogene itself to form a recombinant subgroup virus such as FeLV-B that can induce new neoplastic activity in any cell the recombinant virus enters.

The most recent classification system for FeLV labels infections as progressive, abortive, regressive, and focal. Progressive infections are defined by uninhibited viral replication with subsequent persistent viremia and probable eventual manifestation of clinical disease. Previously, most adult cats were thought to have abortive infections in which transient viremia was

followed by complete clearance of viral infection. However, improved sensitivity of PCR testing has revealed that antigen-negative cats may still harbor FeLV provirus in tissues; this is termed regressive infection. It is believed that cats with regressive infections generally are aviremic, do not shed infectious virus, and do not develop FeLV-associated diseases; however, they are considered carriers with the potential for reactivation and future shedding. It is likely that FeLV can be transmitted by blood transfusion from cats with regressive infection, so feline blood donors should have PCR testing performed as a screening test before donating. The incidence of regressive infections and the causes and frequency of reactivation of viral shedding among these cats are incompletely understood. Focal infections, rare in natural infections, involve viral replication in specific tissues, such as the eyes or bladder, releasing low levels of viral antigen and, therefore, variable results on diagnostic testing.

Disorders Caused by FeLV: FeLV related disorders are numerous and include anemia, neoplasia, immunosuppression, immune-mediated diseases, reproductive problems, enteritis, neurologic dysfunction, and stomatitis.

The anemia caused by FeLV is typically nonregenerative and normochromic. Less commonly, macrocytosis or regenerative hemolytic anemia is seen in only 10% of FeLV-induced anemia cases. The cause of nonregenerative anemia is usually bone marrow suppression due to viral infection of the hematopoietic stem cells and the supporting stromal cells. Platelet dysfunction, thrombocytopenia, and neutropenia are all possible sequelae as well.

Lymphoma is the most frequently diagnosed malignancy of cats. Tumors such as lymphoma and lymphoid leukemia develop in as many as 30% of cats with progressive FeLV infections. Regressive infections are also implicated in the occurrence of these tumors in the absence of viremia, but cats with progressive infections may face an increased risk of lymphoma development as high as 60-fold. Most American cats with mediastinal, multicentric, or spinal forms of lymphoma are FeLV-positive. However, these forms of lymphoma are becoming less common as the prevalence of FeLV decreases. Diffuse GI lymphoma is now more likely to be found in FeLV-negative cats of middle or older age and can be difficult to differentiate from inflammatory bowel disease. Fibrosarcomas and

quasi-neoplastic disorders such as multiple cartilaginous exostoses (osteochondromatosis) can be FeLV-associated. Other types of tumors share a suspected but not yet clearly defined link with the FeLV virus.

Leukemia is characterized by the neoplastic proliferation of hematopoietic cells originating in the bone marrow, including neutrophils, basophils, eosinophils, monocytes, lymphocytes, megakaryocytes, and erythrocytes. Feline leukemias are strongly associated with FeLV infection and typically involve neoplastic cells circulating in the blood. Lymphoid leukemias are further classified as acute and chronic. Acute lymphocytic leukemia is characterized by lymphoblasts circulating in the blood, whereas chronic lymphocytic leukemias have an increased number of circulating lymphocytes with mature morphology.

The immunosuppression caused by FeLV creates increased susceptibility to bacterial, fungal, protozoal, and viral infections. Numbers of neutrophils and lymphocytes in the peripheral blood of affected cats may be reduced, and those cells that are present may be dysfunctional. Many FeLV-positive cats have low blood concentrations of complement; this contributes to FeLV-associated immunodeficiency and oncogenicity, because complement is vital for some forms of antibody-mediated tumor cell lysis.

Immune complexes formed in the presence of moderate antigen excess can cause systemic vasculitis, glomerulonephritis, polyarthritis, and a variety of other immune disorders. In FeLV-infected cats, immune complexes form under conditions in which FeLV antigens are abundant and anti-FeLV IgG antibodies are sparse, a situation ideal for the development of immune-mediated disease.

Reproductive problems are commonly associated with FeLV infection. Fetal death, resorption, and placental involution may occur in the middle trimester of pregnancy, presumably as a result of in utero infection of fetuses by virus transported across the placenta in maternal leukocytes. Abortion typically occurs in late gestation accompanied by risk of bacterial endometritis, especially in neutropenic queens. Transmission during birth and nursing constitutes the greatest risk of producing live, viremic kittens. There is some evidence that regressively infected queens may pass virus on to their kittens either in utero or in milk. Neonatal kittens are at risk of rapidly progressive infection with clinical manifestations of hypothermia, dehydration, failure to nurse,

and early mortality collectively termed "fading kitten syndrome." It is likely that transmission from infected queens to their kittens is the single greatest source of FeLV infections.

Coinfection with FeLV and feline panleukopenia virus (FPV) has been implicated in feline panleukopenia-like syndrome (FPLS), which is also termed FeLV-associated enteritis. FPLS resembles feline panleukopenia both clinically and histopathologically and is characterized clinically by progressive anorexia, depression, vomiting, hemorrhagic diarrhea, weight loss, gingivitis, oral ulceration, severe neutropenia, and septicemia. FPV antigen is inconsistently present on diagnostic testing in these cases, and the pathogenesis and exact role of each virus in the development of this syndrome are incompletely understood.

Although neurologic disorders associated with FeLV are most often caused by compression of the brain and spinal cord by lymphoma tumor tissue, a mechanism for neuropathology is also suspected to result in peripheral neuropathies, urinary incontinence, and ocular pathology, including anisocoria, mydriasis, Horner syndrome, and central blindness even in the absence of visible compressive lesions on diagnostic imaging. If antineoplastic therapy is planned, it is important to distinguish neoplasia from neuropathy.

Stomatitis is more classically associated with FIV infection, but FeLV infection can also predispose cats to chronic ulcerative proliferative gingivostomatitis. Clinical sequelae include pain, anorexia, and tooth loss. An immune-mediated mechanism is likely, particularly in combination with coinfections such as feline calicivirus.

Diagnosis: Testing for FeLV infection is recommended when cats are first acquired, before vaccination against FeLV, if there has been potential exposure or bite wound from a cat of unknown or positive retroviral status; annually if they live in a household with FeLV-positive cats; before blood donation; and regularly if they have outdoor access. For cats entering a new home or known to be at high risk of exposure, testing should be repeated 30 days after the first test in case of recent infection that has not yet resulted in detectable circulating antigen. Documentation of a previous negative test does not negate the need for repeat testing in the above situations. Prior vaccination does not interfere with diagnostic testing unless performed immediately before blood collection for antigen testing.

Three types of tests are now readily available for clinical use: immunochromatography (such as ELISA), immunofluorescent assay (IFA), and PCR. Virus isolation is considered the gold standard diagnostic test but is not generally available to private practitioners. ELISA or other point-of-care antigen test kits can be used in the veterinary clinic to detect the presence of soluble FeLV p27 antigen in whole blood or serum using a lateral flow test kit or a multi-well plate. Saliva and tears are not considered to be reliable samples for testing purposes. Several different test kits are available; most have sensitivities and specificities of ~98%.

IFA tests for the presence of FeLV p27 and other structural core antigens in the cytoplasm of cells. In clinical practice, peripheral blood smears are usually used for IFA, but cytologic preparations of bone marrow or other tissues can also be used. IFA requires submission to a diagnostic laboratory and cannot detect infection until bone marrow involvement occurs. False-negative test results may occur because of leukopenia or lack of bone marrow involvement, whereas technical error is most often the cause of false-positive results. Like ELISA, IFA cannot detect regressive infection because of the lack of sufficient viral antigen production. Historically, cats with nonregenerative anemia or other cytopenias and negative FeLV antigen tests on blood samples were subjected to bone marrow testing in search of occult FeLV infections. Several recent studies have indicated this is unnecessary, because cats with FeLV-associated bone marrow suppression invariably have positive results on blood tests.

Discordant results between tests, often a positive initial ELISA followed by negative results on either repeat ELISA or IFA, may reflect the inconsistent antigen circulation during various stages of FeLV infection, technical error, or possibly regressive infection status. These cats are generally considered presumptively infected and potential sources of infection until further clarification is possible. Standard recommendations to resolve discordant testing dictate repeating both tests in 30–60 days using serum instead of whole blood. It is not uncommon for cats, especially kittens, to test negative on a subsequent test. This could indicate a false-positive on the first test, a false-negative on the second test, or development of a regressive or abortive infection status. Once a single positive test result has been obtained, it can be difficult to ever know the true status of the cat, even if subsequent tests are negative.

PCR testing on whole blood, bone marrow, and other tissues is increasingly available through diagnostic laboratories, although validated sensitivity and specificity studies are often lacking. Real-time PCR offers great potential to provide extremely sensitive detection of FeLV rapidly after infection and can be useful to detect regressive infections and resolve conflicting test results if a positive result is obtained.

Diagnosis of FeLV-induced neoplasia is similar to that of other tumors. Cytologic examination of fine-needle aspirates of masses, lymph nodes, body cavity fluids (eg, pleural effusion), and affected organs may reveal malignant lymphocytes. Bone marrow examination may reveal leukemic involvement, even when the peripheral blood appears normal. Biopsy with histopathologic examination of abnormal tissues is often necessary for diagnostic confirmation. Cellular phenotyping via flow cytometry, immunocytochemistry, or other techniques can provide additional diagnostic information.

Treatment and Prognosis: Unfortunately, no curative treatment currently exists to eradicate retroviral infection.

In vitro studies have yielded cautiously promising results suggesting virus-suppressing activity of FDA-approved drugs used to treat HIV and other myelodysplastic syndromes against FeLV virus (eg, raltegravir, tenofovir, gemcitabine, decitabine). Further research is needed to demonstrate efficacy and safety in vivo and in field trials, as well as to address affordability of these drugs for most cat owners. Feline interferon omega and human interferon alpha have been associated with improved survival, but concerns surrounding availability, cost, and absence of strong evidence in controlled field studies have limited their widespread integration into standard treatment protocols for FeLV.

Anecdotal reports of various antiviral and immunotherapeutic agents to reverse viremia, improve clinical signs, and prolong survival are abundant. Controlled studies using naturally infected cats have either not been performed or have not confirmed anecdotal observations. Treatment efficacy must be demonstrated in controlled clinical trials, because spontaneous reversion to seronegative status or prolonged survival is not uncommon, even in the absence of medical treatment.

Some FeLV-positive cats can live without major disease complications for years with routine prophylactic care, good husbandry, minimal stress, and avoidance of secondary infections. Infected cats should be kept

strictly indoors to reduce the risk of exposure to infectious agents and to prevent transmission of the virus to other cats. Routine vaccinations should be administered based on individual risk assessment and in compliance with local laws. Use of inactivated vaccines could be considered because of concerns regarding use of live vaccines reverting to virulence in immunocompromised animals, although this does not appear to be common. FeLV vaccinations should not be administered, because there is no evidence to suggest a benefit after infection. Physical examinations focusing on external parasites, skin infections, dental disease, lymph node size, and body weight should be performed semiannually, along with a routine program for parasite control and annual fecal, CBC, chemistry panel, and urinalysis testing. All infected cats should be neutered. Owners should be advised to watch for signs of FeLV-related disease, particularly secondary infections. Although FeLV-positive cats often respond well to treatment, therapy for such infections or other illnesses should be early and aggressive because of immunocompromise.

Because FeLV is historically associated with rapid and grave disease, the modern prognosis varies considerably depending on husbandry, veterinary care, and individual immune system variation. Large-scale studies have demonstrated an average survival of 2.4 yr after diagnosis among positive cats (versus 6 yr after testing for negative control cats), with 50% mortality in 2 yr and 80% mortality by 3 yr after diagnosis. Progression of disease is much more rapid in kittens, whereas some adult cats remain healthy for many years and may succumb to conditions unrelated to their retroviral status.

Lymphoma Treatment: Feline lymphoma can be treated with cytotoxic drugs. These drugs may cause significant toxicities if not dosed and administered properly. Most cytotoxic drugs are also carcinogens and must be handled properly. Before administering these drugs, veterinarians should familiarize themselves with proper dosing and administration procedures, appropriate monitoring of the patient, toxicities and complications, and safe handling to prevent exposure of veterinary personnel and owners to the agents and their metabolites.

Approximately 50% of cats with lymphoma that are treated obtain a complete remission, defined as no clinical evidence of disease. FeLV-negative cats that

attain a complete remission live an average of 9 mo, whereas survival among FeLV-positive cats averages 6 mo. Cats not treated or those not responding to treatment survive an average of 2–6 wk.

Many protocols for treatment of feline lymphoma have been published; most use similar drugs with differing schedules of administration. One widely used protocol consists of an intensive induction phase (vincristine weekly for 4 wk, cyclophosphamide every 3 wk on the same day as vincristine, and prednisolone daily), followed by a less intensive maintenance phase (vincristine and cyclophosphamide given every 3 wk on the same day, and prednisolone continued daily). Treatment is continued for 1 yr or until relapse. With this protocol, 79% of cats attained remission, and average survival was 150 days. Changing the maintenance protocol to doxorubicin every 3 wk provided an average remission of 281 days. When relapse occurs, the drug regimen can be changed and a second remission achieved; however, second remissions seldom last as long as the first.

Another popular chemotherapy protocol involves an initial treatment with L-asparaginase and vincristine. Treatment is continued with daily prednisolone and alternating doses of cyclophosphamide, vincristine, and doxorubicin for a total of three cycles. When relapse occurs, the protocol is started again. Using this protocol, the median survival has been reported to be 210 days. Other protocols incorporating alkylating agents such as mustargen and procarbazine have demonstrated efficacy as well, sometimes even after other combination therapies have not achieved remission.

Most lymphomas have an intermediate or high histopathologic grade and are clinically aggressive, except for a subset identified as small-cell lymphoma or lymphocytic lymphoma. Small-cell lymphomas are characterized by a diffuse infiltration of malignant lymphocytes throughout affected organs, typically intestines, and can often be successfully treated with less aggressive chemotherapy. Administration of prednisolone and chlorambucil orally daily for 4 consecutive days every 3 wk has been used. Using these drugs in clinical trials to treat small-cell lymphoma involving the GI tract produced a median survival of 963 days. If other sites were involved, with or without GI disease, the median survival was 636 days.

In addition to small-cell lymphoma, large granular lymphocyte lymphoma also affects

the intestinal tract. This is an extremely aggressive disease, with a response to chemotherapy of ~30% and a median survival of 57 days. An intestinal mass is usually present and may cause intestinal obstruction.

Acute lymphocytic leukemia is treated with the same protocol as lymphoma, but only ~25% of cats obtain remission for an average of 7 mo. Chronic lymphocytic leukemia typically carries a much better prognosis than the acute form and is best treated with chlorambucil and prednisolone given every other day on alternating days. Leukemias other than lymphocytic are rarely treated because of severity of illness at diagnosis and poor response to therapy.

Prevention and Control: FeLV virus is unstable in the environment and is susceptible to all common detergents and disinfectants. In a hospital or boarding setting, infected cats may be kept in the general population as long as they are housed in separate cages. Medical and surgical equipment contaminated with body fluids, even when dried, can be fomites for infection. Thorough cleaning and sterilization of equipment, strict attention to washing contaminated hands, and avoiding reuse and sharing of single use and consumable supplies between patients are critical practices to prevent iatrogenic transmission.

FeLV vaccines are non-core and are intended to protect cats against FeLV infection or to reduce the likelihood of persistent viremia. Types of vaccines include killed whole virus, subunit, and genetically engineered. Vaccines may vary in protective effect, and manufacturers' claims and independent comparative studies should be carefully noted. Vaccines are indicated only for uninfected cats, because there is no benefit in vaccinating an FeLV-positive cat.

The American Association of Feline Practitioners (AAFP) Feline Retrovirus

Management Guidelines include the recommendation that all kittens should receive the two-dose FeLV vaccination as a component of the routine initial vaccination series and should also receive a booster vaccination 1 yr later. This is prudent, because rehoming and lifestyle changes such as outdoor access frequently occur as cats mature. Annual revaccination after maturity would depend on the cat's risk of FeLV exposure.

The adult cat's risk of exposure to FeLV-positive cats should be assessed, and vaccines used only for those cats at risk. FeLV vaccines have been associated with development of sarcomas at the vaccination site, although the risk of tumor development is very low. Uninfected cats in a household with infected cats should be vaccinated; however, vaccination is not universally protective, and other means of reducing transmission to uninfected cats, such as physical separation, should also be used.

While testing of cats in an animal shelter environment is considered optional for individual housing, FeLV status should be determined before placement in group housing and is recommended at the time of adoption or foster home placement. Because tests are not 100% accurate, shelter cats placed in group housing should be vaccinated against FeLV, especially in long-term conditions such as sanctuaries. Because of the equivalent prevalence of FeLV among feral and free-roaming pet cats and the role of neutering in decreasing the spread of infection, expending resources on FeLV testing is not considered a mandatory component of community trap-neuter-return programs.

Zoonotic Risk: Some strains of FeLV can be experimentally grown in human tissue cultures, leading to concerns of potential for transmission to people. Studies addressing this concern have shown no evidence that any zoonotic risk exists, and there are no known cases of zoonotic transmission.

FELINE PANLEUKOPENIA

(Feline infectious enteritis, Feline parvoviral enteritis)

Feline panleukopenia is a highly contagious, often fatal, viral disease of cats that is seen worldwide. Kittens are affected most severely. The causative parvovirus is very resistant; it can persist for 1 yr at room

temperature in the environment, if protected in organic material. Feline panleukopenia is now diagnosed infrequently by veterinarians, presumably as a consequence of widespread vaccine use.

However, infection rates remain high in some unvaccinated cat populations, and the disease occasionally is seen in vaccinated, pedigreed kittens that have been exposed to a high virus challenge.

Etiology, Transmission, and Pathogenesis:

Feline panleukopenia virus (FPV) is closely related to mink enteritis virus and the type 2 canine parvoviruses (CPV) that cause canine parvoviral enteritis. FPV can cause disease in all felids and in some members of related families (eg, raccoon, mink), but it does not harm canids. Conversely, some currently circulating CPV strains (CPV-2a, -2b, and -2c) have been shown to cause a panleukopenia-like illness in domestic cats and larger felids. In some parts of Asia, CPV strains are reported to rival FPV as the major cause of feline panleukopenia, although FPV still dominates worldwide. Vaccines that contain FPV only provide some protection to cats against disease caused by CPV, but it has been suggested by some authorities that inclusion of CPV-2c in feline vaccines would broaden and improve the degree of protection provided.

Virus particles are abundant in all secretions and excretions during the acute phase of illness and can be shed in the feces of survivors for as long as 6 wk after recovery. Being highly resistant to inactivation, parvoviruses can be transported long distances via fomites (eg, shoes, clothing). However, FPV can be destroyed by exposure to a 1:32 dilution of household bleach (6% aqueous sodium hypochlorite), 4% formaldehyde, and 1% glutaraldehyde for 10 min at room temperature. Peroxygen disinfectants are also highly effective.

Cats are infected oronasally by exposure to infected animals, their feces, secretions, or contaminated fomites. Most free-roaming cats are thought to be exposed to the virus during their first year of life. Those that develop subclinical infection or survive acute illness mount a robust, long-lasting, protective immune response.

FPV infects and destroys actively dividing cells in bone marrow, lymphoid tissues, intestinal epithelium, and—in very young animals—cerebellum and retina. In pregnant queens, the virus may spread transplacentally to cause embryonic resorption, fetal mummification, abortion, or stillbirth. Alternatively, infection of kittens in the perinatal period may destroy the germinal epithelium of the cerebellum, leading to cerebellar hypoplasia, incoordination, and tremor. FPV-induced cerebellar ataxia has become a relatively rare diagnosis, because

most queens passively transfer sufficient antibodies to their kittens to protect them during the period of susceptibility.

Clinical Findings: Most infections are subclinical, as evidenced by the high seroprevalence of anti-FPV antibodies among unvaccinated, healthy cats. Those cats that become ill are usually <1 yr old. Peracute cases may die suddenly with little or no warning (fading kittens). Acute cases show fever (104°–107°F [40°–41.7°C]), depression, and anorexia after an incubation period of 2–7 days. Vomiting usually develops 1–2 days after the onset of fever; it is typically bilious and unrelated to eating. Diarrhea may begin a little later but is not always present. Extreme dehydration develops rapidly. Affected cats may sit for hours at their water bowl, although they may not drink much. Terminal cases are hypothermic and may develop septic shock and disseminated intravascular coagulation.

Physical examination typically reveals profound depression, dehydration, and sometimes abdominal pain. Abdominal palpation—which can induce immediate vomiting—may reveal thickened intestinal loops and enlarged mesenteric lymph nodes. In cases of cerebellar hypoplasia, ataxia and tremors with normal mentation are seen. Retinal lesions, if present, appear as discrete gray foci.

The duration of this self-limiting illness is seldom >5–7 days. Mortality is highest in young kittens <5 mo old.

Lesions: There are typically few gross lesions, although dehydration is usually marked. Bowel loops are usually dilated and may have thickened, hyperemic walls. There may be petechiae or ecchymoses on the intestinal serosal surfaces. Perinatally infected kittens may have a noticeably small cerebellum. Histologically, the intestinal crypts are usually dilated and contain debris consisting of sloughed necrotic epithelial cells. Blunting and fusion of villi may be present. Eosinophilic intranuclear inclusion bodies are seen only occasionally in formalin-fixed specimens; use of Bouin's or Zenker's fixative will increase the likelihood of seeing these.

Diagnosis: A presumptive diagnosis is usually based on compatible clinical signs in an inadequately vaccinated cat and the presence of leukopenia (nadir 50–3,000 WBC/ μ L). Neutropenia is a more consistent finding than lymphopenia. Total WBC counts <2,000 cells/ μ L are associated with a poorer prognosis. During recovery from

infection, there is typically a rebound neutrophilia with a marked left shift. Diagnosis can sometimes be confirmed using an in-office immunochromatographic test kit intended for detection of fecal CPV antigen. However, fecal antigen is detectable only for a short time after infection. False-negative results are common.

Differential diagnoses include other causes of profound depression, leukopenia, and GI signs. Salmonellosis (*see* p 195) and infections with feline leukemia virus (FeLV, *see* p 790) and feline immunodeficiency virus (*see* p 821) should be considered. Concurrent infection with FeLV and FPV can cause a panleukopenia-like syndrome in adult cats.

Treatment and Prevention: Successful treatment of acute cases requires vigorous fluid therapy and supportive nursing care in the isolation unit. Electrolyte disturbances (eg, hypokalemia), hypoglycemia, hypoproteinemia, anemia, and opportunistic secondary infections often develop in severely affected cats. Anticipation of these possibilities, close monitoring, and prompt intervention are likely to improve outcome. IV fluid replacement and maintenance with a balanced isotonic crystalloid solution (eg, lactated Ringer's solution with calculated potassium supplementation) is the foundation of therapy. B vitamins should be added to the infusion, together with 5% glucose if hypoglycemia is suspected or proved. In addition to crystalloid infusion, transfusion of fresh-frozen plasma helps support plasma oncotic pressure and provides clotting factors to severely ill, hypoproteinemic kittens. Whole blood is

preferable for the occasional cat that is severely anemic. Parenteral, broad-spectrum antibiotic therapy is indicated; however, nephrotoxic drugs (eg, gentamicin, amikacin) should be avoided until dehydration has been corrected. Antiemetic therapy (eg, metoclopramide, ondansetron, maropitant) may provide some relief and allow earlier enteral feeding of soft, easily digested food. Parenteral nutrition is indicated for severely affected cases. Recombinant feline interferon omega (rFeIFN; 1 MU/kg/day SC for 3 days) should be considered for use in the treatment of feline panleukopenia. Although rFeIFN is not approved by the FDA for this purpose, it is approved and effective in the treatment of canine parvoviral enteritis.

Excellent inactivated and modified-live virus vaccines that provide solid, long-lasting immunity are available for prevention of feline panleukopenia. Live vaccines should not be given to cats that are pregnant, immunosuppressed, or sick, or to kittens <4 wk old. Most authorities recommend that kittens receive two or three modified-live vaccine doses SC, 3–4 wk apart. The first vaccination is usually given at 6–9 wk of age. The last dose of the initial vaccination series should not be administered before the kitten is 16 wk old, to ensure that interfering maternal antibodies do not inactivate the modified-live virus. Exposure to virus should be avoided until 1 wk after the initial vaccination series has been completed. Cats should be revaccinated 1 yr later, and triennially or less frequently thereafter, although some manufacturers continue to recommend annual revaccination.

INFECTIOUS CANINE HEPATITIS

Infectious canine hepatitis (ICH) is a worldwide, contagious disease of dogs with signs that vary from a slight fever and congestion of the mucous membranes to severe depression, marked leukopenia, and coagulation disorders. It also is seen in foxes, wolves, coyotes, bears, lynx, and some pinnipeds; other carnivores may become infected without developing clinical illness. In recent years, the disease has become uncommon in areas where routine immunization is done, but periodic outbreaks, which may reflect maintenance

of the disease in wild and feral hosts, reinforce the need for continued vaccination.

Etiology and Pathogenesis: ICH is caused by a nonenveloped DNA virus, canine adenovirus 1 (CAV-1), which is antigenically related only to CAV-2 (one of the causes of infectious canine tracheobronchitis, *see* p 1491). CAV-1 is resistant to lipid solvents (such as ether), as well as to acid and formalin. It survives outside the host for weeks or months, but a 1%–3%

solution of sodium hypochlorite (household bleach) is an effective disinfectant.

Ingestion of urine, feces, or saliva of infected dogs is the main route of infection. Recovered dogs shed virus in their urine for ≥ 6 mo. Initial infection occurs in the tonsillar crypts and Peyer patches, followed by viremia and disseminated infection. Vascular endothelial cells are the primary target, with hepatic and renal parenchyma, spleen, and lungs becoming infected as well. Chronic kidney lesions and corneal clouding ("blue eye") result from immune-complex reactions after recovery from acute or subclinical disease.

Clinical Findings: Signs vary from a slight fever to death. The mortality rate ranges from 10%–30% and is typically highest in very young dogs. Concurrent parvoviral or distemper infection worsens the prognosis. The incubation period is 4–9 days. The first sign is a fever of $>104^{\circ}\text{F}$ (40°C), which lasts 1–6 days and is usually biphasic. If the fever is of short duration, leukopenia may be the only other sign, but if it persists for >1 day, acute illness develops.

Signs are apathy, anorexia, thirst, conjunctivitis, serous discharge from the eyes and nose, and occasionally abdominal pain and vomiting. Intense hyperemia or petechiae of the oral mucosa, as well as enlarged tonsils, may be seen. Tachycardia out of proportion to the fever may occur. There may be subcutaneous edema of the head, neck, and trunk. Despite hepatic involvement, there is a notable absence of icterus in most acute clinical cases.

Clotting time is directly correlated with the severity of illness and is the result of disseminated intravascular coagulation induced by vascular endothelial compromise, coupled with failure of the liver to rapidly replace consumed clotting factors. It may be difficult to control hemorrhage, which is manifest by bleeding around deciduous teeth and by spontaneous hematomas. CNS involvement is unusual and is typically the result of vascular injury. Severely infected dogs may develop convulsions from forebrain damage. Paresis may result from brain stem hemorrhages, and ataxia and central blindness have also been described. Foxes more consistently have CNS signs and intermittent convulsions during the course of illness, and paralysis may involve one or more limbs or the entire body. Respiratory signs usually are not seen in dogs with ICH; however, CAV-1 has been recovered from dogs with signs of infectious tracheobronchitis despite high serologic titers against parenteral disease.

Clinicopathologic findings reflect the coagulopathy (prolonged prothrombin time, thrombocytopenia, and increased fibrin degradation products). Severely affected dogs show acute hepatocellular injury (increased ALT and AST). Proteinuria is common. Leukopenia typically persists throughout the febrile period. The degree of leukopenia varies and seems to be correlated with the severity of illness.

On recovery, dogs eat well but regain weight slowly. Hepatic transaminase activities peak around day 14 of infection and then decline slowly. In ~25% of recovered dogs, bilateral corneal opacity develops 7–10 days after acute signs disappear and usually resolves spontaneously. In mild cases, transient corneal opacity may be the only sign of disease.

It has long been thought that chronic hepatitis may develop in dogs that have low levels of passive antibody when exposed, although a recent PCR-based study did not confirm this theory.

Lesions: Endothelial damage results in "paint-brush" hemorrhages on the gastric serosa, lymph nodes, thymus, pancreas, and subcutaneous tissues. Hepatic cell necrosis produces a variegated color change in the liver, which may be normal in size or swollen. Histologically, there is centrilobular necrosis, with neutrophilic and monocytic infiltration, and hepatocellular intranuclear inclusions. The gallbladder wall is typically edematous and thickened; edema of the thymus may be found. Grayish white foci may be seen in the kidney cortex.

Diagnosis: Usually, the abrupt onset of illness and bleeding suggest ICH, although clinical evidence is not always sufficient to differentiate ICH from distemper (*see* p 777). Definitive antemortem diagnosis is not required before institution of supportive care but can be pursued with commercially available ELISA, serologic, and PCR testing. PCR or restriction fragment length polymorphism is required to definitively distinguish CAV-1 from CAV-2, if clinically necessary. Postmortem gross changes in the liver and gallbladder are more conclusive, and diagnosis is confirmed by virus isolation, immunofluorescence, characteristic intranuclear inclusion bodies in the liver, or PCR or fluorescence in situ hybridization studies of infected tissue.

Treatment: Treatment is symptomatic and supportive. The goals of therapy are to

limit secondary bacterial invasion, support fluid balance, and control hemorrhagic tendencies. Broad-spectrum antibiotics and intravenously administered balanced electrolyte solutions with 5% dextrose supplementation are indicated. Plasma or whole blood transfusions may be necessary in severely ill dogs.

Although the transient corneal opacity (which may be seen during the course of ICH or associated with vaccination with attenuated CAV-1 vaccines) usually requires no treatment, atropine ophthalmic ointment may alleviate the painful ciliary spasm sometimes associated with it. Dogs with corneal clouding should be protected against bright light. Systemic corticosteroids are contraindicated for treatment of corneal opacity associated with ICH.

Prevention: Modified-live virus (MLV) injectable vaccines are available and are

often combined with other vaccines.

Vaccination against ICH is recommended at the time of canine distemper vaccinations. Maternal antibody from immune bitches interferes with active immunization in puppies until they are 9–12 wk old. Attenuated CAV-1 vaccines have produced transient unilateral or bilateral opacities of the cornea, and the virus may be shed in urine. For these reasons, CAV-2 attenuated live virus strains, which provide cross-protection against CAV-1, are preferentially used because they have very little tendency to produce corneal opacities or uveitis, and the virus is not shed in urine. Historically, annual revaccination against ICH was standard, and vaccines are labeled for annual use. Increasing evidence suggests that immunity induced by MLV CAV-1 injectable vaccines lasts ≥3 yr, although this remains an extra-label use of commercially available vaccines.

LEISHMANIOSIS

(Visceral leishmaniasis)

Leishmaniosis is a disease caused by protozoan parasites of the genus *Leishmania* and transmitted through the bites of female phlebotomine sand flies. More than 23 species of *Leishmania* have been described, most of which are zoonotic. The most important *Leishmania* parasite to affect domestic animals is *L. infantum*, also known as *L. chagasi* in Latin America. Dogs are the main reservoir host for human visceral leishmaniosis caused by *L. infantum*, and the disease is potentially fatal in dogs and people. Because the internal organs and skin of the dog are affected, the canine disease is termed viscerocutaneous or canine leishmaniosis. Cats, horses, and other mammals can be infected by *L. infantum* or other *Leishmania* species. The disease in cats is rarer than in dogs and may manifest in cutaneous or visceral organs. *L. braziliensis*, the cause of tegumentary canine leishmaniosis, is widespread in regions of South America and may geographically overlap with *L. chagasi*.

Canine leishmaniosis is a major zoonosis endemic in >70 countries. It is prevalent in southern Europe, Africa, Asia, South and Central America, and sporadically in the

USA. It is also of concern in nonendemic countries where imported disease constitutes a veterinary and public health problem.

Transmission: *Leishmania* is a diphasic parasite that completes its life cycle in two hosts: a sand fly that harbors the flagellated extracellular promastigote form and a mammal in which the intracellular amastigote parasite form develops.

Transmission is a complex process that requires special adaptation between the sand fly host and the particular *Leishmania* species transmitted. There are numerous species of sand flies, only a minority of which are competent vectors of *Leishmania*. Dogs with or without clinical signs are infectious to sand flies and may transmit leishmaniosis. Congenital vertical transmission of canine leishmaniosis from an infected dam to its offspring has been reported but appears to be uncommon. Transmission by transfusion of blood products from infected dogs has been shown to cause infection in recipients. Direct dog-to-dog transmission by contact has been suggested as a mode of disease

transmission in an effort to explain the spread of infection among kennel Foxhounds in the USA in the absence of proven sand fly vectors. At present, the validity of direct transmission is unknown.

Clinical Findings: Dogs are infected by *L. infantum* promastigotes deposited into the skin via the bites of infected sandflies. The promastigotes invade host macrophages and replicate as intracellular amastigotes. The immune responses mounted at the time of infection and thereafter appear to be the most important factor in determining whether a persistent infection will develop and progress from subclinical to clinical disease. The incubation period may last months to years, during which the parasite disseminates from the skin throughout the host's body (primarily to the hemolymphatic system organs). Age, breed, host genetics, nutrition, concurrent diseases, and other factors may also influence the progression from infection to clinical disease.

Canine leishmaniosis is a multisystemic disease with a highly variable spectrum of immune responses and clinical manifestations. In endemic areas, the prevalence of dogs carrying infection is much higher than those demonstrating clinical disease. Clinical disease is associated with a marked antibody response that does not confer protection. In fact, immune-mediated mechanisms are responsible for much of the pathology in canine leishmaniosis.

The typical history reported by owners of dogs with clinical disease due to *L. infantum* includes the appearance of skin lesions, ocular abnormalities, or epistaxis. These are frequently accompanied by weight loss, exercise intolerance, and lethargy. The main physical examination findings are dermal lesions in 80%–90% of the dogs, lymphadenomegaly in 62%–90%, ocular disease in 16%–81%, splenomegaly in 10%–53%, and abnormal nail growth (onychogryphosis) in 20%–31%. Other clinical findings may include polyuria and polydipsia due to kidney disease, vomiting, colitis, melena, and lameness due to joint, muscle, or bone lesions. The sole presenting signs of disease could be epistaxis, ocular abnormalities, or manifestations of kidney disease without dermal abnormalities. The dermal lesions associated with canine leishmaniosis include exfoliative dermatitis, which can be generalized or localized over the face, ears, and limbs. Ulcerative, nodular, or mucocutaneous dermatitis are also seen. Cutaneous ulcers over the ears or other locations may be associated with

considerable bleeding. A mild form of papular dermatitis has been reported in dogs with no other signs of disease. Ocular or periocular lesions include keratoconjunctivitis and uveitis.

Clinical laboratory findings include mild to moderate nonregenerative or more rarely regenerative anemia in 60%–73% of the dogs; thrombocytopenia is less common. The most consistent serum biochemistry findings in dogs with clinical canine leishmaniosis are serum hyperproteinemia with hyperglobulinemia and hypoalbuminemia, frequently expressed by a decreased albumin:globulin ratio. Marked hyperglobulinemia with no apparent cause in dogs from *Leishmania*-endemic regions should suggest possible canine leishmaniosis. Grossly increased activities of liver enzymes or azotemia are found in only a minority of infected dogs. Some degree of renal pathology is present in most dogs with canine leishmaniosis. Subsequent renal failure due to immune-complex glomerulonephritis may eventually develop and is believed to be the main natural cause of death. The presence of proteinuria should be evaluated and kidney disease staged with measurement of the urine protein:creatinine ratio.

Lesions: The typical histopathologic finding in canine leishmaniosis is granulomatous inflammation associated with a variable number of *Leishmania* amastigotes with macrophages. Protective immunity against *Leishmania* parasites is mediated through CD4⁺T_H cells and the activation of a complex cascade of cytokine mediators. Circulating immune complexes and antinuclear antibodies can be detected in animals with canine leishmaniosis, and deposition of immune complexes in the kidneys, blood vessels, and joints occurs as infection progresses. Glomerulonephritis associated with the renal immune complexes is a hallmark of this disease. Renal pathology, including glomerulonephritis and interstitial nephritis, is evident by histopathology, even if not manifested clinically in most dogs infected with *L. infantum*.

Diagnosis: Diagnostic tests include a CBC, biochemical profile, urinalysis, and one or more specific tests to confirm infection. Quantitative serology is useful, especially when compatible clinical signs are present. High antibody titers are found in 80%–100% of dogs with clinical disease and could be conclusive of a diagnosis. Various quantitative serologic methods to detect anti-*Leishmania* antibodies have

been developed, including indirect immunofluorescence assays, ELISA, and direct agglutination assays. Purified recombinant antigens such as rk39 are also used to detect leishmaniosis in dogs and people. Serologic cross-reactivity with trypanosomes may be found in regions where *Trypanosoma* infection is prevalent, particularly with *T. cruzi* in Latin America.

Detection of parasite-specific DNA by PCR allows sensitive and specific diagnosis of infection. Several different assays with various target sequences using genomic or kinetoplast DNA (kDNA) have been developed for canine leishmaniosis. PCR can be performed on DNA extracted from tissues, blood, or even from histopathologic specimens. Assays based on kDNA are the most sensitive for direct detection in infected tissues. Bone marrow, lymph node, conjunctival swabs, or spleen samples are superior to blood with most of the current PCR techniques.

Leishmania amastigotes can be demonstrated by cytology from lymph nodes, spleen, skin impressions, bone marrow, or joint fluids stained with Giemsa stain or a quick commercial stain. Detection of amastigotes by cytology is sometimes unrewarding because of a low number of detectable parasites, even in dogs with full-blown clinical disease. *Leishmania* parasites may also be viewed in histopathologic formalin-fixed, paraffin-embedded biopsy sections of the skin or other infected organs. Identification of parasites within tissue macrophages may be difficult; immunolabeling with immunohistochemical staining can verify the presence of *Leishmania* in the tissue.

Detection of infection in dogs with no clinical disease for purposes such as importation to nonendemic countries or use as blood donors may require PCR, which is the most sensitive diagnostic technique. Cross-sectional studies of dog populations in highly endemic areas have shown that infection rates can reach 65%–80%. Typically, only approximately 10%–13% manifest clinical signs of disease, 26% are seropositive and include sick and subclinically infected dogs, and an additional 40%–60% are carriers positive only by tissue PCR.

Treatment: The main protocol used for treatment of canine leishmaniosis includes N-methylglucamine antimoniate (not approved for use in dogs in the USA) at

75–100 mg/kg, SC, for 4–8 wk combined with allopurinol (10 mg/kg, PO, bid, for 6–12 mo or longer as needed). Allopurinol may also be used as a single therapeutic agent at the same dose. Miltefosine (not approved for use in dogs in the USA) at 2 mg/kg/day, PO, for 4 wk can also be combined with allopurinol (10 mg/kg, PO, bid) as an alternative to N-methylglucamine antimoniate. Treatment frequently achieves only temporary clinical improvement in dogs and often does not eliminate the parasites. Treated dogs can remain carriers of infection and may relapse. They may remain infectious to sand flies. Stopping treatment with allopurinol is recommended only when clinical signs disappear, hematologic and serum biochemistry abnormalities return to normal, and the animal becomes seronegative by a quantitative laboratory serologic test.

Specific repellent topical insecticides effectively reduce sand fly bites and disease transmission. A deltamethrin-impregnated collar and a spot-on formulation of permethrin and imidacloprid have been shown to confer protection against sand fly bites. The application of protective insecticides is recommended for dogs in *Leishmania*-endemic areas, dogs traveling to sites of infection, and infected dogs (to reduce potential transmission). Purified-fraction commercial vaccines against canine leishmaniosis are marketed in Europe and Brazil, and other vaccines are under development.

Zoonotic Risk: Human visceral leishmaniosis caused by *L. infantum* is a serious public health problem in areas where canine leishmaniosis is endemic and dogs are the main reservoir of infection. It is mostly a disease of young children. Malnutrition has been recognized as a risk factor and may explain why this disease is more prevalent among children in poor countries than among those in affluent ones, despite high prevalence rates in the canine populations. Human disease is also prevalent in immunosuppressed individuals; HIV patients are the predominant risk group for human leishmaniosis in southern Europe. HIV and leishmaniosis coinfection has been reported from >33 countries worldwide and does not respond well to therapy. Efforts to control canine leishmaniosis and the human disease in endemic areas focus on disrupting the transmission of infection and preventing canine infection at the population level.

RICKETTSIAL DISEASES

EHRLICHIOSIS AND RELATED INFECTIONS

In the past, a number of obligate intracellular organisms that infect eukaryotic cells were classified in the genus *Ehrlichia* on morphologic and ecologic grounds. With newer genetic analyses, these agents have been reclassified into the genera of *Ehrlichia*, *Anaplasma*, and *Neorickettsia*, all of which are in the family Anaplasmataceae. However, usage of the term "ehrlichiosis" to broadly describe these infections may still persist.

Etiology: Canine ehrlichiosis is primarily caused by *Ehrlichia canis*, which predominantly involves monocytes; although it is not considered a primary zoonosis, human infection with this agent has been occasionally reported. Another common ehrlichial pathogen of dogs is *E. chaffeensis*, which causes a monocytic form of illness and is the primary species causing human ehrlichiosis infection in the USA. Human cases are reported throughout the mid to southeastern and central USA. Several published reports of monocytic ehrlichiosis in cats suggest that feline infection may occur, albeit uncommonly. *E. ewingii*, which primarily infects the granulocytes of susceptible hosts, has been isolated from dogs and people in the southern, western, and midwestern USA. In 2009, an organism either identical or related to *E. muris* was identified as a cause of human illness in the upper Midwest; the role of this *E. muris*-like (EML) agent as a possible pathogen of dogs or cats is currently unknown.

A. phagocytophilum, formerly known as both *E. equi* and the agent of human granulocytic ehrlichiosis, has been reported as a cause of illness in dogs. It is known to cause human illness in the USA, primarily in northeastern, upper midwestern, and western states. Infection with this agent is most appropriately referred to as anaplasmosis, and the pathogen is found predominantly in granulocytes.

A. platys, which infects platelets, is the cause of infectious cyclic thrombocytopenia of dogs.

Epidemiology: *E. canis* is transmitted by the brown dog tick, *Rhipicephalus*

sanguineus, which is found worldwide; accordingly, canine monocytic ehrlichiosis also has a worldwide enzootic distribution. Acute *E. canis* cases may resemble infection with *Rickettsia rickettsii* (the agent of Rocky Mountain spotted fever, which can also be transmitted by the brown dog tick). *Rhipicephalus* ticks become infected with *E. canis* after feeding on infected dogs, and ticks transmit infection to other dogs during blood meals taken in successive life stages. Blood transfusions, or other means by which infected WBCs can be transferred, may also transmit the pathogen. *E. chaffeensis* and *E. ewingii* have sylvan cycles in the environment that involve tick species and wildlife reservoir hosts. In the USA, *E. chaffeensis* and *E. ewingii* are transmitted by *Amblyomma americanum*, the lone star tick, and white-tailed deer are thought to play an important role as reservoir hosts. Dogs are also considered a possible reservoir for *E. ewingii*. A case of human *E. ewingii* contracted via blood infusion has been reported, and organ transplantation of *E. chaffeensis* infection has been suspected. The ecologic cycle for the EML agent has not yet been elucidated but is suspected to involve *Ixodes scapularis*, the black-legged tick.

A. phagocytophilum is transmitted by *Ixodes* species of ticks; in the northeastern USA, infection is transmitted by *I. scapularis*, whereas infection in western states is primarily associated with *I. pacificus*, the Western black-legged tick. In nature, the enzootic cycle is most likely associated with small rodents. People and domestic animals are incidental hosts of these pathogens. Human-to-human transmission via transfusion of packed RBCs has been reported; the risk of canine-associated infections after blood transfusion is unknown.

A. platys is transmitted by *R. sanguineus* and is enzootic in many parts of the USA and worldwide. Coinfection with *E. canis* may occur, because the same tick vector is responsible for transmission of both pathogens.

Clinical Findings: In dogs, *E. canis* causes the most potentially severe clinical presentation of the *Ehrlichia* spp. Signs arise from involvement of the hemic and

lymphoreticular systems and commonly progress from acute to chronic, depending on the strain of organism and immune status of the host. In acute cases, there is reticuloendothelial hyperplasia, fever, generalized lymphadenopathy, splenomegaly, and thrombocytopenia. Variable signs of anorexia, depression, loss of stamina, stiffness and reluctance to walk, edema of the limbs or scrotum, and coughing or dyspnea may be seen. Most acute cases are seen in the warmer months, coincident with the greatest activity of the tick vector. Chronic cases may present at any time of year.

During the acute phase of *E canis* infection in dogs, the hemogram is usually normal but may reflect a mild normocytic, normochromic anemia; leukopenia; or mild leukocytosis. Thrombocytopenia is common, but petechiae may not be evident, and platelet decreases may be mild in some animals. Vasculitis and immune-mediated mechanisms induce a thrombocytopenia and hemorrhagic tendencies. Lymph node aspiration reveals hyperplasia. Death is rare during this phase; spontaneous recovery may occur, the dog may remain asymptomatic, or chronic disease may ensue.

Chronic ehrlichiosis caused by *E canis* may develop in any breed, but certain breeds, eg, German Shepherds, may be predisposed. Seasonality is not a specific hallmark of chronic infection, because appearance of chronic signs may be variably delayed after acute infection. In chronic cases, the bone marrow becomes hypoplastic, and lymphocytes and plasmacytes infiltrate various organs. Clinical findings vary based on the predominant organs affected and may include marked splenomegaly, glomerulonephritis, renal failure, interstitial pneumonitis, anterior uveitis, and meningitis with associated cerebellar ataxia, depression, paresis, and hyperesthesia. Severe weight loss is a prominent finding.

The hemogram is usually markedly abnormal in chronic cases. Severe thrombocytopenia may cause epistaxis, hematuria, melena, and petechiae and ecchymoses of the skin. Variably severe pancytopenia (mature leukopenia, nonregenerative anemia, thrombocytopenia, or any combination thereof) may be seen. Aspiration cytology reveals reactive lymph nodes and, usually, marked plasmacytosis. Frequently, polyclonal, or occasionally monoclonal, hypergammaglobulinemia develops.

Other ehrlichial infections caused by *E chaffeensis*, *E ewingii*, or *A phagocytophi-*

lum appear clinically similar to acute *E canis* infection, but the clinical course is usually more self-limiting. Shifting leg lameness and fever of unknown origin may be present. Thrombocytopenia and mild leukopenia or leukocytosis may occur during the acute course of infection, which is clinically more discrete. Chronic canine disease, as seen with *E canis* infection, is not typically seen with other infections.

Dogs infected with *A platys* generally show minimal to no signs of infection despite the presence of the organism in platelets. The primary finding is cyclic thrombocytopenia, recurring at 10-day intervals. Generally, the cyclic nature diminishes, and the thrombocytopenia becomes mild and slowly resolves.

Lesions: During the acute or self-limiting phase of *E canis* infections, lesions generally are nonspecific, but splenomegaly is common. Histologically, there is lymphoreticular hyperplasia and lymphocytic and plasmacytic perivascular cuffing. In chronic cases, these lesions may be accompanied by widespread hemorrhage and increased mononuclear cell infiltration in perivascular regions of many organs.

Diagnosis: Because thrombocytopenia is a relatively consistent finding with these infections, a platelet count is an important screening test. Clinical diagnosis may be confirmed by demonstrating the organisms within WBCs or platelets, seen in intracytoplasmic inclusion bodies called morulae. This method of diagnosis lacks sensitivity, because low numbers of organisms make demonstration difficult. More commonly, a diagnosis is made by a combination of clinical signs, positive serum indirect fluorescent antibody (IFA) titer, and response to treatment. In-house tests for *E canis*, *A phagocytophilum*, *A platys*, and *E ewingii* based on enzyme immunoassay methods are also available. The antibody response may be delayed for several weeks; thus, serologic testing may not be a reliable diagnostic tool early in the course of the disease. Furthermore, antibodies can persist for months or years after infection, making in-house tests for the organisms problematic for confirmation of acute infection, particularly in highly enzootic areas where many dogs may have antibodies to these agents because of previous infections. Testing of paired sera and demonstration of increased antibody titers is recommended to confirm infection when possible, although treatment of suspected cases should never be delayed or withheld

on the basis of test results, either positive or negative. Serologic cross-reactivity is strong between *E canis*, *E chaffeensis*, and *E ewingii*; some cross-reactivity to *A phagocytophilum* is also seen. In people, the EML agent shows cross-reactivity to *E chaffeensis*. In some areas, ~50% of dogs infected with *E canis* also have a titer to *A platys*, which likely reflects coinfection; cross-reactivity between these agents is not seen.

PCR has been used to detect and identify specific *Ehrlichia* and *Anaplasma* species in infected people and animals. Samples appropriate for PCR include blood, tissue aspirates, or biopsy specimens of reticuloendothelial organs, such as lymph nodes, spleen, liver, or bone marrow. PCR can also be used to detect the effectiveness of treatment in clearing infection. PCR is not routinely available through commercial veterinary laboratories, although some veterinary schools and research institutions offer it. PCR is available through several commercial human laboratories.

During the acute stage, differential diagnoses include other causes of fever and lymphadenomegaly (eg, Rocky Mountain spotted fever, brucellosis, blastomycosis, endocarditis), immune-mediated diseases (eg, systemic lupus erythematosus), and lymphosarcoma. During the chronic stage of *E canis* infection, differential diagnoses include estrogen toxicity, myelophthisis, immune-mediated pancytopenia, and other multisystemic diseases associated with specific organ dysfunction (eg, glomerulonephritis).

Treatment: The drug of choice for infection with *Ehrlichia* and *Anaplasma* spp is doxycycline because of its superior intracellular penetration and bacteriostatic properties against rickettsiae. Doxycycline is recommended for dogs of all ages. If infection is suspected, dogs should be treated empirically; treatment should not be withheld or delayed pending laboratory results. Early seronegative tests should not be considered a reason to stop therapy, because antibodies may take ≥ 1 wk to develop in acute cases. The recommended dosage of doxycycline in dogs is 5–10 mg/kg/day, PO or IV, for 10–21 days. Tetracycline (22 mg/kg, PO, tid) can also be used for ≥ 2 wk in acute cases and 1–2 mo in chronic cases. Two doses of imidocarb dipropionate (5–7 mg/kg, IM), 2 wk apart, are variably effective against both ehrlichiosis and some strains of babesiosis. In acute cases receiving appropriate antibiotic

therapy, body temperature is expected to return to normal within 24–48 hr after treatment. In chronic cases associated with *E canis* infection, the hematologic abnormalities may persist for 3–6 mo, although clinical response to treatment often occurs much sooner. Supportive therapy may be necessary to combat wasting and specific organ dysfunction; platelet or whole-blood transfusions may be required if hemorrhage is extensive. Concurrent broad-spectrum antibiotics may be needed if the dog has severe leukopenia. The *E canis* antibody titer should be measured again within 6 mo of illness to confirm a low or seronegative status indicative of successful therapy. Serum titers that persist at lower but positive levels should be rechecked in another 6 mo to ensure that they are not increasing.

Prevention: Prevention is enhanced by controlling ticks on dogs, through use of reliable methods. In particular, medications and products with proven efficacy against *R sanguineus* are important to use. Because *R sanguineus* infestations can be problematic in kennels and around homes, and longterm tick control is needed for management, use of effective long-acting collars on all susceptible dogs might be considered; collars containing propoxur, amitraz, or flumethrin have proven activity against *R sanguineus*. Prevention of transfusion-associated transmission can be reduced by using seronegative screened blood donors, although new donors with a negative screen cannot be presumed free of infection for several weeks because they may be incubating infection. Prophylactic administration of tetracycline at a lower dosage (6.6 mg/kg/day, PO) is effective in preventing *E canis* infection in kennels where disease is endemic. Treatment must be extended for many months through at least one tick season if the endemic cycle is to be successfully eliminated, and tick control should be implemented as well.

Zoonotic Risk: *E chaffeensis*, *E ewingii*, and *A phagocytophilum* are considered zoonoses. Despite the occurrence of disease in both animals and people, the involvement of a required intermediate tick vector for transmission means dogs and other infected animals do not pose a direct transmission risk in normal circumstances. Infection in dogs may indicate a heightened risk of human infections related to tick exposure in a given area.

ROCKY MOUNTAIN SPOTTED FEVER

(*Rickettsia rickettsii* infection)

Etiology: Rocky Mountain spotted fever (RMSF) is a disease of people and dogs caused by *Rickettsia rickettsii*. *R. rickettsii* and closely related members of the spotted fever group of rickettsiae are considered endemic throughout much of North, South, and Central America. These pathogens are transmitted primarily through the bites of infected ticks. The ability of genetically similar rickettsial organisms, such as *R. parkeri*, to cause clinically similar disease in dogs is unknown. Because of their susceptibility to *R. rickettsii* and relatively higher rates of tick exposure, dogs may serve as excellent sentinels of risk for *R. rickettsii* infection in people. Clusters of disease are frequently reported in defined geographic areas, and temporally associated infections may be seen in both dogs and their owners.

Epidemiology: In the USA, *Dermacentor variabilis* (the American dog tick) and *D. andersoni* (the Rocky Mountain wood tick) are considered the primary vectors for *R. rickettsii*. In South America, several *Amblyomma* spp of ticks have been implicated in transmission. The organism has also been isolated from *Rhipicephalus sanguineus* ticks (the brown dog tick), which appear to be the primary vector in some focal areas of Arizona, particularly on American Indian tribal lands, and may also play an as-yet unappreciated role in outbreaks elsewhere in the USA. *R. sanguineus* ticks are also associated with transmission of *R. rickettsii* in Central America and with large city-based outbreaks in Mexico. The pathogen is acquired by larval and nymph stages of ticks while feeding on infected vertebrate hosts and is also passed from female ticks to progeny through transovarial transmission. An estimated <1% of *Dermacentor* spp ticks carry *R. rickettsii*, even in areas considered highly endemic. In highly enzootic regions of Arizona where *R. rickettsii* is transmitted by the brown dog tick, as many as 5% of ticks may be infected.

Seroprevalence in dogs from endemic areas ranges from 4.3%–77%, but these values do not accurately reflect infection rates because of the detection of cross-reacting antibodies to other genetically similar rickettsiae. RMSF transmission through blood transfusion has been

documented in a single human case and should be considered when selecting canine blood donors. Direct transmission from dogs to people has not been reported, although human infection may occur after contact of abraded skin or conjunctiva with tick hemolymph or excreta during removal of engorged ticks from pets.

Clinical Findings: Dogs are highly susceptible to clinical infection with *R. rickettsii*; in contrast, it is rarely diagnosed in cats. Early signs in dogs may include fever (up to 105°F [40.5°C]), anorexia, lymphadenopathy, polyarthritis, coughing or dyspnea, abdominal pain, vomiting and diarrhea, and edema of the face or extremities. Petechial hemorrhages of the conjunctiva and oral mucosa may be seen in severe cases. Focal retinal hemorrhage may be seen during the early course of disease. Neurologic manifestations such as altered mental states, vestibular dysfunction, and paraspinal hyperesthesia may occur.

Thrombocytopenia is common. Leukopenia develops during the early stages of infection and, in untreated cases, is followed by progressive leukocytosis. Serum biochemical abnormalities may include hypoproteinemia, hypoalbuminemia, azotemia, hyponatremia, hypocalcemia, and increased liver enzyme activities. Case fatality rates of ~1%–10% are expected.

Lesions: Vascular endothelial damage is due to direct cytopathic effects of the rickettsiae. Severity of the necrotizing vasculitis can be directly correlated to the infective dose. Vascular endothelial damage and thrombocytopenia contribute to development of petechiae and ecchymoses. Necrosis of the extremities (acral gangrene) or disseminated intravascular coagulation can develop in severely affected dogs.

Diagnosis: Currently, there are no in-house diagnostic tests available for diagnosis of acute RMSF in dogs. Indirect fluorescent antibody titer (IFA) is preferred for serologic testing. However, because of the high incidence of cross-reacting antibodies to a variety of nonpathogenic spotted fever group rickettsiae, as well as longterm persistence of antibodies after acute RMSF infection, demonstration of a 4-fold rise in titer should be documented in conjunction with a compatible clinical syndrome. Differential diagnoses include other causes of fever of unknown origin. The therapeutic response is usually dramatic, as it is in other canine rickettsial diseases. Animals with neurologic

dysfunction may have residual deficits. Immunity appears to be lifelong after natural infection; therefore, recurrent episodes should not be attributed to RMSF.

Treatment: Antibiotic treatment should be administered based on clinical suspicion without waiting for results of serologic tests, because delayed administration of antibiotics may result in higher rates of severe or fatal outcome. Doxycycline is the treatment of choice, regardless of age of the dog, and should be administered at a dosage of 5–10 mg/kg/day, PO or IV, for 10–21 days. Tetracycline at 22 mg/kg, PO, tid for 2 wk is also effective. Chloramphenicol has been used to treat RMSF in the past, but its use is associated with higher rates of fatal outcome in human patients, and it is not recommended. Other broad-spectrum antibiotics are ineffective against *R. rickettsii* infection, and there is some evidence in human cases that use of fluoroquinolones may actually worsen infection. Early seronegative tests should not be considered a reason to stop therapy, because antibodies may take ≥ 1 wk to develop in acute cases. Supportive care for dehydration and hemorrhagic diathesis may be necessary. Because of alterations in vascular integrity, conservative rates of fluid administration are advised. Precautions should be taken for the safe removal and control of ticks. In settings in which *R. rickettsii* transmission from *R. sanguineus* is suspected, medications and products with proven efficacy against this tick species are important to use. Because *R. sanguineus* infestations can be problematic in kennels and around homes, and long-term tick control is needed for outbreak control, use of effective long-acting tick collars on all susceptible dogs might be considered; collars containing propoxur, amitraz, or flumethrin have proven activity against *R. sanguineus*.

Zoonotic Risk: *R. rickettsii* is considered a zoonotic pathogen. The potential for household clustering and large urban outbreaks, particularly in areas with transmission by brown dog ticks, makes RMSF a disease of significant public health concern. Although clinical disease occurs in both animals and people, the involvement of a required intermediate tick vector for transmission means dogs and other infected animals do not pose a direct transmission risk in normal circumstances. Infection in dogs indicates a heightened risk of human infections related to tick exposure in a given area, and serologic

studies of dogs in emerging areas may help predict human risk of infection. Particularly in areas where transmission occurs via *R. sanguineus*, close cooperation between veterinary, medical, and public health officials is important to achieve control.

MURINE TYPHUS

(*Rickettsia typhi* infection, *R. felis* infection)

Rickettsia typhi, the causative agent of murine typhus, and *R. felis* are zoonotic pathogens maintained primarily in rodent reservoirs (rats, mice) that may also be associated with enzootic cycles involving opossums and domestic cats. Infection is transmitted to people and other animals through contact with infected fleas.

Epidemiology: Infection in people is primarily thought to occur through exposure of abraded skin with infectious flea feces; aerosolization of infectious materials may occur in limited settings. Dogs and cats are presumably exposed in a similar fashion. Although known to occur worldwide, currently fewer than several hundred human cases of murine typhus are reported in the USA each year. Enzootic infection is the most commonly reported from southern Texas, California, and Hawaii, although the disease is believed to be underreported.

Clinical Findings: Clinical illness associated with canine and feline infection with *R. typhi* and *R. felis* is not well documented, but evidence of exposure based on presence of antirickettsial antibodies has been noted, particularly in association with outbreaks of human disease. Although a role as a possible reservoir for infection has been suggested, particularly for cats, the importance of domestic animals in maintenance of enzootic cycles has not been well elucidated. Nonetheless, dogs and cats may, at a minimum, serve as a source of fleas that may pose a transmission risk to people. Regular flea control is recommended to reduce risk of flea-associated transmission to people.

Diagnosis: An indirect fluorescent antibody (IFA) titer assessed in paired sera is preferred for serologic testing and is most commonly used in conjunction with environmental assessments around a human outbreak. There is some degree of antibody cross-reactivity with antibodies

from other rickettsial infections, including *R. rickettsii*, so assessments should ideally be made with paired sera. PCR of whole blood may also be used, but its utility in assessing canine and feline infection is unknown because the animals may not exhibit clinical signs during periods of rickettssemia, making it difficult to determine the optimal time for assessment.

Treatment: In the absence of clinical signs, specific treatment is not recommended. If clinical illness associated with *R. typhi* or *R. felis* infection is suspected in a dog or cat, doxycycline may be administered at a dosage of 5–10 mg/kg/day, PO or IV, for 10–21 days. Animals should be provided with routine preventive treatments to control fleas. Control programs involving animal removal from an area of enzootic activity should be accompanied by pesticide treatment of the environment to prevent fleas feeding on people after the removal of preferred blood-meal hosts.

Zoonotic Risk: *R. typhi* is considered a zoonotic pathogen. Serologic evidence of exposure or past infection in dogs or cats indicates a heightened risk of human infections in a given area, and flea control for pets is an essential component of disease control.

SALMON POISONING DISEASE AND ELOKOMIN FLUKE FEVER

(*Neorickettsia* spp infection)

Salmon poisoning disease (SPD) is an acute, infectious disease of canids, in which the infective agent is transmitted through the various stages of a fluke in a snail-fish-dog life cycle. The name of the disease is misleading, because no toxin is involved. Elokomin fluke fever (EFF) is an acute infectious disease of canids, ferrets, bears, and raccoons that resembles SPD but has a wider host range. In people, *Neorickettsia sennetsu* causes a disease known as Sennetsu ehrlichiosis, and in horses *N. risticii* causes a disease known as Potomac horse fever; these have not been reported as a cause of illness in dogs except for one report of *N. risticii* in Illinois.

Etiology: SPD is caused by *N. helminthoeca* and is sometimes complicated by a second agent, *N. elokominica*, which causes EFF. The vector for these *Neorickettsia* agents is a small fluke, *Nanophyetus salminalcola*. Dogs and other animals

become infected by ingesting trout, salmon, or Pacific giant salamanders that contain the encysted metacercaria stage of the rickettsia-infected fluke. In the dog's intestine, the metacercarial flukes excyst, embed in the duodenal mucosa, become gravid adults, and transmit the rickettsiae to monocytes-macrophages. The fluke infection itself produces little or no clinical disease. A recent report of SPD in two captive Malayan sun bears underscores the need to consider this etiology in non-native exotic species with compatible exposure and clinical histories.

Epidemiology: The life cycle of *Neorickettsia helminthoeca* is maintained by the release of infected fluke ova in the feces of the mammalian host. Infected miracidia develop from these ova and infect the snails *Juga plicifera* and *Juga silicula* to form infected rediae. Rediae develop into infected cercariae that are released from the snail, penetrate the salmon or trout, and develop into encysted metacercariae infected with *Neorickettsia*. The cycle is completed when mammals eat the fish, and infected metacercariae become infected gravid adults and pass *Neorickettsia* to fluke eggs. Although *Neorickettsia* infection of dogs is not required for the life cycle of *Neorickettsia*, mammalian infection is required to maintain the trematode life cycle. Transmission by cage-to-cage contact, rectal thermometers, or aerosols is rare.

There are no age, sex, or breed predilections; however, the disease prevalence is higher when the availability of trematode-infected fish is greater. Infected fish are found in the Pacific Ocean from San Francisco to the coast of Alaska, but SPD is more prevalent from northern California to Puget Sound. It is also seen inland along the rivers of fish migration. SPD also has been reported in southern California and Brazil. The snail is the primary factor for geographic limitation, but dogs fed undercooked or raw fish from the supermarket may have developed SPD.

Clinical Findings: In SPD, signs appear suddenly, usually 5–7 days after eating infected fish, but may be delayed as long as 33 days, and persist for 7–10 days before culminating in death in up to 90% of untreated animals. Body temperature peaks at 104°–107.6°F (40°–42°C) 1–2 days later, then gradually declines for 4–8 days and returns to normal. Frequently, animals are hypothermic before death. Fever is accompanied by depression and complete

anorexia in virtually all cases. Persistent vomiting usually occurs by day 4 or 5. Vomiting occurs in most cases, and diarrhea, which develops by day 5–7, often contains blood and may be severe. Dehydration and extreme weight loss occur. When severe, the GI signs are clinically indistinguishable from those of canine parvoviral infection. Generalized lymphadenopathy develops in ~60% of cases. Nasal or conjunctival exudate may be present and mimic signs of distemper. Neutrophilia is common, but a marked, absolute leukopenia with a degenerative left shift may occur. Thrombocytopenia is reported in 94% of the cases. Serum chemistry values are normal.

Clinically, EFF is a milder infection than SPD. Severe GI signs are less commonly seen in EFF infections, and lymphadenopathy may be a more pronounced finding. Case fatality rates with EFF are lower, at ~10% of untreated cases.

Lesions: Infection appears to chiefly affect the lymphoid tissues and intestines. There is enlargement of the GI lymph follicles, lymph nodes, tonsils, thymus, and to some extent, the spleen, with microscopic necrosis, hemorrhage, and hyperplasia. Remarkable abdominal or mesenteric lymphadenomegaly may be seen. A variable but often severe nonhemorrhagic enteritis is seen throughout the intestine with SPD but is less commonly seen with EFF. Microscopic foci of necrosis also appear apart from the follicles. Nonsuppurative meningitis or meningoencephalitis has been identified in some dogs.

Diagnosis: Fluke ova are found on fecal examination in ~92% of cases, which supports the diagnosis. The ova are oval,

yellowish brown, rough-surfaced, and ~87–97 × 35–55 μm, with an indistinct operculum and a small, blunt point on the opposite end. During the first day or two, few ova may be passed. Intracellular organisms have been demonstrated by Romanowsky staining on lymph node aspirates in ~70% of cases. PCR testing to detect DNA-specific *N. helminthoeca* (or *Neorickettsia* genus) is recommended for accurate diagnosis. Serologic testing using the *N. helminthoeca* organism has been developed. Other causes of fever of unknown origin, generalized lymphadenopathy, vomiting, and diarrhea are differential diagnoses. When diarrhea and exudative conjunctivitis occur, distemper should be considered.

Prevention and Treatment: Currently, the only means of prevention is to restrict the ingestion of uncooked salmon, trout, steelhead, and similar freshwater fish. In animals that recover, a profound humoral immune response persists, but there is no cross-resistance between *N. helminthoeca* and *N. elokominica*. Sulfonamides are not effective and may exacerbate the clinical disease. Recommended treatment is parenteral oxytetracycline (7 mg/kg, IV, tid for 5 days) or doxycycline (10 mg/kg, bid for 7 days). Oral tetracycline or doxycycline is contraindicated because of impinging GI signs. Animals usually succumb because of dehydration, electrolyte and acid-base imbalances, and anemia. Therefore, general supportive therapy to maintain hydration and acid-base balance, while meeting nutritional requirements and controlling diarrhea, is often essential. Judicious use of whole blood transfusions may be helpful.

THE BIOLOGY OF THE IMMUNE SYSTEM

Animals are under constant threat of invasion by a diverse range of microorganisms that seek to enter the body and exploit its resources for shelter and food. To ensure survival and prevent such exploitation, the body combats the most dangerous of these invaders with an equally complex set of defensive mecha-

nisms that can be thought of as a series of barriers. These mechanisms include physical barriers to invasion such as a tough, thick skin or the ability to cough and sneeze. The second line of defense is a “hard wired” system of innate immunity that depends on a rapid, stereotyped response to stop and kill both bacterial

and viral invaders. This is typified by the process of acute inflammation and by the classic sickness responses such as a fever. The third line of defense is the highly complex, adaptable, and incredibly effective adaptive immune system.

Innate immune responses are highly effective against opportunistic organisms or those of low virulence, but by their very nature cannot do more than delay highly pathogenic microbial invaders. Long-term resistance and survival depends on adaptive immunity. The adaptive immune system is effective against a wide variety of pathogens. Its effectiveness improves each time it is activated in response to microbial invasion. Because the body accumulates immune memory cells as it ages, adaptive immunity provides an almost insurmountable barrier to most potential invaders. In its absence, the animal dies.

The adaptive immune system faces complex challenges. Many different microorganisms, including bacteria, viruses, protozoa, and helminths, may attempt invasion. The optimal immune responses to this diversity of invaders must also be very diverse. For example, invaders such as bacteria that live outside body cells are best attacked by an antibody-mediated (or humoral) immune response, whereas viruses living within cells are best destroyed by the killing of infected cells through cell-mediated mechanisms.

PHYSICAL BARRIERS

The physical barriers on the surface of the body play a significant role in slowing or blocking microbial invasion. Very few microorganisms can penetrate intact skin; instead, invaders usually enter through wounds or by being injected, such as by mosquito bites. Skin wounds heal rapidly to reestablish the protective barrier. A complex population of normal skin bacteria tends to exclude new invaders, while antimicrobial molecules in sweat can kill many would-be invaders. In the airways, the structure of the upper respiratory tract serves as an effective filter of small particles. The airways themselves are lined with a layer of adhesive mucus that can entrap microbes. The mucus contains multiple antimicrobial proteins such as defensins, lysozyme, and surfactants. "Dirty" mucus is constantly being replaced by clean material as ciliary action carries it to the pharynx where it is swallowed. Coughing and sneezing remove larger irritants from the airways and nasal passages and are essential defensive reactions. The defense of the intestine

centers largely on the presence of the huge and immensely complex normal commensal microbiota. Potential invaders may be unable to colonize the intestine in the presence of a well-adapted population of commensal microbes. If all else fails, invaders may be rapidly removed from the GI tract by vomiting and diarrhea.

The intestinal microbiota plays a critical role in maintaining animal health. First, it is a source of nutrients, especially in herbivores, in which it provides a means of exploiting a cellulose-rich diet and a source of essential vitamins. This microbiota also plays a critical role in the defense of the body. The large, well-adapted microbial population excludes many potential pathogens through competition. More importantly, the constant stimulus provided by the presence of the microbiota effectively stimulates the correct development of the adaptive immune system and regulates the level of inflammation mediated by innate immune systems.

INNATE IMMUNITY

Microbes that succeed in penetrating the physical barriers of the body are rapidly detected, and the innate defenses are activated. Although multiple innate mechanisms exist, acute inflammation is the central feature of innate immunity. The first step in the inflammatory process is the early detection of either invading organisms or damaged tissues. Most invaders are recognized by pattern-recognition receptors that bind and recognize conserved molecules expressed on microbial surfaces. There are many different pattern-recognition receptors, but the most important are the toll-like receptors (TLRs). TLRs are a family of at least 10 different receptors found on the surface or in the cytoplasm of cells such as macrophages, intestinal epithelial cells, and mast cells. The TLRs on cell surfaces bind to molecules commonly expressed by extracellular bacteria such as lipopolysaccharides or lipoproteins. The cytoplasmic TLRs, in contrast, bind to the nucleic acids of intracellular viruses. Once they bind their ligands, the TLRs trigger the production of proteins such as interleukin 1 (IL-1) or interferon α (IFN- α).

IL-1 and the other cytokines produced in response to TLR stimulation then trigger acute inflammation. They initiate the adherence of circulating leukocytes to blood vessel walls close to sites of invasion. These leukocytes, especially neutrophils, then leave the blood vessels and migrate to invasion sites, attracted by microbial

products, small proteins called chemokines, and molecules from damaged cells. Once they arrive at the invasion site, the neutrophils bind invading bacteria, ingest them through the process of phagocytosis, and kill the ingested organisms. This killing is largely mediated by a metabolic pathway called the respiratory burst that generates potent oxidants such as hydrogen peroxide and hypochloride ions. Neutrophils, however, have minimal energy reserves and can undertake only few phagocytic events before they are depleted.

Even if the initial inflammatory response is successful in killing all invaders, the body must still remove cell debris, eliminate any surviving microbes and dying neutrophils, and repair the damage. This is the task of macrophages. Tissue macrophages originate as blood monocytes. They, like neutrophils, are attracted to sites of microbial invasion and tissue damage by chemokines and damaged tissues, where they finish off any surviving invaders. They also ingest and destroy any remaining neutrophils, thus ensuring that the neutrophil oxidants are removed without toxic spills occurring in the tissues. Finally, another population of these macrophages begins the process of tissue repair. Macrophages that complete the destructive process are optimized for microbial destruction and are called M1 cells. Macrophages optimized for tissue repair and removal of damaged tissues are called M2 cells.

Many of the molecules produced as a result of inflammation and tissue damage, such as IL-1 and tumor necrosis factor, can reach the bloodstream where they circulate. They enter the brain and trigger sickness behavior; for example, they alter the thermoregulatory centers to cause a fever, act on appetite-controlling centers to suppress appetite, and act on sleep centers to produce sleepiness and depression. They also mobilize energy reserves from adipose tissue and muscle. This sickness behavior is believed to enhance the defense of the body by redirecting energy toward fighting off invaders.

Circulating cytokines from inflammatory sites also act on liver cells, causing the cells to secrete a mixture of "acute-phase proteins," so-called because their blood levels climb steeply when acute inflammation develops. Different species have different acute-phase proteins, including serum amyloid A, C-reactive protein, and many different iron-binding proteins. Acute-phase proteins also serve to promote innate immunity.

Complement

Although acute inflammation is central to the processes of innate immunity, the body possesses other innate defenses. Tissues contain antimicrobial peptides that can bind and kill invading bacteria. These include detergent-like molecules such as the defensins or cathelicidins that can lyse bacterial cell walls, enzymes such as lysozyme that kill many gram-positive bacteria, and iron-binding proteins such as hepcidin or haptoglobin that prevent bacterial growth by depriving them of essential iron supplies. Perhaps the most important of these innate defenses is the complement system, which consists of a complex group of ~30 proteins that act collectively to kill invading microbes. The primary function of the complement system is to bind two proteins called C3 and C4 irreversibly to microbial surfaces. Once bound, these complement components may either kill microbes by rupturing them using another protein called C9 or simply coat them so that they are rapidly and effectively phagocytized by leukocytes.

The complement system can be activated in three ways. One way, called the alternative pathway, is triggered by the presence of bacterial surfaces that consist largely of carbohydrates and can bind the complement protein C3. Once bound, the C3 acts as an enzyme to activate and bind more C3. These C3-coated bacteria are rapidly and effectively phagocytized and destroyed. Alternatively, surface-bound C3 can activate additional complement components that eventually cause a protein called C9 to insert itself within bacterial cell walls, where it causes bacterial rupture. A second complement-activating pathway is triggered when bacterial surface carbohydrates bind to a mannose-binding protein in serum. This binding activates an enzyme pathway that leads to activation of C3 or C9. The third, or classic, pathway of complement activation is triggered when antibodies bind to microbial surfaces. It is thus triggered by adaptive immune responses. As with the mannose pathway, this eventually leads to activation of C3 and C9. Because of its potential ability to cause severe tissue damage, the complement system is carefully regulated through multiple complex regulatory pathways.

Cells of Innate Immunity

The key to an effective innate immune response is prompt recognition of invasion and a rapid cellular response. Several cell types function as sentinel cells; three of the

most important are macrophages, dendritic cells, and mast cells. These cell types express pattern recognition receptors such as TLRs and can sense the presence of microbial invaders. They also express multiple other receptors that can detect microbes and tissue damage. When these receptors are engaged, they signal through a molecule called NF- κ B to turn on the production of cytokines such as IL-1, IFN- α , and TNF- α . They also release vasoactive and pain molecules such as histamine, leukotrienes, prostaglandin, and specialized peptides that initiate the vascular events in inflammation.

The purpose of inflammation is to ensure that leukocytes are delivered as promptly as possible to sites of microbial invasion. This involves attracting these cells from the bloodstream where they circulate and inducing them to migrate through the tissues to the invasion sites where they engulf and kill invaders. There are three major leukocyte populations that can kill invaders. Granulocytes are especially effective at killing invading bacteria. They engulf the invaders, activate a metabolic pathway called the respiratory burst, and generate lethal oxidizing molecules such as hydrogen peroxide and hypochloride ions that kill most ingested bacteria. Eosinophils are specialized killers of invading parasites. They contain enzymes that are optimized to kill migrating helminth larvae. The third major killing cell population are M1 macrophages. These cells migrate into areas of microbial invasion more slowly than granulocytes. However, they are capable of sustained and effective phagocytosis. They contain the highly lethal antimicrobial factor nitric oxide and thus can kill organisms resistant to neutrophil killing.

When inflammation leads to activation of macrophages, they secrete a cytokine called IL-23. This, in turn, acts on a population of T cells (called Th17 cells), causing them to secrete IL-17. IL-17 recruits granulocytes to sites of inflammation, infection, and tissue damage.

While many leukocytes are optimized to kill invading bacteria, viruses also present a potent threat. Natural killer (NK) cells are a population of innate cells optimized to kill virus-infected cells. NK cells, a form of lymphocyte, can kill virus-infected or other "abnormal" cells that fail to express major histocompatibility complex (MHC) class I molecules. MHC class I molecules bind to NK cell receptors and switch off their killing abilities. In the absence of this signal, the NK cells bind to target cells, inject them with apoptosis-inducing proteins, and kill them.

ADAPTIVE IMMUNITY

Innate immunity, although critical to the defense of the body, is insufficient to guarantee protection. It lacks the flexibility to respond optimally to a diversity of microorganisms and by its very nature may cause significant tissue damage. A third layer of defense is required that can act automatically in response to microbial invasion, generate resistance proportional to the threat, and improve with experience. These are the key features of the adaptive immune system. Adaptive immune responses are of two major types: antibody (humoral) immunity directed against extracellular invaders, and cell-mediated immunity directed against intracellular invaders.

Adaptive immune responses are complex and must be very carefully regulated. The immune defenses of the body constitute a potent system of protection that must be carefully controlled to minimize damage to normal tissues. As a result, a major portion of the immune system is devoted to the production of regulatory cells that function to ensure that adaptive immune responses occur only under appropriate circumstances. If these regulatory pathways fail, disease or death may result.

The adaptive immune system functions through a series of steps that must occur sequentially for either an antibody-mediated or cell-mediated immune response to occur. The first step involves the capture and processing of foreign antigens. Once processed, these antigens are transported to cell surfaces, where they can be recognized by lymphocytes carrying receptors for specific antigens. Each antigen receptor is highly specific, and each lymphocyte expresses only a single form of antigen receptor. Thus, millions of cells have the potential to recognize millions of antigens. To ensure that only foreign antigens trigger adaptive immunity, cells with receptors that bind and respond to normal body antigens are selectively killed early in their development. The surviving cells are located within lymphoid organs at sites where they can most effectively encounter antigens on microbial invaders, triggering them to respond by mounting immune responses. There are three major populations of lymphocytes: **B cells** that are responsible for antibody responses, **effector T cells** that are responsible for cell-mediated immune responses, and **regulatory T cells** that control these responses and minimize inappropriate responses.

Antibody Responses (Humoral Immunity)

Antibodies are protein molecules that serve as B-cell antigen receptors that can be synthesized in large quantities and secreted by the cell into the bloodstream where they circulate. These proteins are produced by B cells and from B cell–derived plasma cells. Antibodies bind to foreign molecules and mark them for destruction by phagocytic cells or complement-mediated lysis. Plasma cells are differentiated B cells optimized to synthesize and secrete enormous quantities of antibodies. Antibodies are critical to host defense against extracellular invaders such as most bacteria, some blood parasites, and viruses traveling between cells.

B cells originate in the bone marrow and reside in lymphoid tissues such as lymph nodes, bone marrow, Peyer's patches, and the spleen. Each B cell is covered by several thousand identical antigen receptors and can bind and respond to only a single antigenic molecule. When a microbe enters the body, it will inevitably encounter B cells that can bind to some of its surface antigens. As a result of antigen binding, and under suitable circumstances, these B cells divide repeatedly and differentiate into two subpopulations. One subpopulation is composed of antibody-producing plasma cells, which are capable of enormously increased protein synthesis and are the major sources of antibodies. The other subpopulation is composed of B cells that develop into memory B cells and persist in lymphoid tissues for months or years. When an animal encounters an antigen for a second time, these memory B cells respond rapidly, producing large numbers of plasma cells (and more memory cells). As a result, the animal mounts a vastly improved antibody response and the invader is rapidly eliminated. Subsequent exposure to a microbe leads in turn to the accumulation of more memory cells, resulting in better protection and virtually guaranteeing that the organism will never be able to cause disease in that animal. This response is the basis of all vaccination programs.

Although simple in concept, B cell responses and antibody production are made more complex by the need to ensure their careful regulation. Thus, a B cell is not usually able to respond to a bound foreign antigen unless it also receives "permission" in the form of a second signal from cells called helper T cells. These T cells in turn can only be activated if they are presented with antigen under carefully controlled circumstances.

Antibodies: Antibodies are composed of proteins called immunoglobulins. Mammals use five different classes of antibodies: immunoglobulin G (IgG), IgM, IgA, IgE, and IgD. The class of immunoglobulin secreted by B cells and plasma cells depends on their location. Cells located in lymphoid organs within the body secrete IgM and IgG, whereas cells located on body surfaces secrete IgM, IgA, and IgE.

IgG is the most abundant immunoglobulin found in the bloodstream and plays the major role in eliminating organisms that succeed in penetrating deep into the body. IgM serves as a "back-up" for IgG and is usually confined to the bloodstream. IgM is produced early in the antibody response, when its high effectiveness compensates for its low quantity.

IgA is produced by B cells and plasma cells located on mucosal surfaces. As a result, IgA is produced and secreted in large amounts into the upper respiratory tract, the GI tract, tears, sweat, etc. In these locations, it complements the physical barriers of the body and prevents microbial invasion. IgE serves as a "back-up" for IgA and is also mainly produced on body surfaces. IgE is optimized to control invasion by parasites such as helminths or arthropods. However, it also mediates a rapid acute inflammation in allergic states and hence may mediate life-threatening anaphylaxis. The function of IgD is unclear, but it is believed to be of minimal significance.

T Cell Help: Most antibody responses are regulated by the need to receive prior approval from T cells. The T cells in turn are activated only when they bind antigen fragments presented by specialized antigen-presenting cells called dendritic cells.

Dendritic cells are macrophage-like cells that capture and process foreign antigens. Their name derives from their many long, thin, filamentous processes or dendrites that extend through tissues to form an effective antigen-trapping web. For example, a subpopulation of dendritic cells (Langerhans cells) is found in the dermis, where its web of dendrites traps microorganisms seeking to enter the body through damaged skin. Dendritic cells capture and phagocytize invading microorganisms. Fragments of these foreign antigens persist within the dendritic cells, where they become attached to receptor molecules (major histocompatibility complex [MHC] molecules). Once formed, these antigen-receptor complexes move to the cell surface where they can be recognized by T cells.

The receptors in dendritic cells that bind and present antigen fragments are specialized proteins encoded by genes clustered together in the MHC (originally identified as the antigens that cause graft rejection, hence their unusual name). There are many thousands of different MHC molecules expressed within an animal population but relatively few (3–6) different molecules expressed in any individual animal. Because they play a critical role in binding antigen fragments and activating T cells, MHC molecules effectively determine whether an individual can respond to a foreign antigen. An individual animal possesses MHC molecules that can bind many, perhaps most, foreign antigens, but not all of them. If an animal lacks MHC molecules that can bind an antigen, it will be unable to respond to that specific antigen. The set of antigens to which an individual can respond (and against which it is protected) are determined by its MHC haplotype. All domestic animal species possess their own unique MHC. The receptors coded for these genes are named after the specific species; thus, BoLA is the name of these molecules in cattle, ELA in horses, SLA in swine, etc.

As with B cells, T cells possess specific antigen receptors on their surface that are generated randomly when the cells are first produced. As T cells mature within the thymus, cells with receptors that can bind normal body components are killed. Surviving T cells can respond only to foreign antigens. The antigen receptors on T cells, like those on B cells, are identical on any single cell. Unlike those on B cells, however, the receptors can recognize antigen only when it is bound to an MHC molecule. Thus, when a dendritic cell presents MHC-associated antigen to T cells, only those T cells with appropriate receptors will bind to the dendritic cells. Once in contact, the cells exchange signals that confirm that the T cell is responding to a correctly processed antigen. After T cells receive all the necessary signals, they secrete a mixture of cytokines that permit their attached B cells to respond to antigens and allow antibody production to proceed.

Antibodies are produced in response to, and directed against, extracellular bacteria. Cell-mediated responses, in contrast, are directed against viruses and intracellular bacteria. The determination as to the appropriate form of the immune response is made at an early stage in the immune response. Thus, there are two populations of dendritic cells that can trap and process antigens. One population (DC1 cells) triggers cell-mediated immunity,

whereas the other (DC2 cells) triggers antibody formation. These dendritic cell populations send different messages to T cells, because they use different cytokines for signaling; DC1 cells secrete IL-12, whereas DC2 cells secrete IL-1. In turn, these different cytokines stimulate two different T cell populations: Th1, which promotes cell-mediated immunity, and Th2, which promotes B cell responses and antibody production. Th1 cells secrete a mixture of cytokines typified by interferon- γ (IFN- γ). Th2 cells secrete a mixture of cytokines typified by IL-4. B cells will usually respond optimally to a foreign antigen only if they are stimulated by the presence of IL-4 from Th2 cells.

Cell-mediated Immunity

As described above, cell-mediated immune responses are required to combat intracellular invaders such as viruses and some intracellular bacteria. The immune system blocks virus infections by killing the cells that they infect. The cells responsible are called effector, or cytotoxic, T cells. Like T cells, effector T cells undergo development and selection within the thymus, so any T cells capable of killing normal healthy cells are eliminated. The surviving T cells are released into the body, where they circulate continuously through the tissues seeking out abnormal cells.

All nucleated cells produce many different proteins when functioning normally. Virus-infected cells, however, are forced by the virus to produce viral proteins. The body therefore requires that all nucleated cells send a sample of their newly synthesized proteins to the cell surface. This involves the cell diverting a small sample of each newly formed protein and fragmenting it in a complex enzyme system called a proteasome. The resulting protein fragments are then attached to MHC molecules and carried to the cell surface, where they are available for inspection by effector T cells. If the cell's receptors do not engage a protein fragment, nothing happens. If, however, their antigen receptors bind to a foreign antigen fragment in an MHC-protein complex, the T cell will be signaled to kill the offending cell. Like B cells, effector T cells function only if they receive permission from a helper T cell, specifically a Th1 cell. The cytokines from Th1 cells, especially IFN- γ , must be present if an effector T cell is to kill its target.

Effector T cells bind tightly to target cells expressing foreign antigens and then signal them to destroy themselves through apoptosis. The T cells inject their targets

with enzymes called granzymes that trigger this process. As a result, effector T cells eliminate virus-infected cells but not normal, healthy cells. Most effector T cells die within a few days once they are no longer needed, but a few survive to become long-lived memory cells that respond rapidly should the animal encounter the virus again.

Effector T cells are especially effective at killing target cells that produce foreign antigens. However, some intracellular organisms, especially intracellular bacteria, are best destroyed by other cell-mediated mechanisms. In these cases, IFN- γ from Th1 cells activates M1 macrophages. As a result, bacteria that can survive within normal macrophages are rapidly destroyed by activated macrophages.

Immunologic Memory

The effectiveness of adaptive immunity is largely a result of its ability to recognize antigens encountered previously and to mount an enhanced and accelerated response against them. The more an animal encounters an antigen, the greater will be its immune response. Immunologic memory depends on the presence of persistent populations of memory cells that accumulate as an animal ages. These memory cells may be very long-lived or, more likely, turn over very slowly. As a result, animals may make small amounts of antibodies to vaccine antigens for many years after vaccination. Cell-mediated memory may also be due to the development of very long-lived populations of memory T cells. The effectiveness of vaccines in inducing long-lasting immunity depends in large part on their ability to induce memory cell populations.

Cytokines

The cells of the adaptive immune system communicate in several ways. They can

come into physical contact and exchange signals through receptors within the contact area or immunologic synapse. Examples include the contact between T cells and dendritic cells or between effector T cells and their targets. Immune cells can also signal nearby cells by secreting small signaling proteins called cytokines. Several hundred different cytokines have been identified. Signaling cells secrete a mixture of cytokines that then bind to receptors on nearby cells. The target cell receives multiple signals that it must integrate to respond appropriately. Cytokines, acting through their specific receptors, can turn the synthesis of specific proteins on or off. They can cause the target cell to divide or differentiate, and they may trigger apoptosis. With hundreds of different cytokines acting in complex mixtures it is sometimes difficult to predict exactly how a specific target cell will respond. Major families of cytokines include the interleukins that mediate signaling between leukocytes, interferons that mediate interactions between cells and have significant antiviral activity, growth factors that regulate growth and differentiation of many different cell types, and tumor necrosis factors that modulate inflammatory responses.

Regulatory Cells

The adaptive immune system is carefully regulated by several different cell populations. The most important are T_{reg} cells, which secrete a mixture of cytokines that inhibit conventional immune responses. They serve to turn off an immune response once it has completed its task and the invading microorganism is eliminated. T_{reg} cells also play a central role in preventing the development of autoimmunity. Another important population of regulatory T cells are called Th17 cells. These cells, so called because they secrete IL-17, regulate the innate immune system and the development of inflammation.

IMMUNOLOGIC DISEASES

The primary role of the immune system is the detection and destruction of invading microorganisms. Because of the great diversity of microbial invaders, the immune system has evolved an equally complex mixture of protective mechanisms. These may be simply classified as innate

immunity (see p 812) and adaptive immunity (see p 814). Protection within the first few days of microbial invasion is the responsibility of the "hard-wired" innate immune system. Longterm protection is the responsibility of the adaptive immune system.

In general, disease associated with the immune system takes two forms: insufficient immune function causing immunodeficiencies, manifested as increased susceptibility to infections, and diseases resulting from excessive immune function, resulting in hypersensitivities and autoimmunity.

Under certain circumstances, normally protective immune responses can cause significant tissue damage. In general, excessive innate immune responses do this by triggering inappropriate inflammation leading to collateral damage to nearby tissues, or by producing vastly excessive amounts of inflammatory cytokines. Excessive adaptive immune responses, in contrast, can cause damage by multiple mechanisms. One simple classification divides diseases due to excessive adaptive immune responses into four distinct types. Each involves the activities of different cell populations or complement. Type I is mediated by mast cells and eosinophils, Type II by complement and some macrophages, Type III by neutrophils, and Type IV is T cell-mediated.

Inflammation and limited tissue destruction are features of the normal innate and adaptive immune responses. Clinical disease occurs when this inflammation is excessive or in an inappropriate location. This may be due to external environmental factors, such as the composition of the intestinal microflora, together with genetic and hormonal influences.

IMMUNODEFICIENCY DISEASES

Immunodeficiency diseases manifest clinically as a predisposition to infections. They are usually recognized when an animal makes multiple visits to a veterinarian for infections that would normally be relatively easy to control. Two major groups of immunodeficiency disease occur. One group is inherited as a result of mutations or other genetic disease. These primary or congenital immunodeficiency diseases usually develop in very young animals (<6 mo old). The second group of immunodeficiency diseases are secondary to some other stimulus such as a viral infection or tumor. These secondary or adaptive diseases tend to occur in adult animals. One other general rule in diagnosing immunodeficiencies is that defects in the innate and antibody-mediated immune systems tend to result in uncontrollable bacterial infections, whereas defects in the cell-mediated immune system tend to result in overwhelming viral and fungal infections.

PRIMARY IMMUNODEFICIENCIES

Defects in Innate Immunity

Phagocytosis is a central feature of innate immunity. Phagocytic cells are found underlying the mucous membranes and skin and in the bloodstream, spleen, lymph nodes, meninges, synovial membrane, bone marrow, and around blood vessels throughout the body. Phagocytes are either in the tissue (histiocytes, synovial macrophages, Kupffer cells, etc) or in the blood (neutrophils and monocytes). Phagocytes have receptors for immunoglobulins and complement on their surfaces that assist in the engulfment (opsonization) of foreign material coated with specific antibody (opsonins) or complement, or both. Phagocytosis involves chemotaxis of the phagocyte toward foreign, noxious, or damaged tissues; adherence of microorganisms to the plasma membrane of the phagocyte; incorporation of the organisms into a phagosome; and activation of the respiratory burst and lysosomal enzymes in the phagosome, leading to microbial death and destruction.

Deficiencies in Phagocytosis:

Deficiencies in phagocytic activity can be due to acquired or congenital defects in any of these steps, or simply to a deficiency of phagocytic cells themselves. They often manifest as an increased susceptibility to bacterial infections of the skin, respiratory system, and GI tract. These infections respond poorly to antibiotics. Secondary phagocytic deficiencies include disorders that lead to profound and chronic depressions of WBCs. Feline leukemia virus infection, feline panleukopenia virus infection, feline immunodeficiency virus infection, tropical canine pancytopenia, idiopathic granulocytopenias, drug-induced granulocytopenias (antineoplastic drugs, estrogens, anticonvulsants, sulfonamides, etc), and myeloproliferative disorders are some of the conditions in which secondary infections can develop as life-threatening complications.

A cyclic decrease of all cellular elements, most notably neutrophils, occurs in the peripheral blood and lowers the resistance to infection of certain lines of gray Collies and Collie crosses.

Congenital abnormalities that lead to impaired phagocytosis are well documented in people. Deficiencies of opsonins, complement factors, chemotactic abilities, and myeloperoxidase have been recognized in people but not in other animals. Chediak-Higashi syndrome results from a defect in

phagosomal function and has been recorded in cats, mink, cattle, and orcas. Chronic granulomatous disease has been recognized as an X-linked defect in some Irish Setters (canine granulocytopenia syndrome). Some lines of Weimaraners develop bacterial septicemias (usually manifested by bone and joint infections) as puppies. The underlying causes of these defects are unknown; some of the affected dogs have lower than normal levels of IgM and IgG, and their WBCs have a bactericidal defect.

Leukocyte Adhesion Deficiency:

Leukocyte adhesion deficiency is an autosomal recessive primary immunodeficiency. It has been described in people, Irish Setters, and Holstein cows. The deficiency results from the absence of an integrin, an essential surface glycoprotein expressed on leukocytes. Clinically, it is characterized by recurrent severe bacterial infections, impaired pus formation, and delayed wound healing. Infected animals usually have severe pyrexia, anorexia, and weight loss. Response to antibiotic therapy is usually poor. Extreme, persistent leukocytosis may occur ($>100,000$ WBCs/mL) and consists predominantly of mature neutrophils. The integrin deficiency prevents blood leukocytes from leaving blood vessels and entering the tissues, so they cannot contribute to the defense of tissues against infections.

Complement Deficiencies:

A congenital deficiency of C3 has been described in Brittany Spaniels. These dogs developed recurrent bacterial infections, especially skin diseases and pneumonias. Although complement is necessary for opsonization and neutrophil chemotaxis, bacterial infections do not always develop in people or laboratory animals with complement deficiencies, because the existence of multiple pathways provides a way to activate the system even if one pathway is blocked. Diagnosis is based on a blood test showing reduced C3 levels.

A congenital deficiency in the C1 inhibitor has been recognized in people and occurs rarely in dogs. This can lead to uncontrolled complement activation and inflammation. Affected animals have recurrent bouts of facial edema.

There is no specific treatment for complement deficiencies. Vaccination and antibiotics are used to prevent and treat infection. As with all inherited diseases, subsequent breeding programs must be carefully assessed to prevent the reappearance of the disease in future generations.

Deficiencies in Adaptive Immunity

Humoral Immunodeficiencies: These deficiencies may be acquired or congenital. Acquired deficiencies are seen in neonates that do not receive adequate maternal antibodies (failure of passive transfer) or in older animals due to conditions that decrease active immunoglobulin synthesis. Failure of passive transfer occurs in species that use colostrum as the major source of maternal antibodies. It is commonly associated with recurrent infections in calves, lambs, and foals. Failure of passive transfer can occur when the young animal fails to nurse properly during the first several days of life or when the dam's colostrum contains low levels of specific antibodies. Defects in the absorption of immunoglobulin from ingested milk may also occur. Immunoglobulin levels <400 mg/dL in a postnursing serum sample indicate a failure of passive transfer in foals. Premature weaning of calves is a problem in dairy herds and is a leading cause of failure of passive transfer in dairy calves. Newborn animals that do not receive sufficient maternal antibodies often succumb to fatal bacterial or viral infections of the GI and respiratory tracts.

Hypogammaglobulinemia of clinical significance can be associated with any disorder that interferes with antibody synthesis. Tumors, such as plasma cell myelomas or lymphosarcomas that secrete large amounts of monoclonal antibody, can be associated with profound antibody deficiencies. This is because the tumor cells outcompete normal immunoglobulin-producing cells, or because regulatory pathways inhibit immunoglobulin production. Animals with tumors that produce monoclonal antibodies may have severe secondary infections. Some viral infections, eg, canine distemper and canine parvovirus, may damage the immune system so severely that antibody production is virtually stopped.

Congenital hypogammaglobulinemia

has been recognized either alone or in combination with defects in cell-mediated immunity (combined immunodeficiency, *see* p 816). Deficiencies in IgG subclasses have been seen in some breeds of cattle; IgM deficiency has been described in horses; and IgA deficiencies have been described in Beagles, German Shepherds, and Chinese Shar-Pei. Cattle with IgG subclass deficiency are usually asymptomatic. Older foals with IgM deficiencies develop respiratory infections. Dogs with IgA deficiency, like their human counter-

parts, are prone to chronic skin infections, chronic respiratory infections, and possibly allergies. IgA deficiency of Beagles appears to be due to a defect in the secretion of IgA, because IgA-positive cells are present in normal numbers. Some German Shepherds have lower IgA levels than other breeds and a higher incidence of intestinal infections. IgA deficiency in Shar-Pei is highly variable; some have negligible serum and secretory levels, and some have normal serum levels and low or negligible secretory levels. Like German Shepherds, affected Shar-Pei have more problems than expected with allergies. Dogs with these immunodeficiency syndromes may have a higher than usual incidence of autoimmune diseases and autoantibodies, such as autoimmune hemolytic anemia, thrombocytopenia, and systemic lupus erythematosus. Long-term treatment with broad-spectrum antibiotics is required and is often unsatisfactory.

Transient hypogammaglobulinemia has been recognized most frequently in foals and puppies. It may be more common in Spitz-type puppies than in other breeds. It results from a delayed onset of immunoglobulin production in the newborn and is associated with defects in both T_H function and the B cell response to foreign antigens. Puppies with this condition develop recurrent respiratory infections at 1–6 mo of age but recover by 8 mo. Affected foals frequently develop clinical signs of hypogammaglobulinemia (usually respiratory infections) at ~6 mo of age when their maternal antibody reaches a very low level. After another 3–5 mo they begin to produce immunoglobulin. Appropriate antibiotic treatment and supportive therapy is often sufficient.

Deficiencies in Cell-mediated

Immunity: Deficiencies in cell-mediated immune responses are associated with **thymic aplasia**, an absent or very small thymus. This has been seen in some inbred lines of dogs, cats, and cattle; these animals were deficient in cell-mediated immune functions, as well as having pituitary dysfunction.

Combined Immunodeficiency

Diseases: If both humoral and cell-mediated immune responses are deficient, they are classified as combined immunodeficiencies (CID). These result from inherited defects in the earliest lymphocyte progenitors. An autosomal recessive CID has been identified in Arabian foals and Basset Hounds. It results from a defect in DNA repair enzymes and prevents the

production of functional antigen receptors. Sporadic cases of CID have also been seen in Toy Poodle, Rottweiler, and mixed-breed puppies. Affected dogs are frequently asymptomatic during the first several months of life but become progressively more susceptible to microbial infections as maternal antibody wanes. Puppies with CID are clinically normal until 6–12 wk of age. The most common cause of death from CID is canine distemper as a consequence of routine immunization with modified-live virus distemper vaccine. Arabian foals with CID frequently succumb to adenovirus pneumonia or other infections when ~2 mo old. The foals are persistently lymphopenic. Precolostral serum samples have no detectable IgM antibody. Immunoglobulin levels are normal initially but then progressively decrease compared with levels in normal foals. At necropsy, the thymus is difficult to identify and is architecturally abnormal. Lymphocyte numbers are depleted in the lymph nodes, Peyer's patches, and spleen. A PCR test can confirm CID in foals and the presence of the gene in heterozygote animals. As a result of such testing, the prevalence of equine CID has declined significantly.

Selective Immunodeficiencies: A large number of immunodeficiency diseases have yet to be fully analyzed, so their precise mechanisms remain unknown. For example, Rottweiler puppies have a breed predilection for severe and often fatal canine parvovirus infections (*see* p 373). Their resistance to other infections is essentially normal, and the basis of this selective immunodeficiency is unknown.

Persian cats have a predilection toward severe, and sometimes protracted, dermatophyte infections (*see* p 874). In some Persian cats, the fungal infections invade the dermis and cause granulomatous disease (mycetomas).

Mink with the Aleutian coat color mutation are susceptible to chronic parvovirus infection and so develop Aleutian disease (*see* p 1872). Other strains of mink are susceptible to infection with this virus but do not develop clinical disease. This is due to inherited Chediak-Higashi syndrome.

Focal and systemic aspergillosis (*see* p 633), and mycoses due to related fungi, affect certain types of dogs. Long-nosed breeds, in particular German Shepherds and Shepherd-crosses, are prone to develop focal aspergillosis in the nasal passages. Systemic aspergillosis is seen almost exclusively in German Shepherds. It is

characterized by fungal pyelonephritis, osteomyelitis, and discospondylitis. The organism can be isolated readily from blood and urine.

Diagnosis of Primary Immunodeficiencies

Recurrent persistent infections in young animals suggest some form of immunodeficiency. A complete differential leukocyte count will reveal whether all leukocyte types are present in appropriate numbers. Immunoglobulin deficiencies can only be detected by means of a quantitative immunoassay such as radial immunodiffusion, although turbidity tests such as those used for the diagnosis of failure of passive transfer are relatively easy to perform and may provide useful diagnostic information.

Primary immunodeficiencies as genetic diseases are generally not treatable and, if diagnosed, steps should be taken to ensure that parent animals that carry defective traits are no longer used for breeding.

SECONDARY IMMUNODEFICIENCIES

In adult animals, immunodeficiencies often occur as a consequence of virus infections, malnutrition, stress, or toxins. These are called secondary immunodeficiencies.

Virus-induced secondary immunodeficiencies are the most important of these.

Virus-induced Immunodeficiencies

One way in which viruses survive in infected animals is by immunosuppression. For example, canine distemper virus infects and kills lymphocytes, causing a profound combined immunodeficiency in affected puppies. This infection is associated with a progressive decline in immunoglobulin levels and increased susceptibility to organisms normally controlled by cellular immunity such as *Pneumocystis* and *Toxoplasma*. Parvoviral infection in both dogs and cats also causes a profound depression in the resistance to fungal infections such as aspergillosis, mucormycosis, or candidiasis in the immediate postrecovery period.

Feline Leukemia Virus (FeLV): FeLV is associated with an increased susceptibility to secondary and opportunistic infections. Acquired immunodeficiency in FeLV infection is multifactorial. Infected cats can have deficiencies of neutrophils, decreased synthesis of antibodies (especially to

bacterial antigens), decreased cellular immunity, and reduced complement levels. Immune responses to FeLV infection also appear to suppress immunity to the feline infectious peritonitis (FIP) coronavirus and may lead to reactivation of quiescent FIP. (See also p 790.)

Simian Type D Retrovirus: This viral infection of macaques has a similar pathogenesis to that of FeLV infection of cats but can induce even more severe immunodeficiency. Type D retrovirus infection of macaques can cause severe disease in adolescent animals. Affected macaques may either die within several months with fever, lymphadenopathy, and opportunistic infections of the CNS, respiratory tract, and intestines; become lifelong asymptomatic carriers; or sometimes recover fully.

Simian Immunodeficiency Virus (SIV):

This lentivirus is closely related to human immunodeficiency virus. Many strains of SIV exist in nature. The common hosts are African primates such as African green monkeys, sooty mangabays, mandrills, baboons, and other guenons. Transmission between infected and noninfected monkeys is probably a result of bites or in utero exposure. SIV is not present in native populations of Asian primates. It rarely causes disease in the host African species. If infected animals are under heavy stress, as in captivity, some may develop AIDS-like disease. SIV, especially of sooty mangabey origin, causes severe disease in macaques (rhesus, stump-tail, pig-tail, bonnet, etc). The immunosuppression associated with SIV can last for weeks or years. Encephalitis (usually asymptomatic except for wasting) and lymphomas are frequent consequences of SIV infection in macaques.

Feline Immunodeficiency Virus (FIV):

FIV has been identified in domestic and wild felids. The infection is endemic in cats throughout the world. Virus is shed in the saliva, and biting is the principal mode of transmission. As a result, free-roaming, male, and aged cats are at greatest risk of infection. FIV infection is uncommon in closed purebred catteries. After infection, there is a transient fever, lymphadenopathy, and neutropenia. Most cats then recover and appear to be clinically normal for many months or years before progressive immunodeficiency develops. Cats with acquired immunodeficiency induced by FIV then develop chronic secondary and

opportunistic infections of the respiratory, GI (including mouth), and urinary tracts, as well as the skin. FIV-infected cats have a higher than expected incidence of FeLV-negative lymphomas, usually of the B-cell type, and myeloproliferative disorders (neoplasia and dysplasias).

Bovine Immunodeficiency-like Virus:

This lentivirus has been isolated from cattle with persistent lymphocytosis, hemolymphadenopathy, and BLV-negative lymphosarcomas. The overall prevalence in North American cattle appears to be ~1%, although in some herds it may be as much as 15%. The virus does not appear to be pathogenic.

EXCESSIVE IMMUNE FUNCTION

There are many different ways by which excessive immune function can cause disease or death. These include excessive innate responses, excessive adaptive responses, and tumors of the immune system.

EXCESSIVE INNATE RESPONSES

While acute inflammation is a defensive process and central to innate immunity, it may occur without appropriate provocation and in locations where it causes discomfort, tissue damage, or systemic disease. This results in significant morbidity and resulting disability.

Canine Rheumatoid Arthritis: This disease results from excessive, uncontrolled inflammation around joints. It manifests initially as a shifting lameness with soft-tissue swelling around involved joints. Within weeks or months, the disease localizes in individual joints, and characteristic radiographic changes develop. The earliest radiographic changes consist of soft-tissue swelling and a loss of trabecular bone density in the area of the joint. Lucent cyst-like areas frequently are seen in the subchondral bone. The most prominent lesion is a progressive erosion of cartilage and subchondral bone in the area of synovial attachments, resulting in loss of articular cartilage and collapse of the joint space. Angular deformities often occur, and luxation of the joint is a frequent sequela. Deformities are most frequent in the carpal, tarsal, and phalangeal joints and less frequent in the elbow and stifle. Synovial fluid examination shows a sterile, inflammatory synovitis, with increased cell count and

a high proportion of neutrophils in the synovial fluid cell population. The excessive inflammation is believed to be due to the deposition of immune complexes in the synovia with subsequent complement activation.

An erosive arthritis has also been recognized in cats. It tends to occur in older male cats and frequently is associated with feline syncytia-forming virus infection. The development of disease in cats is much more insidious than in dogs.

Canine rheumatoid arthritis responds poorly to systemic glucocorticoids alone. Immunosuppressive agents with anti-inflammatory activity such as cyclophosphamide and azathioprine are used with glucocorticoids to treat these disorders; NSAIDs (eg, aspirin, carprofen, etodolac, meloxicam) may bring relief.

Plasmacytic-Lymphocytic Synovitis:

Possibly a variant of rheumatoid arthritis, this synovitis occurs in medium-sized and large breeds of dogs. Although multiple joints often are involved, the disease has a predisposition for the stifle. The most common clinical sign is hindlimb lameness and anterior drawer motion of the stifles. Lymphocytes, plasma cells, and neutrophils predominate in the synovial fluid, although in some cases the fluid is essentially normal. Gross inspection of the joint shows proliferation of the synovial membrane and stretching or rupture of the cruciate ligaments. Treatment is as for canine rheumatoid arthritis, above.

Idiopathic Polyarthritis: Arthritis of unknown etiology is most common in large dogs, particularly German Shepherds, Doberman Pinschers, retrievers, spaniels, and pointers. In toy breeds, it is most frequent in Toy Poodles, Yorkshire Terriers, and Chihuahuas, or mixes of these breeds. There is no evidence of a primary chronic infectious disease process or of systemic lupus erythematosus. Arthritis is often the sole manifestation.

Diagnosis is based on the history of cyclic antibiotic-unresponsive fever, malaise, and anorexia, with stiffness or lameness. Bony changes are not seen on radiographs until the disease is well established. Even then, radiographic changes are mild and can mimic degenerative joint disease. Synovial fluid contains leukocytes but is sterile.

The disease may be controlled with daily high-dose glucocorticoids followed by low-dose, alternate-day therapy. Treatment usually can be discontinued after 3–5 mo. Dogs with poor response to such therapy (>50%) may be treated with more potent

immunosuppressive drugs such as azathioprine or cyclophosphamide in addition to glucocorticoids. Gold salts help augment glucocorticoid therapy in some animals.

Immune-mediated Meningitis: This disease occurs in adolescent or young adult Beagles, Boxers, German Shorthaired Pointers, and Akitas but is very rare in other pure and mixed breeds. The clinical signs consist of cyclic episodes of fever, severe neck pain and rigidity, reluctance to move, and depression. Each attack lasts 5–10 days, with intervening periods of complete or partial normality lasting approximately a week. During attacks, protein and neutrophils in the CSF are increased. The lesion is an arteritis, primarily of the meningeal vessels, but occasionally of other organs as well. The disease is often self-limiting over several months; attacks become milder and less frequent. Glucocorticoid therapy reduces the severity of attacks. In some animals, the disease becomes chronic and only partially amenable to therapy.

A more severe form of this meningitis has been reported in young Bernese Mountain Dogs. The disease in this breed is somewhat cyclical, but the resolution in intervening periods is less than in other species. CSF abnormalities resemble those seen in other breeds. The condition requires longterm, high-dose glucocorticoid therapy.

A syndrome of meningitis, often associated with polyarthritis, is seen in young Akitas. The dogs show severe episodes of fever, depression, cervical pain and rigidity, and generalized stiffness. Affected dogs grow slowly and often appear unthrifty. The condition responds poorly to glucocorticoid and combination immunosuppressive therapy, and most affected dogs are euthanized as young adults. In older Akitas, a milder and more drug-responsive form of the disease is seen, which may be associated with pemphigus foliaceus, uveitis, and plasmacytic-lymphocytic thyroiditis.

Systemic Inflammatory Response Syndrome

In severe infections or after massive tissue damage, large amounts of cytokines and reactive oxygen and radicals enter the bloodstream and cause a form of shock known as systemic inflammatory response syndrome.

Septic shock is the name given to the systemic inflammatory response syndrome specifically caused by severe infections and associated with trauma, ischemia, and tissue injury. Animals with severe infections

may generate vastly excessive cytokine production, most notably IL-1, TNF- α , IL-8, and IL-6. This massive cytokine release has been called “a cytokine storm.” High doses of cytokines are toxic and induce severe acidosis, fever, lactate release in tissues, an uncontrollable drop in blood pressure, increased plasma catecholamines, and eventually renal, hepatic, and lung injury and death. The procoagulant-anticoagulant balance is upset so that endothelial procoagulant activity is enhanced, while many anticoagulant pathways are inhibited, leading to disseminated intravascular coagulation and capillary thrombosis.

All these effects are initiated by excessive triggering of toll-like receptors leading to a massive and uncontrolled release of cytokines. The cytokines damage vascular endothelial cells, activating them so that procoagulant activity is enhanced, which leads to blood clotting. The nitric oxide causes vasodilation and a drop in blood pressure. The widespread damage to vascular endothelium eventually causes organ failure. Multiple organ dysfunction syndrome is the end stage of severe septic shock. It is characterized by hypotension, insufficient tissue perfusion, uncontrollable bleeding, and organ failure caused by hypoxia, tissue acidosis, tissue necrosis, and severe local metabolic disturbances. The severe bleeding is due to disseminated intravascular coagulation. The sensitivity of mammals to septic shock varies greatly. Species with pulmonary intravascular macrophages (cat, horse, sheep, and pig) tend to be more susceptible than dogs.

EXCESSIVE ADAPTIVE RESPONSES

Excessive activity of the adaptive immune system can lead to inflammation and tissue damage, autoimmunity, or amyloidosis. For many years it has been customary to classify excessive adaptive immune system function into four types on the basis of the mechanisms involved.

Type I Reactions

(Atopic disease, Anaphylactic reactions)

Type I, or immediate hypersensitivity, encompasses these IgE-mediated reactions to other, nonparasitic antigens. This inflammation may be minor or local, or severe and generalized. In its most extreme form, it causes a potentially lethal shock syndrome called anaphylaxis. Anaphylaxis is an acute systemic manifestation of the interaction of an antigen (allergen) binding

to IgE antibodies attached to mast cells and basophils. This binding of antigens to cell-bound IgE antibodies triggers the release of biologically active inflammatory mediators, including histamine, leukotrienes, eosinophilic chemotactic factors, platelet activating factor, kinins, serotonin, proteases, and cytokines. These molecules directly affect both the vascular system, causing vasodilation and increased vascular permeability, and smooth muscles, causing contraction. Additionally, they attract pro-inflammatory eosinophils to the triggering site.

The severity of anaphylaxis depends on the type of antigen, the amount of IgE produced, and the amount of antigen and route of exposure. If the animal has been previously sensitized by exposure to an allergen (antigen) and produces IgE antibodies, then injection of the sensitizing antigens directly into the bloodstream can result in anaphylactic shock and related reactions (eg, hives, urticaria, facial-conjunctival edema). If the sensitizing allergen enters through the mucous membranes or the skin, allergic reactions tend to be more localized. Agents that can trigger anaphylactic and allergic reactions are numerous and include the venom of stinging and biting insects, vaccines, drugs, foods, and blood products.

Systemic Anaphylaxis (Generalized Anaphylactic Reactions): Anaphylactic shock occurs in sensitized animals after exposure to antigens in sensitizing vaccines or drugs, ingestion of foods, or insect bites. Clinical signs occur within seconds to minutes after exposure to the allergen. In most domestic animals, the lungs are the primary target organs, and the portal-mesenteric vasculature is a secondary target; this is reversed in dogs. Mast cell degranulation in the pulmonary vasculature causes constriction of bronchial airways or pulmonary veins and pooling of blood and edema in the pulmonary vascular bed, which results in severe respiratory distress. Mast cell degranulation in the portosystemic vasculature causes venous dilatation and pooling of blood in the intestines and liver.

Clinical signs can be localized or generalized and include restlessness and excitement, pruritus around the head or site of exposure, facial edema, salivation, lacrimation, vomiting, abdominal pain, diarrhea, dyspnea, cyanosis, shock, incoordination, collapse, convulsions, and death. In dogs, the major organ affected by anaphylactic shock is the liver, and signs are

associated with constriction of hepatic veins, which results in portal hypertension and visceral pooling of blood. GI signs rather than respiratory signs are more apt to be seen in dogs. Supportive therapy, in addition to treating respiratory distress, consists of the administration of epinephrine (both locally and systemically as needed). IV fluids for the treatment of shock, antihistamines (systemically for severe acute anaphylaxis or orally as a means to control chronic signs of allergy or milder allergic signs), and corticosteroids if needed. Ancillary support of blood pressure and respiration may be necessary.

Urticarial reactions (hives or angioedematous plaques) of the skin and subcutaneous tissue and acute edema of the lips, conjunctiva, and skin of the face (facial-conjunctival angioedema) are less severe forms of Type I hypersensitivity. Hives are the least severe reaction and may not be associated with other clinical abnormalities. Facial-conjunctival edema is more severe and can be associated with mild to moderately severe systemic anaphylaxis. These reactions usually follow administration of vaccines or drugs, ingestion of certain foods, or insect bites. Urticarial reactions and facial-conjunctival edema occur in most species and usually resolve spontaneously within 24 hr. Not all urticarial reactions are mediated by Type I hypersensitivity. (See also URTICARIA, p 857.)

Milk allergy occurs occasionally in cows and less frequently in mares. This occurs when a cow makes IgE autoantibodies to its own milk components, notably casein. When intramammary pressure rises, these milk proteins gain access to the circulation and induce a Type I hypersensitivity. The reaction can be localized or systemic. Recovery occurs once the animal is milked.

Localized Anaphylactic Reactions: **Allergic rhinitis**, manifest by serous nasal discharge and sneezing, is less common in domestic animals than in people. Often, it is seasonal, correlating with pollen exposure. Nonseasonal rhinitis may be associated with exposure to ubiquitous allergens, such as molds, danders, bedding, and feeds. Recurrent airway obstruction in horses (see p 1455) is probably a reaction to chronic exposure to molds present in moldy hay and poorly ventilated stables. Summer snuffles is a seasonal allergic rhinitis occurring commonly in Guernsey or Jersey cattle placed on certain types of flowering pastures in late summer and early autumn. Allergic rhinitis can be diagnosed tentatively by the following: 1) identification of

eosinophils in the nasal exudate, 2) demonstration of a favorable response to antihistamines, 3) disappearance of signs when the offending allergen is removed, or 4) occasionally, its seasonal nature. Skin testing is not an accurate means to diagnose nasal allergies in animals.

Chronic allergic bronchitis has been characterized in dogs. A dry, harsh, hacking cough that is easily precipitated by exertion or by pressure on the trachea is a characteristic clinical sign. The disease may be seasonal or occur year-round. Usually, it is not associated with other signs of illness. The bronchial exudate is rich in eosinophils and free of bacteria. Chest radiographs are normal, and there may or may not be a low-grade peripheral eosinophilia. The condition is treated with bronchodilators and expectorants (aminophylline and potassium iodide or guaifenesin). Glucocorticoids will alleviate clinical signs, especially when their use can be limited to certain seasons or to low-dose, alternate-day therapy. Avoidance of the offending allergen(s) usually is not possible.

Allergic bronchiolitis is most common in cats. It is manifest by a low-grade cough, wheezing, some dyspnea, and increased peribronchiolar density on radiographs, and it may be mistaken for other conditions (allergic asthma or lungworm disease). Early in the course of the disease, clinical signs can be modified by antihistamine therapy, but if the disease increases in severity, moderate to high dosages of corticosteroids may be necessary. The offending allergen usually is not identified.

Eosinophilic bronchopneumopathy occurs most frequently in dogs but has been recognized in all species. It is associated with diffuse inflammatory infiltrates in the lungs and a pronounced peripheral eosinophilia; frequently, the serum globulins are increased. Unlike in allergic bronchitis, affected animals are often dyspneic or tire easily with exercise. Diffuse bronchial exudate contains numerous eosinophils. The specific offending allergen is rarely identified. Glucocorticoids are the treatment of choice. A similar syndrome is also associated with resident or migratory parasitic infections of the lungs in young animals.

Allergic asthma occurs most frequently in cats, in which the signs are similar to those in people. It occurs more frequently in summer and after going outdoors; individual attacks can be transient and mild, or protracted and severe (status asthmaticus). Mild attacks may manifest as wheezing and coughing; in severe attacks, there may be expiratory dyspnea, hyperin-

flation of the lungs, aerophagia, cyanosis, and frantic attempts to obtain air.

Intestinal allergies (food allergies) are principally seen in dogs and cats, particularly kittens. (See also p 855 and p 2379.) Allergic gastritis is manifest by vomiting, which occurs 1 to >12 times weekly, within 1–2 hr of eating. The vomitus may be tinged with bile. In cats, vomiting may be the sole sign; dogs may also have intermittent loose feces. Cats and dogs with allergic gastritis are usually healthy except for vomiting, although there can be loss of weight and coat condition in severe cases. Allergic enteritis is associated with a mild inflammation of the small intestine but with little or no eosinophilia. Feces usually are normal in volume and frequency but vary from semiformal to watery. They may be extremely odorous, especially in cats. Affected animals may be excessively thin despite good appetite. Skin lesions and poor coat are commonly associated with food allergies in cats but less commonly in dogs. The allergy often develops after episodes of viral, bacterial, or protozoal enteritis (a phenomenon known as allergic breakthrough). Eosinophilic enteritis, the most severe form of allergic intestinal disease, manifests by moderate to severe inflammation of the intestines and a pronounced eosinophilia. Diarrhea, weight loss, and poor coat condition are usually evident. The prevalence of allergic colitis is greater in cats than in dogs, although in general it is not common. In dogs, it is often associated with frequent defecation and soft, mucus-laden and sometimes bloody feces; in cats, it most frequently manifests by more normal feces coated or spotted with fresh blood. (For diagnosis and treatment of food allergies, see p 855.)

Atopic dermatitis (see p 853) is a complex pruritic, chronic skin disorder that occurs in many species but has been studied mostly in dogs. Some animals with atopic dermatitis may have a genetic predisposition that leads to excessive production of reaginic (IgE) antibodies. It has been estimated that ~10% of all dogs suffer from atopy, with a breed predisposition in terriers, Dalmatians, and retrievers. Atopic dermatitis of dogs often is triggered by inhaled allergens, eg, house dust mites, pollens, molds, and danders. Atopic dogs often chew at their feet and axillae. Excessive sweating is especially noticeable in hairless areas. The severity of the skin lesions are greatly increased by licking, scratching, flea infestation, and secondary bacterial or yeast

infection. Atopic skin lesions in cats are either miliary (small scabs) and widespread, or larger and more localized. Localized lesions are often pruritic.

In cats, food allergens probably are a more common cause of skin lesions than are inhaled allergens. Sweet itch (*see* p 887) is a seasonal allergic dermatitis of horses associated with certain insect bites, especially night-feeding *Culicoides*. Intensely pruritic lesions appear along the dorsum from the ears to tail head and perianal area. Similar allergic skin reactions to insect bites can be seen around the ears and face of cats and dogs. (For diagnosis and treatment, *see* p 853.)

Type II Reactions

(Antibody-mediated cytotoxic reactions)

Type II reactions occur when an antibody binds to an antigen present on the surface of cells. This bound antibody can then activate the classical complement pathway, resulting in cell lysis, phagocytosis, or antibody-mediated cytotoxicity. Many different antigens may trigger this cell destruction, but an infection in a genetically predisposed animal appears to be a major triggering pathway. Cross-reactive antibodies can develop during infections. These cross-reactive antibodies directed toward an infectious agent may bind to normal tissue antigens and trigger antibody-mediated cytotoxicity. For example, in streptococcal infection in horses, a cross-reaction between *Streptococcus equi* antigen and vascular basement membranes can occur, leading to purpura hemorrhagica. Pathogens such as *Babesia* or *Mycoplasma haemofelis*, which parasitize cells, trigger an immune response that destroys those cells as part of the protective mechanism. The most common manifestations of Type II hypersensitivity involve blood cells. These include hemolytic anemia if RBCs are involved, leukopenia involving WBCs, or thrombocytopenia involving platelets. Under some circumstances, a cytotoxic attack on vascular epithelial cells will cause a vasculitis with local vascular leakage.

Immune-mediated Hemolytic Anemia (IMHA) and Thrombocytopenia:

The production of autoantibodies against erythrocyte or platelet antigens leads to anemia and thrombocytopenia, the most common Type II reactions. Antibody and complement attach to RBCs either directly or indirectly via an absorbed antigen and then mediate RBC destruction, resulting in a severe, life-threatening anemia. Concurrent

thrombocytopenia is found in 60% of cases. IMHA can be associated with systemic lupus erythematosus or with lymphoreticular malignancies. Drugs or infections may trigger episodes of hemolytic anemia or thrombocytopenia in many species. More often than not, the initiating cause is unknown.

IMHA occurs in several clinical forms: peracute, acute or subacute, chronic, cold agglutinin disease, and red cell aplasia. Most cases are treatable, but relapses are common. (*See also* p 10.)

Peracute IMHA is seen mainly in middle-aged, larger breeds of dogs. Affected dogs are acutely depressed and have a rapid decrease in PCV within 24–48 hr with bilirubinemia, variable icterus, and sometimes hemoglobinuria. Initially, the anemia is nonresponsive, but it may respond within 3–5 days. Thrombocytopenia may also be present. Antiglobulin tests are often negative, and spherocytes may or may not be present, but tube or slide agglutination of RBCs is marked. The autoagglutination is not dispersed by saline dilution, hence the term hemolytic anemia with in-saline agglutinins. The serum usually contains autoantibodies that cause agglutination of most donor RBCs. The prognosis of peracute IMHA is poor even with prompt and vigorous therapy. The most effective therapy involves immediate use of high dosages of glucocorticoids plus cyclophosphamide, together with a compatible blood transfusion. If incompatible blood must be used, the animal should first be heparinized and maintained on heparin for 10 days. Even without transfusion, heparinization may be beneficial for the first 2 wk or more. Bovine hemoglobin blood substitute and human immunoglobulins can be used as supportive therapy until immunosuppressive treatment reduces the destruction of RBCs.

Acute IMHA is the most common form of the disease, with a breed predilection in Cocker Spaniels. Initial signs are pallor, fatigue, and less commonly, icterus. Hepatosplenomegaly is a prominent sign. The WBC count may be increased due to bone marrow hyperplasia. Autoagglutination of RBCs is uncommon, and the antiglobulin test is generally positive. These animals usually respond well to glucocorticoid therapy. If a favorable response is not seen within 7–10 days, cytotoxic drugs (cyclophosphamide or azathioprine) should be added to the regimen.

Chronic IMHA differs from the acute form in that the PCV falls to a constant level and remains there for weeks or months. The bone marrow is either normal or hyperresponsive, and the antiglobulin test

is often negative. Chronic IMHA is relatively more common in cats than in dogs. Usually, the anemia is responsive early in the course of disease but responds minimally or not at all by the time it becomes severe. Initial treatment is with glucocorticoids; if there is no response within 2 wk, cytotoxic drugs may be added to the regimen.

Cold agglutinin disease is an IMHA of dogs and horses. Its cause is usually unknown but may be secondary to infection, other autoimmune diseases, or neoplasia. The IgM autoantibodies can be agglutinating or nonagglutinating. Complete agglutination does not occur at body temperature but only when the blood is chilled; thus, it is more frequent in colder climates and seasons. Initial signs may be of a hemolytic disease; in the agglutinating type, vascular blockage may lead to necrosis of the nose, tips of the ears and tail, digits, scrotum, and prepuce. Diagnosis is based on a reversible autoagglutination that occurs only at 4°C. The direct antiglobulin reaction is usually negative for IgG, frequently positive for C3, and usually positive for IgM if the reaction is performed in the cold. Mortality is high. In the absence of an obvious initiating cause such as infection or neoplasia, the disease is best controlled with high doses of glucocorticoids in combination with cyclophosphamide.

Red cell aplasia (see p 13) is most common in dogs. It occurs in two forms, one in postweanling to adolescent puppies and the other in adults. Unlike in IMHA, the bone marrow shows a selective depression of erythroid elements; granulocytes and platelets are unaffected. Therefore, the peripheral anemia is unresponsive. The immune attack is directed against erythroid stem cells, and the antiglobulin test is usually negative. Treatment is usually as for chronic IMHA, but recovery may be very slow.

Immune-mediated thrombocytopenia is common in dogs. It occurs more often in females than males. The most frequent clinical signs are hemorrhages of the skin and mucous membranes. Melena, epistaxis, and hematuria may be accompanying features and can cause profound anemia. Hemolytic anemia and thrombocytopenia sometimes occur together. Immune-mediated thrombocytopenia usually is diagnosed on the basis of low peripheral platelet counts despite a pronounced megakaryocytosis in the marrow. Occasionally, megakaryocytes may be selectively absent from the marrow. Tests for antiplatelet antibodies are difficult to conduct, so diagnosis is usually made on clinical presentation and response to therapy. (See also p 46.)

Animals with immune-mediated thrombocytopenia that show only petechial and ecchymotic hemorrhages, with no significant blood loss and megakaryocytes in the marrow, may be treated initially with glucocorticoids. The clinical signs should abate and the platelet count begin to rise after 5–7 days. If the platelet count has not increased significantly by 7–10 days, cyclophosphamide, azathioprine, or vincristine can be added to the glucocorticoid regimen. In animals with megakaryocytes in the marrow and severe blood loss, a more rapid response to therapy is desirable. Such animals are treated with a single injection of vincristine combined with daily glucocorticoids; a favorable response usually occurs after 3–5 days. If the blood loss is life-threatening, platelet-rich whole blood should be administered. If the platelet count has risen by day 7, remission is maintained on glucocorticoids alone. If there is no response after 7 days, a second dose of vincristine is given. If the platelet count is still low after 2 wk, vincristine is discontinued and either cyclophosphamide or azathioprine is added. Animals with thrombocytopenia and no megakaryocytes respond much more slowly to glucocorticoids, or to glucocorticoids and vincristine. Preferred treatment for these animals is with prednisolone and cyclophosphamide, and a response should not be expected earlier than 1–2 wk after beginning therapy. Therapy may be discontinued in most animals with immune-mediated thrombocytopenia 1–3 mo after the platelet count returns to normal. Some animals have a persistent thrombocytopenia despite drug therapy, or they can be maintained in remission only with chronic high-dose treatment. The alternatives are to allow the animal to live with the thrombocytopenia if signs are minimal or to use long-term combination drug therapy with glucocorticoids and either vincristine, azathioprine, or cyclophosphamide. Splenectomy is seldom curative by itself but may allow use of lower and safer dosages of immunosuppressive drugs.

Autoimmune Skin Disorders: In these diseases, affected animals make autoantibodies against the intracellular cement proteins in the epidermis. This promotes local proteolysis, leading to separation of the epidermal cells (acantholysis) and development of vesicles within the skin. Although not strictly a Type II disease, it is best considered here.

Pemphigus foliaceus is the most common of these diseases, occurring more often in dogs than in cats and horses.

It is characterized by the development of erosions, ulcerations, and thick encrustations of the skin and mucocutaneous junctions. The absence of lesions in the mouth, and the widespread thick, crusty nature of the skin lesions, tend to differentiate pemphigus foliaceus from the much rarer pemphigus vulgaris. Autoantibodies in the skin react with intracellular cement (desmoglein), resulting in its degradation and separation of the cornified and uncornified cell layers. Immunosuppression is required to treat the disease. High doses of glucocorticoids are used initially, but low-dose, alternate-day therapy is used once the disease is under control. More potent immunosuppressive drugs such as cyclophosphamide or azathioprine may be used with glucocorticoids in cases unresponsive to steroids. Animals that respond poorly to initial therapy, or require high dosages of drugs to control lesions, have a poor longterm prognosis.

Pemphigus vulgaris is a much less common autoimmune skin disease than pemphigus foliaceus. It is characterized by vesicle formation along the mucocutaneous junctions of the mouth, anus, prepuce, and vulva, and in the oral cavity. Other areas of the skin are only mildly involved. Because the epidermis of animals is relatively thin (compared with human skin), these blisters rupture rapidly and form erosions; consequently, characteristic bullae are seldom seen. The vesicles develop as a result of suprabasilar acantholysis. Secondary bacterial infection often complicates the lesions, and if untreated, the disease is often fatal. It is treated with high doses of glucocorticoids alone or in combination with other drugs such as cyclophosphamide, azathioprine, or gold salts. Pemphigus vulgaris is difficult to maintain in remission, and the longterm prognosis of affected animals is fair to poor.

Bullous pemphigoid is a rare canine skin disease recognized most often in Collies and Doberman Pinschers. Lesions are often widespread but tend to be concentrated in the groin. The involved skin resembles a severe scald. Bullae also develop; they are subepidermal and may be full of eosinophils. Autoantibodies to the basal lamina can be detected in immunohistopathologic sections. The treatment of choice is prednisolone and azathioprine used in combination; remission is frequent, but continual drug therapy at relatively high dosages may be required to keep the disease under control. The longterm prognosis is poor.

Myasthenia Gravis: Myasthenia gravis is an autoimmune disease in which autoantibodies directed against the acetylcholine receptors on muscle cells cause receptor degradation or blockage and so block neuromuscular transmission. The disease is characterized by extreme generalized muscle weakness, which is accentuated by mild exercise. Megaesophagus due to paralysis of esophageal muscles is a frequent primary or accompanying complaint in dogs. Thymomas are often associated with myasthenia gravis in people but are uncommon in domestic species. Administration of a short-acting anticholinesterase (edrophonium chloride) produces a dramatic increase in muscle strength. Treatment is with a long-acting anticholinesterase. Chronic immunosuppressive drug therapy for this disease is logical. Autoantibodies to the acetylcholine receptors can be detected in the serum of affected animals by an indirect immunohistopathologic assay using normal muscle as a substrate.

Type III Reactions

(Immune complex disease)

Antigen-antibody complexes (immune complexes) deposited in tissues may cause acute inflammation. By activating the classical complement pathway, the complexes produce potent chemoattractants that attract large numbers of neutrophils. These cells, especially if they release their enzymes and oxidants, cause acute inflammation and tissue damage. The most frequently affected sites include the joints, skin, kidneys, lungs, and brain.

The prerequisite for the development of immune complex disease is the persistent presence of soluble antigen and antibody. These form insoluble immune complexes that become trapped on the basement membrane of small blood vessels. The deposited immune complexes then activate the classical complement pathway. Complement fragments attract neutrophils and are also directly vasoactive, triggering a vasculitis. Antigens persist for a number of reasons, including chronic infections and certain neoplastic conditions, particularly lymphoreticular neoplasms. Chronic antigen exposure also occurs with inhaled antigens and, in such cases, immune complexes form in the alveolar walls. Lastly, some animals respond to self-antigens, which then act as a source of chronic antigen exposure. In many cases, the origin of the antigen within these immune complexes cannot be determined.

The location of the immune complexes is largely determined by the route by which antigen enters the body. Inhaled antigens give rise to a pneumonitis, antigens that enter through the skin cause local skin lesions, and antigens that access the bloodstream form immune complexes that are deposited in renal glomeruli or joints. Clinical signs are therefore variable but may include fever, cutaneous signs (such as erythema multiforme), and polyarthritis (shifting-leg lameness or painful, swollen joints). Other signs include ataxia, behavior change, proteinuria, isosthenuria, polydipsia, polyuria, or nonspecific signs such as vomiting, diarrhea, or abdominal pain. Diagnosis is based on the elimination of more common causes of clinical signs. Supporting evidence to confirm the diagnosis includes establishing a temporal relationship if a drug or infectious agent is suspected as the cause, identifying chronic infections or malignancies, and performing histopathology and immunohistochemistry on biopsies to identify immune-mediated vasculitides or nephritis.

Therapy should include supportive treatment, removal of the causative agent, or treatment of the underlying disorder (eg, appropriate antibiotic therapy for bacterial infections, surgical drainage of abscesses or infected tissue, therapy for heartworm disease, the withdrawal of drugs). Immunosuppressive therapy may be needed to prevent the continued deposition of immune complexes.

Membranoproliferative Glomerulonephritis: This lesion is caused by immune complexes that form within the bloodstream and are filtered out in the glomeruli (see p 1517). In effect, the insoluble complexes collect on the glomerular basement membrane. Depending on their size, they may be deposited on the subendothelial or subepithelial surface of the membrane. Secondary glomerulonephritis occurs as a sequela of chronic infectious, neoplastic, or immunologic disorders. Animals with idiopathic glomerulonephritis (>50% of cases) usually have signs of renal disease, whereas secondary glomerulonephritis is often a relatively minor part of a more serious disease.

Hypersensitivity Pneumonitis: When inhaled antigens meet circulating antibodies in the walls of the alveoli, immune complexes form in the alveolar walls and trigger acute inflammation. Hypersensitivity pneumonitis is most common in large animals exposed over a long time to

antigenic dusts. The most potent antigens of this type are those contained in the spores of thermophilic actinomycetes from moldy hay. Inhalation of these spores causes farmer's lung disease in people and a similar condition in cattle (see p 1441). Hypersensitivity pneumonitis is characterized by the onset of respiratory distress 4–6 hr after exposure to moldy hay. The most effective treatment is removal of the source of the antigen; otherwise, corticosteroid therapy may help.

Systemic Lupus Erythematosus (SLE):

This complex autoimmune disease occurs in dogs, is rare in cats, and has been reported in large animals. It has two consistent immunologic features: immune complex disease and a tendency to produce multiple autoantibodies. Clinically, it reflects a combination of Type II and III mechanisms. Antibodies to nucleic acids are the diagnostic hallmark of SLE, but in many individuals, antibodies to RBCs, platelets, lymphocytes, clotting factors, immunoglobulin (rheumatoid factors), and thyroglobulin are also present. The presence of autoantibodies to nucleic acids, antinuclear antibodies (ANA), can be diagnostic of the disease. Either the immune complex or the autoantibody component of the disease tends to predominate in a given animal. Immune complex deposition around small blood vessels may lead to synovitis, dermal reactions, oral erosions and ulcers, myositis, neuritis, meningitis, arteritis, myelopathy, glomerulonephritis, or pleuritis. Glomerulonephritis is one of the major life-threatening complications of SLE in cats but not in dogs. Psychosis, a major sign of SLE in people, is also seen in animals with SLE. Autoimmune hemolytic anemia or thrombocytopenia, or both, are the most common presentations of SLE in animals.

SLE is characterized by the presence of ANA, and tests for these or the associated lupus cells may help in diagnosis. However, some healthy animals may have ANA, and not all animals with SLE have detectable ANA in their blood. Diagnosis of SLE must therefore be based on the entire clinical syndrome—not just on the presence or absence of ANA.

SLE usually can be treated with glucocorticoids. Initially, they are used in high daily doses, and when remission occurs, alternate-day, low-dose therapy is used. Drug treatment should be continued for 2–3 mo after all clinical signs have resolved. Cyclophosphamide or azathioprine, or both, are used in combination

with glucocorticoids in animals with SLE that is difficult to control with glucocorticoids alone.

Vasculitis: Vasculitis mediated by immune complexes occurs in animals, especially dogs and horses. Lesions are most prevalent in the dermis of the distal limbs and mucous membranes of the mouth, particularly the palate and tongue (dogs) and lips (horses). Involvement of the nose, ears, eyelids, cornea, and anus is less common. Early lesions develop as reddened areas that rapidly form shallow erosions. A scab quickly forms over dermal erosions. Limb edema is common in horses and a less frequent but equally striking sign in dogs. Vasculitis is a feature of SLE in some animals but most often is idiopathic. Drug-induced vasculitis has been well recognized in dogs. The vasculitis is detected on histopathologic and immunohistopathologic examination of superficial and deep biopsies taken from the margins of lesions.

Vasculitis is treated by withdrawal of offending drugs and, if necessary, by immunosuppressive drug therapy. Glucocorticoids used alone or in combination with other agents such as azathioprine or cyclophosphamide are usually used to treat non-drug-induced cases.

Periarteritis Nodosa (Polyarteritis Nodosa, Necrotizing Polyarteritis):

This rare disease of domestic animals is caused by deposition of immune complexes and inflammation in walls of small and medium-sized arteries. Among farm animals, it is most common in pigs, usually associated with erysipelas and streptococcal infections, and is attributed to a Type III reaction to these bacteria or to their vaccines. It has been reported in cats, although it may be mistaken for the noneffusive form of feline infectious peritonitis.

Other Type III Reactions: Purpura

hemorrhagica of horses is a severe nonthrombocytopenic purpura (see p 47) that often follows a *Streptococcus equi* respiratory infection; it is mediated by immune complexes of antibody and streptococcal antigen deposited in vascular basement membranes.

Anterior uveitis ("blue-eye," see p 495) is an immune complex-mediated reaction that frequently occurs in the recovery stage of infectious canine hepatitis (see p 798). It results from the reaction of serum antibodies with uveal endothelial cells infected with canine adenovirus 1. Similarly,

Purpura hemorrhagica, ocular lesions, in a horse. Courtesy of Dr. Thomas Lane.

severe **equine recurrent uveitis** (see p 508) is associated with immunologic reactions to *Leptospira* or *Onchocerca* spp. This periodic ophthalmia results from autoimmune attack. Antibodies against some serovars of *Leptospira* can cross-react with retinal antigens and so trigger severe ophthalmia. Uveitis caused by *Toxoplasma* and feline infectious peritonitis virus infections of cats may also have an immunologic basis.

Type IV Reactions

(Cell-mediated immune reactions)

Cell-mediated immune reactions occur when antigen triggers T_H1 responses. Multiple cytokines as well as activated macrophages and cytotoxic T cells are produced. The infiltration of mononuclear cells and the elaboration of a variety of inflammatory molecules from these cells in tissues result in the pathologic processes of cell-mediated immune reactions. The antigens usually responsible for the development of Type IV reactions include intercellular bacteria or parasites, some viruses, chemicals, and (in certain situations) cellular antigens. The lesions commonly occur in the skin (allergic contact dermatitis) when the antigen comes into contact with the skin. The diagnosis is based on eliminating other causes of disease and on histology. The goals of treatment are to identify and eliminate the source of antigen responsible for the reaction and to provide anti-inflammatory or immunosuppressive therapy as required.

Granulomatous Reactions: T cell-mediated granulomatous reactions may also occur around persistent infectious foci. These reactions to microorganisms such as mycobacteria, *Coccidioides* spp, *Blastomyces* spp, and *Histoplasma* spp,

and possibly feline infectious peritonitis virus, may be a result of chronic cell-mediated immune reactions and localized macrophage activation. Although cell-mediated immunity effectively controls these types of infections in most animals, for poorly understood reasons, these same mechanisms are only partially effective in others. These granulomatous reactions are characterized by the development of a fibrous stroma and an infiltration of macrophages, giant cells, and lymphocytes around the persistent antigen.

Lymphocytic Choriomeningitis:

Lymphocytic choriomeningitis, a viral infection of mice (*see* p 2025), results from the destruction of virus-infected cells by T cells, leading to CNS damage and a choriomeningitis.

Old-dog Encephalitis: Old-dog encephalitis (*see* p 777) may also result from cell-mediated immune mechanisms directed against cells persistently infected with canine distemper virus. The initiating canine distemper virus infection is usually clinically inapparent and may precede the development of encephalitis by many years.

Allergic Contact Hypersensitivity:

Allergic contact hypersensitivity results from chemicals reacting with and modifying normal dermal proteins. The modified proteins trigger a cell-mediated immune response, which causes inflammation and damages the skin (eg, poison oak and poison ivy reactions in people). This reaction has been described in dogs, cattle, and horses and usually occurs as a result of contact with sensitizing chemicals incorporated in plastic food dishes, plastic collars, and drugs placed on the skin.

Autoimmune Thyroiditis: Autoimmune thyroiditis in dogs is characterized by destruction of the thyroid gland by an autoimmune process that has both humoral (Type II) and cell-mediated (Type IV) components. It is particularly prevalent in Doberman Pinschers, Beagles, Golden Retrievers, and Akitas. Hypothyroidism (*see* p 553) may be the sole manifestation of the disease or may be a clinical or subclinical component of a broader autoimmune disorder such as systemic lupus erythematosus or panendocrinopathy.

Autoimmune Adrenalitis: Autoimmune adrenalitis has been reported in dogs. The adrenal glands are slowly destroyed by a

plasmacytic-lymphocytic infiltrate. When sufficient glandular tissue is destroyed, the dogs develop Addison syndrome (adrenocortical insufficiency, *see* p 574). The condition is sometimes associated with autoimmune thyroiditis (*see* above).

Keratitis Sicca: Keratitis sicca is a "dry eye" syndrome that occurs in dogs. It can occur in either a primary form or secondary to chronic use of sulfonamides. It results from immune-mediated destruction of the lacrimal glands and is similar to Sjögren syndrome of people. Affected dogs may respond favorably to cyclosporine eye drops.

TUMORS OF THE IMMUNE SYSTEM

The cells of the immune system may become neoplastic. This may result in the production of tumor cells that are nonfunctional and hence lead to immunodeficiencies. Alternatively, they may be functional, and some cancerous B cells may produce large quantities of immunoglobulins.

Tumor cells escape from the immune attack by relying on both immunosuppression and tumor cell modification. The demonstration that even bulky, invasive tumors can undergo complete remission under appropriate stimulation (eg, IL-2) has shown that it is indeed possible to treat some cancers successfully by immune manipulation.

Lymphomas are common tumors in dogs and cats. The normal adaptive response requires a burst of rapid proliferation of lymphocytes. On occasion, however, this proliferation may be uncontrolled, and lymphoid neoplasms result. Because lymphocytes are present in all organs, lymphoid tumor development can occur in any organ. Lymphomas can be multicentric, mediastinal, GI, renal, nervous, or leukemic. Less commonly, they occur in the eyes, skin, or nose. To determine the stage of the disease, CBC, serum chemistry profiles, abdominal ultrasound, abdominal radiographs, and bone marrow analyses are useful. Immunofluorescent staining and immunophenotyping can be performed in dogs and cats to characterize lymphomas. They may be either T cell or B cell in origin.

Most cases of canine lymphosarcoma, Marek's disease, calf leukosis, and feline leukemia are of T-cell origin, as are thymomas. Many T-cell lymphomas are associated with a simultaneous immunosuppression manifest by a predisposition to recurrent infections.

Adult bovine and ovine leukosis, alimentary feline leukemia, and avian leukosis are usually of B-cell origin. Under some circumstances, neoplastic B cells may develop into plasma cells. Plasma-cell tumors are known as myelomas. Because neoplastic plasma cells can secrete immunoglobulins, they give rise to gammopathies (see below).

GAMMOPATHIES

Gammopathies are conditions in which serum immunoglobulin levels are greatly increased. They can be classified either as polyclonal (increases in all major immunoglobulin classes) or monoclonal (increases in a single homogeneous immunoglobulin).

Polyclonal gammopathies result from chronic stimulation of the immune system. They can therefore be caused by chronic pyodermas; chronic viral, bacterial, or fungal infections; granulomatous bacterial diseases; abscesses; chronic parasitic infections; chronic rickettsial diseases, such as tropical canine pancytopenia; chronic immunologic diseases, such as systemic lupus erythematosus, rheumatoid arthritis, and myositis; or by some neoplasia. In many cases, there is no obvious predisposing cause. In some animals, the gammopathy may initially be monoclonal because of the predominance of a single immunoglobulin class (usually IgG). This has been seen in cats with noneffusive feline infectious peritonitis and in dogs with chronic tropical canine pancytopenia.

Monoclonal gammopathies are characterized by the production of large amounts of a single immunoglobulin protein. Monoclonal gammopathies are either benign (ie, associated with no underlying disease), or more commonly, associated with immunoglobulin-secreting tumors.

Tumors that secrete monoclonal antibodies originate from plasma cells (myelomas). Myelomas can secrete intact

proteins of any immunoglobulin class or immunoglobulin subunits (light chains or heavy chains). Myeloma proteins in dogs are commonly IgG or IgA and less commonly IgM. Myelomas of the IgA type are particularly common in Doberman Pinschers. Myeloma proteins in cats and horses usually are IgG and, uncommonly, IgM, IgG3 (horses), or IgA.

Clinical signs depend on the location and severity of the primary neoplasm and on the amount and type of immunoglobulin secreted. Plasma-cell myelomas frequently develop in marrow cavities of flat bones of the skull, ribs, and pelvis, and in the vertebrae and cause severe bone erosion. Pathologic fractures of diseased bone can lead to spinal pain and lameness.

Disease can result from the presence of the monoclonal protein itself. For example, some forms of amyloidosis (see p 592) are due to deposition of immunoglobulin light chains in tissues (SAA amyloid). Hyperviscosity syndrome occurs in 20% of dogs with IgM or IgA monoclonal proteins if the protein levels in blood are high. In this syndrome, plasma viscosity can be many times normal, resulting in profound vascular disturbances, thrombosis, and bleeding. Depression, blindness, and neurologic manifestations can be due to hemorrhage in the nervous system and retina. Some IgM monoclonal proteins are cryoglobulins and aggregate *in vitro* and *in vivo* when the plasma is cooled. Animals with cryoglobulinemia often develop gangrenous sloughs of the ear tips, eyelids, digits, and tip of the tail, especially during cold weather. Animals with monoclonal gammopathies may have depressed levels of normal immunoglobulins and are therefore immunodeficient.

Immunoglobulin-secreting tumors usually are treated with appropriate chemotherapy. Plasmapheresis may be required to lower serum viscosity in animals with clinical signs of hyperviscosity syndrome.

INTEGUMENTARY SYSTEM INTRODUCTION

The skin is the largest organ of the body and, depending on the species and age, may represent 12%–24% of an animal's body weight. The skin has many functions, including serving as an enclosing barrier and providing environmental protection, regulating temperature, producing pigment and vitamin D, and sensory perception. Anatomically, the skin consists of the following structures: epidermis, basement membrane zone, dermis, appendageal system, and subcutaneous muscles and fat.

Epidermis: The epidermis is composed of multiple layers of cells consisting of keratinocytes, melanocytes, Langerhans cells, and Merkel cells.

Keratinocytes function to produce a protective barrier. They are produced from columnar basal cells attached to a basement membrane. The rate of cell mitosis and subsequent keratinization are controlled by a variety of factors, including nutrition, hormones, tissue factors, immune cells in the skin, and genetics. The dermis may also exert significant control over the growth of the epidermis. It has been hypothesized that photoperiod and reproduction cycles may affect the epidermis in animals. Glucocorticoids decrease mitotic activity; disease and inflammation also alter normal epidermal growth and keratinization. As keratinocytes migrate upward, they undergo a complex process of programmed cell death or keratinization. The goal of this process is to produce a compact layer of dead cells called the stratum corneum, which functions as an impermeable barrier to the loss of fluids, electrolytes, minerals, nutrients, and water, while preventing the penetration of infectious or noxious agents into the skin. The structural arrangement of keratin and

the lipid content of the skin are critical to this function. The vitamin D precursor, 7-dehydrocholesterol, is formed in the epidermis. The epidermis is thickest in large animals. The stratum corneum is continuously shed or desquamated.

Melanocytes are located in the basal cell layer, outer root sheath, and ducts of sebaceous and sweat glands. They are responsible for the production of skin and hair pigment (melanin). Production of pigment is under hormonal and genetic control.

Langerhans cells are mononuclear dendritic cells that are intimately involved in regulating the immune system of the skin. They are damaged by excessive UV light exposure and glucocorticoids. Antigenic and allergenic material is processed by these cells and transported to local and nodal T cells to induce hypersensitivity reactions. Epidermal proteins may also conjugate with exogenous haptens, rendering them antigenic.

Merkel cells are specialized sensory cells associated with skin sensory organs, eg, whiskers and tylotrich pads.

Basement Membrane Zone: This area serves as a site for attachment of basal epidermal cells and as a protective barrier between the epidermis and dermis. A variety of skin diseases, including several autoimmune conditions, can cause damage to this zone. Vesicles are an example of a damaged basement membrane zone.

Dermis: The dermis is a mesenchymal structure that supports, nourishes, and to some degree, regulates the epidermis and appendages. The dermis consists of ground substance, dermal collagen fibers, and cells (fibroblasts, melanocytes, mast cells, and

occasionally eosinophils, neutrophils, lymphocytes, histiocytes, and plasma cells). Blood vessels responsible for thermoregulation, nerve plexuses associated with cutaneous sensation, and both myelinated and unmyelinated nerves are present in the dermis. Motor nerves are primarily adrenergic and innervate blood vessels and arrector pili muscles. Except in horses, apocrine glands do not appear to be innervated. Sensory nerves are distributed in the dermis, hair follicles, and specialized tactile structures. The skin responds to the sensations of touch, pain, itch, heat, and cold.

Appendageal System: These structures grow out of (and are continuous with) the epidermis and consist of hair follicles, sebaceous and sweat glands, and specialized structures (eg, claw, hoof). The hair follicles of horses and cattle are simple, ie, the follicles have one hair emerging from each pore. The hair follicles of dogs, cats, sheep, and goats are compound, ie, the follicles have a central hair surrounded by 3–15 smaller hairs all exiting from a common pore. Animals with compound hair follicles are born with simple hair follicles that develop into compound hair follicles.

The growth of hair is controlled by a number of factors, including nutrition, hormones, and photoperiod. The growing stage of the hair is referred to as anagen, and the resting stage (mature hair) is referred to as telogen. The transitional stage between anagen and telogen is catagen. Animals normally shed their hair coat in response to changes in temperature and photoperiod; most animals undergo a shed in the early spring and early fall. The size, shape, and length of hair is controlled by genetic factors but may be influenced by disease, exogenous drugs, nutritional deficiencies, and environment. Hormones have a significant effect on hair growth. Thyroxine initiates hair growth, and glucocorticoids inhibit hair growth. The primary functions of the hair coat are to provide a mechanical barrier, to protect the host from actinic damage, and to provide thermoregulation. In most species, trapping dead air space between secondary hairs conserves heat. This requires that the hairs be dry and waterproof; the cold-weather coat of many animals is often longer and finer to facilitate heat conservation. The hair coat can also help cool the skin. The warm-weather coat of animals, particularly large animals, consists of shorter thicker hairs and fewer secondary hairs. This anatomic change allows air to move easily through the coat, which facilitates cooling.

The hair coat also helps conceal or camouflage the animal.

Sebaceous glands are simple or branched alveolar, holocrine glands that secrete sebum into the hair follicles and onto the epidermal surface. They are present in large numbers near the mucocutaneous junction, interdigital spaces, dorsal neck area, rump, chin, and tail area; in some species, they are part of the scent-marking system. For example, in cats, sebaceous glands are present on the face, dorsum, and tail in high concentration; cats mark territories by rubbing their face on objects and depositing a layer of sebum laced with feline facial pheromones. Sebum is a complex lipid material containing cholesterol, cholesterol esters, triglycerides, diester waxes, and fatty acids. Sebum is important to keep the skin soft and pliable and to maintain proper hydration; it gives the hair coat sheen and has antimicrobial properties.

Sweat glands (epitrichial [formerly apocrine] and atrichial [formerly eccrine]) are part of the thermoregulatory system. The evaporation of sweat from the skin is the primary body cooling mechanism for horses and primates and, to a lesser degree, pigs, sheep, and goats. There is some clinical evidence to suggest that limited sweating occurs in dogs and cats, and that it may have a minor role in cooling the body. Dogs and cats thermoregulate primarily by panting, drooling, and spreading saliva on their coats (cats). Cats also sweat through their paws, especially when excited; this is most commonly seen as wet paw prints on surfaces, eg, examination tables.

Subcutaneous Muscles and Fat:

The “twitch muscle” (panniculus carnosus) is the major subcutaneous muscle. The subcutaneous fat (panniculus adiposus) serves many functions, including insulation; reservoir for fluids, electrolytes, and energy; and shock absorber.

DERMATITIS

Inflammation of the skin can be produced by numerous agents, including external irritants, burns, allergens, trauma, and infection (bacterial, viral, parasitic, or fungal). It can be associated with concurrent internal or systemic disease; hereditary factors also may be involved. Allergies form an important group of etiologic factors, especially in small animals.

The skin's response to insult is generically called dermatitis and manifests as any combination of pruritus, scaling, erythema, thickening or lichenification of the skin,

hyperpigmentation, oily seborrhea, odor, and hair loss. The usual progression of a skin disease involves an underlying trigger (disease syndrome) that causes primary lesions such as papules, pustules, and vesicles. Pruritus is a common clinical sign in many diseases, and in conditions that are not inherently pruritic, it is often present because of secondary infections or as a result of production of inflammatory mediators. As the inflammatory changes progress, crusting and scaling develop. If the process involves the deeper dermis, exudation, pain, and sloughing of the skin may occur. Secondary bacterial and yeast infections commonly develop as a result of skin inflammation. As dermatitis becomes chronic, acute signs of inflammation (eg, erythema) subside and primary lesions become obscured by signs of chronic inflammation (thickening of the skin, hyperpigmentation, scaling, seborrhea). Often, the skin becomes drier; if pruritus is not a component of the underlying trigger, it will often develop at this stage. Resolution of dermatitis requires identification of the underlying cause and treatment of secondary infections or other complications.

DERMATOLOGIC PROBLEMS

Dermatitis is a nonspecific term usually used until the dermatologic history, clinical signs, and physical examination can more precisely define the problem. Dermatologic problems are a major category of clinical findings that can be caused by a number of skin diseases; many skin diseases look alike and are differentiated by working through diagnostic flow charts and a process of elimination. The most common dermatologic problems include pruritus, alopecia, crusting and scaling, otitis, nonhealing wounds, nodules and tumors, and ulcerative disorders. In some species, such as cats, there may be well-recognized subcategories of dermatologic problems (eg, head and neck pruritus, symmetric alopecia, eosinophilic exudation/dermatitis, etc). Defining the major dermatologic problem will help create a specific differential diagnosis list and aid selection of appropriate diagnostic tests. The animal's dermatologic problem may or may not be the owner's chief complaint. It is important to be sensitive to owners' perceptions of problems or complaints, especially if odor or aesthetics are involved, and to address them (eg, bathing to minimize odor while the key problem is being evaluated).

DIAGNOSIS OF SKIN DISEASES

Definitive diagnosis of the causes of various skin diseases requires a detailed history, physical examination, and appropriate diagnostic tests. Many skin diseases look alike, and a definitive diagnosis is made over time by including or excluding possible causes, evaluating responses to therapy, and/or process of elimination.

History

A careful dermatologic history is critical to interpret the physical examination findings and choose appropriate diagnostic tests. A complete general history should be obtained, including information about prior illnesses, vaccinations, husbandry (housing, feeding practices, etc), changes in attitude and food consumption, elimination practices, exposure to other animals, and travel within the past 6–12 mo. This should be followed by a detailed dermatologic history. Use of a preprinted history form can be very useful for chronic or complicated cases. A good history is important, because many skin diseases that look similar are differentiated based on interpreting clinical signs and historical patterns.

The following information should be obtained: 1) the primary complaint; 2) length of time the problem has been present; 3) age at which the skin disease started (distinct age predilections are seen in many diseases, eg, demodicosis and dermatophytosis in pediatric animals and signs of atopic dermatitis in animals 1–3 yr old); 4) breed (breed predilections include a predisposition of Cocker Spaniels to primary disorders of keratinization, and of terriers to atopic dermatitis); 5) presence and severity of pruritus (including licking, rubbing, scratching, or chewing behaviors—owners often do not realize licking may be a sign of pruritus); 6) how the disease started and its progression (diseases that begin with pruritus may lead to self-trauma and subsequent development of secondary skin lesions [alopecia, seborrhea] or infections [bacterial or yeast pyoderma]); 7) type and progression of lesions noted by the owner; 8) evidence of seasonality (suggesting fleas, allergic skin disease, or weather-related diseases); 9) area on the body the problem was first noticed (ie, regional patterns seen in atopic dermatitis [typically the face and feet], cheyletiellosis [primarily dorsal], scabies [primarily ventral], and endocrine hair loss [usually involves the trunk and spares the head and legs]); 10) any previous treatments

and the responses to such (ie, antibiotic-responsive skin diseases suggest a bacterial cause; pruritus that responds to small doses of glucocorticoids, antihistamines, or essential fatty acids suggests allergic dermatitis); 11) frequency of bathing and when the last bath was given (recent bathing may obscure or change important clinical lesions, excessive bathing and wetting of the skin can predispose to skin disease); 12) presence of fleas, ticks, or mites; 13) other contact animals (ie, evidence of contagion, which suggests fleas, scabies, cheyletiellosis, or dermatophytosis); 14) the environment of the animal (housing changes can influence the development of certain skin diseases, eg, contact dermatitis, contagious diseases); and 15) signs or reports of systemic illness (endocrine [eg, hypothyroidism and hyperadrenocorticism] disorders and metabolic diseases [eg, diabetes mellitus, renal disease, liver disease] should be noted, because the skin can be the first place signs of systemic illness are noted).

Physical Examination

A complete physical examination should always be performed. Many skin diseases are manifestations of systemic diseases, eg, hypothyroidism, hyperadrenocorticism, hepatocutaneous syndrome, systemic lupus erythematosus. (See also MISCELLANEOUS SYSTEMIC DERMATOSES, p 973.) A good dermatologic examination requires very close inspection of the entire hair coat and skin under strong lighting; flashlights may be necessary to examine the skin of large animals. It is important to examine the ventrum of the animal, where many primary lesions and cutaneous parasites are found.

Clinical lesions are described in a variety of ways. Gross lesions can be described as focal, multifocal, or diffuse in distribution, followed by a description of the affected region (eg, mucocutaneous, truncal). On closer inspection, lesions may be further described as primary or secondary. Primary lesions include macules or patches (non-elevated areas of discoloration); papules or plaques (elevated lesions, the latter coalescing); pustules, vesicles, or bullae (fluid-filled lesions); wheals (flat-topped, steep-walled, solid elevations of the skin arising from histamine release); or nodules or tumors (large solid elevations of the skin). Secondary lesions include epidermal collarettes (late stage of a pustule), scars, excoriation (areas of self-trauma), erosions or ulcers (loss of the epidermis), fissures, lichenification (increased thickening and hyperpigmentation of the skin), and calluses.

Some lesions may be either primary or secondary, depending on the cause of the disease. These include alopecia, scale, crusts, follicular casts (plugging of hair follicles with visible keratin), comedones (blackheads), and pigmentary changes.

Laboratory Procedures for Skin Diseases

Skin Scrapings: Skin scrapings are part of the basic database for all skin diseases. There are two types of skin scrapings, superficial and deep. Superficial scrapings do not cause capillary bleeding and provide information from the surface of the epidermis. Deep skin scrapings collect material from within the hair follicle; capillary bleeding indicates that the sampling was deep enough. Skin scrapings are used primarily to determine the presence or absence of mites. Skin scrapings are best performed using a skin-scraping spatula, which is a thin metal weighing spatula commonly found in pharmacy or chemical supply catalogs. These spatulas are reusable and do not cause injury.

Combing of the Hair Coat: This technique, commonly referred to as "flea combing," is useful to collect large amounts of skin debris and trap cutaneous parasites. Combing is particularly useful to find fleas, ticks, lice, and some mites. A clean scrub brush or curry comb can be used to collect material into a flat container (eg, pie plate) in large animals.

Examination of Hairs: Microscopic examination of hair shafts can be used to look for evidence of self-trauma, dermatophyte infections (requires clearing agents and special staining), dysplastic hairs, and sometimes, genetic diseases of the hair coat.

Cytology: Cutaneous and auricular cytology is helpful to identify bacterial, fungal, and, possibly, neoplastic skin diseases. At least 4–6 impression smears should be made; several slides should be saved for examination at a reference laboratory if necessary. When performing impression smears of the skin, the glass slide should be placed directly over the site to be sampled. An index finger or thumb should be placed directly over the slide and very firm pressure exerted. Alternatively, clear acetate tape can be used to sample the skin. Adequate sampling will produce a "thumb print" from the surface. At least one slide should be heat fixed with a match or lighter before staining. In most cases, a

Romanowsky-type stain is adequate. In pruritic animals, material should be scraped from beneath nail beds and smeared onto glass slides for heat fixing, staining, and cytologic examination. Specimens should be examined under 4x, 10x, and oil immersion magnification.

Fungal Cultures: Dermatophyte infections are best identified with a fungal culture on either dermatophyte test medium or on plain Sabouraud agar. Plates that are easily inoculated are preferred; glass, screw-topped jars are difficult to inoculate and obtain samples from and are best avoided. Cats are best sampled using a new toothbrush aggressively combed over the affected lesions. Dogs can be sampled with either a toothbrush or via a hair plucking technique. In large animals, hairs should be gently wiped with alcohol before collecting to minimize contaminant growth. Intermediate and deep fungal organisms are best cultured at a reference laboratory using a skin biopsy specimen (6–8 mm in size).

Bacterial Cultures: Intact pustules can be cultured by rupturing the pustule with a sterile needle and swabbing the lesion with a sterile culture swab. Lesions should not be scrubbed before sampling. Deep pyodermas are best cultured from a skin biopsy (6–8 mm). The reference laboratory should be informed as to what pathogens are suspected, because this may affect how the exudate is cultured. Systemic and topical agents should be withheld for at least 72 hr before sampling.

Biopsy: Skin biopsies are indicated in any case that appears severe, unusual, or does not respond to appropriate therapy. Lesions should not be scrubbed before biopsy, because surface pathology is important in the diagnosis of many skin diseases. Several samples from a variety of lesions should be submitted for examination. Primary lesions should be sampled whenever possible; otherwise, the report is often not very helpful in making a diagnosis or narrowing a list of differential diagnoses. Biopsy specimens require examination by a pathologist familiar with skin diseases of animals. Direct immunofluorescence is not necessary to diagnose autoimmune skin diseases; routine histopathology is the test of choice.

Routine Blood and Urine Tests: In most dermatologic cases, these tests do not help to make a definitive diagnosis. If systemic signs of illness are present, then a CBC, serum chemistry panel, and

urinalysis may be helpful to identify the cause. In dogs with recurrent infections, these tests may identify an underlying subclinical disease.

Intradermal Skin Testing: This test is not necessarily required to make a diagnosis of atopic dermatitis. A positive intradermal skin test reaction indicates past exposure to a particular allergen. Inhalant allergies are best diagnosed based on a compatible history, physical examination findings, and judicious use of intradermal skin testing or in vitro testing for allergies. Intradermal skin testing is recommended for animals in which immunotherapy is indicated because of the severity or duration of allergic signs. Potential drug interactions that can interfere with testing should be considered before intradermal skin testing is performed.

In Vitro Diagnostic Tests: In vitro diagnostic tests (ELISA or RAST tests) are an alternative to intradermal skin testing. Although in vitro tests are considered less reliable because of the large number of false-positive reactions, most complications in interpretation are the result of poor patient selection. Like intradermal skin tests, in vitro tests reflect exposure and must be interpreted in light of the animal's clinical signs and history.

COMMON DERMATOLOGIC PROBLEMS

The two most common dermatologic problems are alopecia and pruritus.

ALOPECIA

(Hair loss)

Alopecia is the partial or complete lack of hairs in areas where they are normally present. If an animal is presented for the problem of hair loss and pruritus is present, the problem of pruritus should be investigated first (see p 843).

Etiology: There are many causes of alopecia; any disease that can affect hair follicles can cause hair loss. There are two broad etiologic categories of alopecia: 1) congenital or hereditary and 2) acquired. Acquired alopecia is further divided into two categories: inflammatory and noninflammatory.

Congenital or hereditary alopecia (see p 846) has been described in cows, horses, dogs, cats, and pigs. Hairless breeds of mice, rats, cats, and dogs have been bred and

developed for personal and research interests. Congenital alopecia may or may not be hereditary; it is caused by a lack of development of hair follicles and is apparent at, or shortly after, birth. Animals with tardive alopecias are born with normal coats, and focal or generalized hair loss occurs when the animal sheds its juvenile coat or when it becomes a young adult. Examples of this include pattern baldness of Dachshunds, color dilution alopecia (most commonly seen in Doberman Pinschers), and certain types of follicular dysplasias.

Acquired alopecia encompasses all other causes of hair loss. In this type of alopecia, the animal is born with a normal hair coat, has or had normal hair follicles at one time, and is or was capable of producing structurally normal hairs. Acquired alopecia may be noninflammatory, as is seen in endocrine alopecia or some types of immune-mediated alopecia, or inflammatory. Inflammatory acquired alopecia is the most common cause of alopecia. Acquired alopecia develops because a disease destroys the hair follicle or shaft, interferes with the growth of hair or wool, or causes the animal discomfort (eg, pain, pruritus), leading to self-trauma and loss of hair.

Diseases that can directly cause destruction or damage to the hair shaft or follicle include bacterial skin diseases, dermatophytosis, demodicosis, severe inflammatory diseases of the dermis (eg, juvenile cellulitis, deep pyoderma), traumatic episodes (eg, burns, radiation), and rarely, poisonings caused by mercury, thallium, and iodine. These diseases tend to be inflammatory.

Diseases that can directly inhibit or slow hair follicle growth include nutritional deficiencies (particularly protein deficiencies), hypothyroidism, hyperadrenocorticism, and excessive estrogen production or administration (hyperestrogenism, Sertoli cell tumors, estrogen injections for mismating). Temporary alopecia in horses, sheep, and dogs can occur during pregnancy, lactation, or several weeks after a severe illness or fever. Marked hair loss (effluvium) is common in cats after respiratory infection. These types of alopecia tend to be noninflammatory unless a secondary skin infection develops.

Pruritus or pain is a common cause of acquired inflammatory alopecia in animals. Diseases that commonly cause pruritus or pain include infectious skin diseases (eg, bacterial pyoderma and dermatophytosis), ectoparasites, allergic skin diseases (eg, atopic dermatitis, food allergy, contact, insect hypersensitivity), and less commonly, neoplastic skin diseases. Friction may cause local hair loss, eg, poorly fitted halters or

collars. Rarely, excessive grooming may be the cause of hair loss in some animals, particularly cats.

Feline endocrine alopecia is no longer recognized as a bona fide syndrome; the current name is feline acquired symmetric alopecia. To date, there is no documented evidence of an endocrine disease in these cats, and the symmetric alopecia seen is a clinical sign of an underlying disease, most commonly a pruritic disease. The most common cause of feline symmetric alopecia is flea allergy dermatitis. In cats that do not have an obvious flea infestation, a CBC with differential is recommended; many cats that have flea allergy dermatitis have an eosinophilia. This finding may help convince owners to pursue flea control as a first diagnostic step.

Clinical Findings and Lesions: The clinical signs of hair loss may be obvious or subtle, depending on the disease. Congenital or hereditary hair loss is commonly symmetric and not accompanied by many inflammatory changes; in some cases, the areas of hair loss are localized to one region (eg, ear flaps) or to well-demarcated areas.

The clinical signs of acquired hair loss are varied and often influenced by the underlying cause(s); the pattern of hair loss may be focal, multifocal, symmetric, or generalized. Inflammatory changes such as hyperpigmentation, lichenification, erythema, scaling, excessive shedding, and pruritus are common. Some causes of acquired alopecia may predispose the animal to development of secondary skin diseases, such as a bacterial pyoderma or seborrhea. Pruritus is variable, depending on the primary cause. In endocrine alopecias, the hair loss usually develops in a symmetric pattern, often in wear areas first; pruritus is uncommon unless there is a secondary infection. Contrary to previous thought, hair loss is not generally an early clinical sign of an endocrine alopecia.

Many owners seek veterinary assistance because of perceived excessive shedding. Shedding may be abnormal (excessive) if it results in obvious loss of the hair coat and areas of alopecia. A common cause of abnormal shedding is bacterial pyoderma. If, however, the shedding is not accompanied by development of patchy or symmetric hair loss, it is likely that it is just a stage in the natural replacement of the hair coat.

Diagnosis: An accurate diagnosis of the cause of alopecia requires a careful history and physical examination. Key points in the history include recognition of breed predispositions for congenital or hereditary alopecias; the duration and progression of

lesions; and the presence or absence of pruritus, evidence of contagion, or nondermatologic problems, eg, polyuria and polydipsia. On physical examination, the distribution of lesions should be noted (focal, multifocal, symmetric, generalized), and the hairs examined to determine whether they are being shed from the hair follicle or broken off—the latter suggesting pruritus. Signs of secondary skin infections or ectoparasites should be noted, and a careful nondermatologic examination should be performed.

Initial diagnostic tests include skin scrapings for ectoparasites (particularly *Demodex* mites); combing of the hair coat for fleas, mites, and lice; impression smears of the skin for evidence of bacterial or yeast infections; fungal cultures for identification of dermatophytosis; and examination of plucked hairs, looking at both the shaft and the ends for evidence of dermatophytosis or that the hairs were chewed off. In many cases of bacterial pyoderma, impression smears of the skin do not show neutrophils and/or cocci, but they may show large numbers of shed keratinocytes. Neutrophils and cocci are seen if pustules or recently ruptured pustules are sampled.

If these tests do not identify or suggest an underlying cause, a skin biopsy may be indicated to evaluate hair follicle structures, numbers, and anagen/telogen ratios and to look for evidence of bacterial, fungal, or parasitic skin infections. In addition, skin biopsies are often needed to confirm congenital or tardive causes of hair loss and to identify inflammatory or neoplastic causes of hair loss. Skin biopsies from normal and abnormal sites should be submitted for evaluation. CBC, serum chemistry panels, and urinalyses are generally only helpful when an endocrinopathy is suspected. Specific endocrine function tests can be performed based on findings of routine laboratory work or clinical signs.

Treatment: Successful therapy depends on the underlying cause and specific diagnosis.

PRURITUS

(Itching)

Pruritus is defined as an unpleasant sensation within the skin that provokes the desire to scratch.

Pathophysiology: Pruritus may be well or poorly localized. It may manifest as a sharp or diffuse, burning sensation. Although the skin is richly innervated, there are no known specialized pruritus receptors. The sensation of itch is transmitted via a specialized set of afferent fibers. Myelinated

fibers that conduct sensations at 10–20 m/sec carry the well-localized pricking itch sensation. In contrast, the sensation of burning itch is transmitted via nonmyelinated fibers that conduct sensations at 2 m/sec. Both of these fibers enter the dorsal root of the spinal cord, ascend through the dorsal column, and cross into the lateral spinothalamic tract. From there they go to the thalamus and on to the sensory cortex.

The mediators of pruritus are controversial and may vary depending on the species. These putative mediators include histamines (released from mast cell degranulation), proteolytic enzymes (proteases), and leukotrienes. Proteases are released by fungi, bacteria, and mast cell degranulation, and during antigen-antibody reactions. Leukotrienes, prostaglandins, and thromboxane A_2 , which are broken down from arachidonic acid, are pro-inflammatory. Essential fatty acids, particularly glonic acid, have been used to counter the inflammation mediated by leukotrienes and thromboxane A_2 . The sensation of pruritus may be affected by a variety of factors, including boredom, competing sensations, and anxiety. Stress may potentiate pruritus via the release of opioid peptides.

Etiology: Pruritus is a clinical sign and not a diagnosis or specific disease. In general, the most common causes of pruritus are parasites, infections, allergic skin diseases, and miscellaneous causes (eg, cutaneous neoplasia). Many diseases that are nonpruritic (eg, endocrinopathies) become pruritic when the animal develops secondary bacterial or yeast infections.

Diagnosis: A thorough dermatologic history and physical examination should be performed. Parasitic causes of pruritus, including *Demodex*, fleas and ticks, contagious mites, and lice, should be excluded, because they are most common. Skin scrapings can exclude (or include) various mite infestations, including *Demodex*. However, some mite infestations (eg, *Sarcoptes*, *Cheyletiella*, *Psoroptes*, *Chorioptes*) might be missed on skin scrapings. If a mite infestation is suspected, a response to therapy trial should be undertaken. The most commonly used drug in these cases is ivermectin. Fleas can be excluded or included based on a history of flea control, response to flea control, or finding evidence of flea infestation via a flea combing. Flea control practices can also exclude louse infestations.

The next most important group of pruritic diseases to exclude is infectious causes of

skin disease. These include bacterial infections (primarily staphylococcal infections, *Malassezia* overgrowth, and dermatophytosis). A fungal culture should be performed in any cat presented for pruritus. It is also highly recommended in dogs that are newly acquired, any animal with a possible history of exposure and/or compatible clinical signs, or when there is a history of people with skin disease. Concurrent bacterial and yeast infections are increasingly recognized as a common cause of pruritus in dogs, cats, and large animals. Bacterial pyoderma is underdiagnosed in cats, and a response to therapy trial may be needed to exclude or include it.

Infectious causes of pruritus commonly induce clinical signs of hair loss, scaling, scales piercing hairs, odor, and/or greasy seborrhea. Marked pedal pruritus and facial rubbing are common in animals with concurrent yeast and bacterial infections. Before pursuing allergies as a cause of pruritus or performing skin biopsies or other more expensive and/or invasive diagnostic testing, a concurrent bacterial and yeast infection should be excluded. A 21–30 day concurrent course of an antibiotic effective against *Staphylococcus* spp (eg, cephalixin 30 mg/kg, PO, bid) and a systemic antifungal (eg, ketoconazole, itraconazole, or fluconazole 5–10 mg/kg/day, PO) should be prescribed. If the pruritus resolves, then existing pruritus was due to a microbial infection.

It is possible that the initial trigger has long passed or is seasonal. However, if the animal's pruritus is unchanged or only somewhat better, the most likely underlying cause is allergic (assuming parasitic causes have been excluded). The most common causes of allergic pruritus are insect bite hypersensitivity (eg, flea allergy, mosquito bite allergy, fly bite), food allergy, and atopic dermatitis. Flea allergy dermatitis and insect bite hypersensitivity are excluded based on response to insect control. Animals that do not have insect bite hypersensitivity but are seasonally pruritic most likely have atopic dermatitis. Animals with year-round allergic pruritus have atopic dermatitis and/or food allergy. Food allergy is excluded or included based on response to a diet trial and provocative challenge. Atopic dermatitis is a clinical diagnosis; in vitro allergy testing and intradermal skin testing show only antigen exposure patterns. These tests are used to determine the contents of an immunotherapy vaccine.

Treatment: Successful therapy depends on identification of the underlying cause.

Animals with idiopathic pruritus or those in which treatment of the underlying disease does not eliminate the pruritus (eg, atopic animals) require medical management of pruritus. Currently, evidence-based reviews of antipruritic do not support the use of antihistamines to control pruritus.

Essential Fatty Acids: Essential fatty acids are rarely effective as sole antipruritic agents and are not suitable for acute flares of pruritus. If they are beneficial, it is a longterm therapy.

Glucocorticoids: Glucocorticoids are the most effective drugs in the management of pruritus. However, they cannot be used safely for longterm management because of adverse effects (eg, suppression of adrenal function, risk of development of diabetes mellitus, risk of secondary urinary tract infections). In addition, owners can rarely tolerate the common adverse effects (polydipsia, polyuria, polyphagia, and panting) for long periods. Anti-inflammatory dosages range from 0.5–1 mg/kg/day, PO, for 5–10 days and then every other day. Topical spray formulations of triamcinolone acetate are highly effective and good alternatives to oral steroids.

Other Systemic Antipruritic Agents: Cyclosporine modified is a highly effective nonsteroidal drug for control of pruritus. The only formulation that can be used is modified cyclosporine. The dosage is 5 mg/kg for dogs and 7 mg/kg for cats. Maximal benefit can take as long as 30 days to observe. Once efficacy is established, dose tapering to every other day can be attempted. Common adverse effects include vomiting and diarrhea (common) and gingival hyperplasia (less common). Another drug for control of pruritus in dogs is oclacitinib, a Janus kinase inhibitor that provides rapid relief from pruritus and inflammation in dogs with short- and longterm allergic skin disease.

PRINCIPLES OF TOPICAL THERAPY

See also SYSTEMIC PHARMACOTHERAPEUTICS OF THE INTEGUMENTARY SYSTEM, p 2571.

Topical therapy is an important part of veterinary dermatology. It is often beneficial in improving the cosmetic appearance or odor of the animal, pending the final diagnosis. It can be beneficial as an adjunct to systemic therapy. Finally, it may be the preferred method of treatment for some diseases, eg, flea infestations.

The following are some basic guidelines to consider when prescribing topical therapy:

1) As much of the hair coat as possible should be removed when treating skin diseases. Good grooming practices facilitate topical therapy and can significantly help shorten the course of disease. 2) The cooperation of the owner (and animal) should be evaluated before any topical therapy is prescribed. 3) Animals tend to groom off topical products and may vomit after ingestion. The risk of toxicity is a constant worry for owners. Local ointments, gels, and sprays are best used sparingly, under occlusion, and for specific diseases. Such medications often sting when applied to the skin, especially many of those instilled into the ears. Many agents also may mat the hair. 4) Tepid water is the temperature of choice for bathing animals. 5) The old adage, "If it's wet, dry it and if it's dry, wet it," has some truth to it; however, this advice should not be carried to extremes. Exudative lesions, eg, areas of pyotraumatic dermatitis, heal faster if they are kept clean and covered with an antibiotic ointment or gel (previous recommendations suggested aggressive astringent use). Dry, lichenified skin is often pruritic, and the judicious use of emollients may be beneficial. 6) The animal should be monitored closely for possible development of irritant or allergic contact dermatitis from topical agents. Many topical agents have very similar bases or ingredients, and changing from one to another may only exacerbate the problem. 7) Owners should be given careful and thorough instructions on how to administer the therapy.

Shampoo Therapy: Shampoos are the most commonly used topical treatments. There are three broad classes of shampoos: cleansing, antiparasitic, and medicated. **Cleansing shampoos** remove dirt and excess oils from the coat. These products include over-the-counter dog grooming shampoos, flea shampoos, and many mild human products. These products lather well and must be rinsed from the coat.

Antiparasitic shampoos are "flea shampoos." In most cases, the amount of insecticide in these products is not adequate to kill all the fleas in a severe infestation. However, these products are excellent routine cleansing products. **Medicated shampoos** include antimicrobial and antiseborrheic products. The most widely used antibacterial shampoos contain chlorhexidine or benzoyl peroxide. Antiseborrheic shampoos contain some combination of tar, sulfur, and salicylic acid—ingredients that are keratoplastic and keratolytic. Tar is recommended for oily seborrhea, and sulfur and salicylic acid are recommended for scaly seborrhea. Most animals benefit from products that contain all three agents; however, tar products are contraindicated in cats.

When a medicated shampoo is used, the animal should be washed in a cleansing shampoo before the medicated shampoo and rinsed well. Medicated shampoos often are not good cleansing agents, do not lather well, or do not work well in the presence of organic debris. The medicated shampoo should be applied evenly to the hair coat after being prediluted in water. Prediluting the shampoo will facilitate it being rinsed from the coat and minimize the potential for irritant or allergic contact dermatitis. Depending on the shampoo, the concentration of shampoo to water will vary between 1:3 and 1:4. If possible, the medicated shampoo should be allowed to have a contact time of 10 min with the skin and then rinsed thoroughly from the coat. Shampoo residue is a common cause of irritant reactions. Finally, the medicated shampoo should be used often, usually 2–3 times/wk during the early stages of therapy.

The use of medicated antimicrobial shampoo therapy is increasing because of concerns over development of methicillin-resistant staphylococcal infections.

CONGENITAL AND INHERITED ANOMALIES OF THE INTEGUMENTARY SYSTEM

Congenital dermatoses of the skin may be genetic or arise during embryogenesis because of nongenetic factors. Genetic mutations that cause skin anomalies may be present at birth or become apparent weeks to months later. These late-onset manifesta-

tions are referred to as tardive developmental defects. Both congenital and tardive developmental dermatoses are fairly common in domestic animals of all species, with the greatest number of well-defined defects described in cattle and dogs.

CONGENITAL ANOMALIES OF THE SKIN

Epitheliogenesis imperfecta (aplasia cutis) is a congenital discontinuity of squamous epithelium. It is seen in cattle (autosomal recessive trait), horses, swine, sheep, cats, and dogs, although it is rare in the latter three species. In cattle, affected breeds include Holstein-Friesian, Hereford, Ayrshire, Jersey, Shorthorn, Angus, Dutch Black Pied, Swedish Red Pied, and German Yellow Pied. It is common in swine, in which large lesions are obvious at birth as glistening red, well-demarcated discontinuities in the skin or mucous membranes. Infection and ulceration are early consequences. One or more hooves or claws may be deformed or absent; in some affected animals, there are other associated congenital anomalies. The condition is fatal when extensive, but small defects can be surgically corrected. Ultrastructural evaluation of this condition in American Saddlebred foals has demonstrated a relationship with junctional epidermolysis bullosa (see p 850).

Focal cutaneous hypoplasia and subcutaneous hypoplasia are congenital, circumscribed hypoplastic defects of multiple or deeper skin layers in swine. The lesions manifest as skin depressions in which all skin layers or the subcutaneous fat layers fail to develop normally.

A **nevus** is a circumscribed developmental defect of the skin, whereas a **hamartoma** is a hyperplastic mass formed as a result of a developmental defect in any organ. Both nevi and hamartomas have been described as congenital skin defects, but the problem may not become obvious until later in life. In dogs, sebaceous nevi, pigmented epidermal nevi, inflammatory linear verrucous epidermal nevi, and

comedonic, linear organoid nevi, and follicular hamartomas are known to occur. In horses, cannon keratosis and linear epidermal nevi have been described. Doubtless, similar defects occur in all species. Mixed, or organoid, nevi consist of circumscribed collections of densely packed adnexal structures (pilosebaceous nevus and pilosebaceousodiferous nevus). Collagenous nevi are nodules composed of focal collagen hyperplasia that displace the normal structures of the skin. Most lesions are alopecic, with pigmented, pitted surfaces. When not extensive, nevi can be excised; otherwise there is no known effective treatment.

Dermoid sinuses or cysts are seen in Thoroughbred horses and Rhodesian Ridgebacks (in which they are inherited) and occasionally other breeds of dogs. These are cystic structures lined with skin in which exfoliated skin, hair, and glandular debris accumulate. They are caused by failure of complete separation of the neural tube from the epidermis during embryogenesis; cysts are found on the dorsal midline and are rarely associated with spinal cord neural deficits. They can be removed by surgical excision.

Follicular cysts develop by abnormal hair follicle morphogenesis and by retention of follicular or glandular products. They may be congenital when caused by the failure of the follicular orifice to develop normally. Congenital cysts are most commonly identified in Merino and Suffolk sheep. Periauricular (dentigerous) cysts are seen in horses and, although present at birth, may not be recognized until adulthood. Wattle cysts are seen in Nubian goats; these arise from the bronchial cleft. Porcine wattles are seen fairly frequently in all breeds of swine. These are teat-like growths on the lower jaw.

HEREDITARY ALOPECIA AND HYPOTRICHOSIS

Alopecia is the absence of hair; **hypotrichosis**, which is much more common, is the presence of less hair than normal. Although these defects can be generalized, they commonly develop in patterns that spare the extremities or correlate with hair color. These ectodermal defects can be congenital or tardive and can be associated with abnormal or absent adnexa, with defects in other ectodermal structures (such as teeth, claws, and eyes), or with skeletal and other developmental defects. There are various modes of inheritance in those instances in which familial occurrence has been studied.

Collagenous nevus in a dog. Courtesy of Dr. Robert Dunstan.

X-linked ectodermal dysplasia has been reported in German Shepherds. Hairless breeds of dogs (eg, Mexican Hairless, Chinese Crested, American Hairless Terrier) and cats (Sphinx) have been bred for these ectodermal defects. Many sporadic cases of ectodermal defects are described in dogs, most often in males. Affected dogs, including most of the hairless breeds, often have patchy or pattern hypotrichosis as well as associated dental anomalies. All animals with abnormal follicular development are prone to comedone formation, hair follicle infections, and hair foreign-body granulomas.

At least 13 types of **hypotrichosis** have been described in cattle, affecting Angus, Ayrshire, Brangus, Holstein-Friesian, Hereford, polled Hereford, Guernsey, Gelbvieh, Jersey, as well as Normandy-Maine, Anjou-Charolais, and Simmental crosses. Most have autosomal recessive or sex-linked modes of inheritance. Associated defects include failure of horn development, hypophyseal hypoplasia, macroglossia, dental anomalies, abnormal coat coloration, and death (lethal hypotrichosis). Viable hypotrichosis, hypotrichosis with anodontia, semihairlessness, streaked hairlessness, black hair follicle dysplasia (Holstein), and cross-related hypotrichosis (rat tail) are specific types described in cattle.

In sheep, hypotrichosis is rarely reported, with the best known syndrome affecting the Polled Dorset. This involves the hair of the face most severely, but the wool is also of poor quality. In goats, hypotrichosis is associated with congenital goiter. In swine, two forms of hypotrichosis are known (Mexican Hairless, German), one of which is associated with goiter and death in the homozygote.

In dogs, there are several **tardive follicle dysplasias**, including color dilution alopecia. This is found in some dogs bearing the coat color genotype dd, which renders black genotypes blue and liver genotypes beige or fawn. This syndrome is best known in Doberman Pinschers but is also commonly seen in color dilute Dachshunds, Italian Greyhounds, Greyhounds, Whippets, Yorkshire Terriers, and tricolor hounds and has been reported in a German Shepherd. Recently, "silver Labrador Retrievers" with color dilution alopecia have been reported. Affected dogs are born with normal hair coats but before 1 yr of age begin to develop folliculitis and hypotrichosis that is progressive and confined to the blue- or fawn-colored areas. Black hair follicle dysplasia, a similar but earlier developing and more complete

hypotrichosis, is seen in black and white piebald dogs. The hypotrichosis develops shortly after birth and affects only the black-colored areas. This syndrome is best known in the Papillon and Bearded Collie. Recent genetic analysis in Large Munsterlanders has indicated an autosomal recessive inheritance in this breed. A similar follicular dysplasia is reported in nonpiebald breeds. Other types of follicular dysplasias of uncertain cause include seasonal flank alopecia of Boxers and Airedale Terriers and various woolly syndromes and post-clipping alopecia in Spitz-type breeds. Familial hypotrichosis of Irish Water Spaniels develops at 2-4 yr of age, and a dominant mode of inheritance has been suggested. The condition formerly known as growth hormone-responsive alopecia in Pomeranians and other breeds is now called alopecia X, reflecting the complexity of factors, hereditary and otherwise, influencing these syndromes.

In cats, follicular dysplasia is seen in the Devon Rex. In horses, both color dilution alopecia and black hair follicle dysplasias are occasionally reported, especially in Appaloosas. Congenital progressive hypotrichosis has been reported in a blue roan Percheron. Reported hair shaft structural abnormalities of dogs and cats include pili torti (American Wirehaired Cat), trichorrhexis nodosa, and spiculus (Kerry Blue Terrier).

HYPERPLASTIC AND SEBORRHEIC SYNDROMES

Many anomalies affect keratinization; some are associated with hereditary hypotrichoses (see p 846), whereas others are associated with systemic metabolic derangements. Those for which none of these associations has yet been made are a diverse group of syndromes that may affect localized parts of the epithelium or that may be generalized. Among the latter are the poorly characterized congenital or familial seborrheic syndromes, the best known of which is idiopathic seborrhea of Spaniels and idiopathic facial dermatitis of Persian cats. **Hereditary congenital follicular parakeratosis** is a syndrome of female Rottweilers and Siberian Huskies. It is a severe keratinization defect associated with various noncutaneous abnormalities.

Cutaneous ichthyoses are characterized by abnormal and hypertrophic epithelial proliferation, with accumulation of extensive scale and hyperkeratosis on the skin surface. Cases have been described mostly in cattle and dogs, but chicken and

several mouse models are also known, and there is one report in a llama. In cattle, the severity varies; some forms are lethal shortly after birth. Affected breeds include Red Poll, Friesian, Holstein, Brown Swiss, Pinzgauer, and Chianina.

Canine ichthyosiform dermatoses are also heterogeneous and occur sporadically in a number of breeds, including Doberman Pinschers, Rottweilers, Irish Setters, Collies, English Springer Spaniels, Cavalier King Charles Spaniels, Golden Retrievers, Labrador Retrievers, and terriers (including Parson Russell Terriers). There is some evidence of a familial inheritance pattern in Parson Russell Terriers and Golden Retrievers. In dogs, the body is covered with large adherent scales that may flake off in large sheets. The planum nasale and digital pads may be markedly thickened in some forms; the latter usually is associated with apparent discomfort. Clinical management is difficult, but signs may be ameliorated with keratinolytic shampoos or solutions (eg, selenium disulfides, lactic acid, benzoyl peroxide) and with humectants (eg, lactic acid, urea, propylene glycol, and essential fatty acid preparations). Experimental use of synthetic retinoids has been helpful. Control of secondary pyoderma is frequently required.

Psoriasiform-lichenoid dermatosis affects young English Springer Spaniels and is presumed to be genetic. The erythematous, symmetric lesions, which consist of papules and plaques on the pinnae and inguinal region, are covered with scales and become increasingly hyperkeratotic if left untreated. In some affected dogs, the lesions may eventually spread, and the skin is severely greasy. Spontaneous remissions and a waxing and waning course are recorded. Some dogs respond to antibiotic treatment or to synthetic retinoids, but most are refractory to therapy. Cyclosporine therapy has been used with mixed results in some dogs.

Pityriasis rosea of pigs is a familial disease in which the mode of inheritance is not known. (See p 979 for clinical findings, diagnosis, and treatment.) **Dermatosis vegetans** of Landrace pigs is a hereditary, possibly congenital, disorder with an autosomal recessive mode of inheritance. It must be differentiated in the early stages from pityriasis rosea. This is a more serious disease and affects the hooves as well as the skin. Lesions begin as macules and papules and are scaly as in pityriasis rosea. They later become covered with brown-black crusts and are associated with coronitis and hoof deformity. Piglets fail to thrive and eventually develop pneumonia; the

disease is not uniformly fatal, but affected survivors are stunted. There is no effective treatment.

Familial footpad hyperkeratosis is reported in Irish Terriers and Dogues de Bordeaux. All pads of all feet are involved from a young age, although the disease is not usually congenital. When hyperkeratosis is severe, horns, fissures, and secondary infection cause pain and lameness. No other skin lesions are present. Treatment is symptomatic, with soaking, keratolytic and emollient treatments, with treatment of bacterial pyoderma. No reports of the use of synthetic retinoids are available. Major differential diagnoses for footpad hyperkeratosis include hepatocutaneous syndrome, a disorder of keratinization, and pemphigus.

Granulomatous sebaceous adenitis is an idiopathic disease that destroys the sebaceous glands and, in some breeds of dogs, is associated with a severe seborrheic and alopecic dermatosis. It is hereditary in Standard Poodles and suspected to be familial in Akitas. It first manifests itself in young adults, but inapparent carriers are known in Poodles. Marked hyperkeratosis precedes development of hair coat abnormalities, which begin as loss of normal hair kinkiness and progress to patchy alopecia. Akitas tend to have more seborrhea oleosa and less alopecia than Poodles. Response to treatment is inconsistent and incomplete. Mildly affected dogs are treated with antiseborrheic shampoos and treatment of pyoderma as needed. Severely affected dogs have benefited from propylene glycol or hot oil treatments. Some dogs respond to oral supplementation with omega-3 fatty acids, and some respond to synthetic retinoids. Spontaneous remission has been recorded. Recently, modified cyclosporine A (5 mg/kg/day, PO) has been very effective in the treatment of many dogs.

PIGMENTARY ABNORMALITIES

Many associations between skin and coat color and developmental anomalies have been recorded in domestic animals. Some of the associations with hypotrichosis are discussed under hereditary alopecia (see p 846).

Albinism appears to be rare in domestic animals. True albinism is always associated with pink or pale irises and with visual defects and increased risk of solar radiation-induced neoplasms of the skin. It has been noted in Icelandic sheep and in Guernsey, Austrian Murboden, Shorthorn,

Brown Swiss, and Charolais cattle. Albinism must be differentiated from extreme white spotting or piebaldism and dominant white. Some animals with extreme piebaldism or dominant white have associated neurologic anomalies or deafness, or suffer death in utero. Lethal white foal syndrome is one that results from breeding two Overo Paints. In dogs and cats, dominant white or extreme piebaldism can be associated with unilateral or bilateral deafness and sometimes with blue irides or iris heterochromia. White cats with bilateral blue eyes have a 75% chance of deafness. In dogs, deafness may also be associated with merle hair coats and is found in Dalmatians, Sealyham Terriers, harlequin Great Danes, Collies, and white Bull Terriers. Cyclic neutropenia may be found in gray or pale merle Collies. In Rhodesian Ridgebacks, pale coat color is associated with cerebellar degeneration. In Chédiak-Higashi syndrome (see p 50) of cats and cattle (Herefords, Japanese Black, Brangus), coat color dilution (blue smoke in cats) is associated with neutrophil and platelet abnormalities and shortened life span. This is inherited as an autosomal recessive trait. Male tricolor cats (calico and tortoiseshell) are sterile because the gene for orange is X-linked and recessive, and males have the abnormal XXY genotype.

Pigmentary abnormalities may be acquired, and some of these may be hereditary or familial, as in **vitiligo**. As a familial disease, vitiligo is best recognized in Arabian horses (Arabian fading syndrome, pinky syndrome); it may also be familial in cattle (Holstein-Friesian), Siamese cats, and

in some breeds of dogs (Belgian Tervuren, Rottweiler). Affected animals develop somewhat symmetric macular depigmentation of the skin that occasionally also affects the hair coat and claws or hooves. The onset is usually in young adulthood. Most lesions are on the face, especially the muzzle or planum nasale or around the eyes. Depigmentation may wax and wane. Complete remission may occur but is rare. There is no accompanying systemic or cutaneous pathology. No treatment is available; treatments used in people with vitiligo are unlikely to provide significant cosmetic results in animals.

Lentigo in orange and orange-faced male cats is marked by the development of asymptomatic, pigmented macules. Lesions are first seen on the lips and eyelids at <1 yr of age. Other sites include the planum nasale and gingivae. Lentiginos are not precancerous and have no medical consequence.

Acquired aurotrichia of Miniature Schnauzers is a familial syndrome in which hair along the dorsal midline changes to golden from the normal black or gray of this breed. The onset is usually in young adulthood. The change may be associated with thinning in the hair coat but no other cutaneous or systemic signs. In most dogs, coat color reverts to normal within 1–2 yr.

DEFECTS OF STRUCTURAL INTEGRITY

This category includes genetic defects in structural elements responsible for the integrity of the epidermis and dermal-epidermal junction, as well as some dermal structural anomalies.

Cutaneous asthenia (dermatosparaxis, Ehlers-Danlos syndrome) is a group of syndromes characterized by defects in collagen production. This results in a variety of clinical signs including loose, hyperextensible, fragile skin; joint laxity; and other connective tissue dysfunctions. These collagen defects have been described in cattle (Belgian Blue and White, Charolais, Hereford, Holstein-Friesian, Simmental), a goat, sheep (Norwegian Dala, Border Leicester-Southdown, Finnish-Merino cross, Romney, White Dorper), pigs (Large White-Essex cross), horses (Quarter horse, Arabian cross), rabbits (New Zealand white), cats (Himalayan and domestic shorthair), mink, and dogs (a litter of Garafiano Shepherds, sporadically in several breeds). The mode of inheritance has been demonstrated for Himalayan cats (recessive) and domestic shorthair cats (dominant).

Vitiligo in an adult Golden Retriever. Courtesy of Dr. Stephen White.

Clinical features include fragile skin from the time of birth, wounds that heal with thin scars, delayed wound healing, pendulous skin, and hematoma and hygroma formation. In lambs, rupture of the GI tract and arterial aneurysms are features, and the disease is fatal in lambs and calves. In horses, the onset is later and the lesions are well circumscribed, consisting of hyperextensible and somewhat fragile skin. In dogs and cats, the disease is not fatal, and older animals develop hanging folds of skin and exhibit extensive scarring; some have joint laxity or ocular anomalies.

Diagnosis is based on clinical signs and histopathologic studies of the collagen structure, which require age and breed-matched controls. For diagnosis in cats and dogs, a skin extensibility index has been developed. There are anecdotal reports of improvement of affected dogs with vitamin C supplementation. The major differential diagnosis in adult cats is feline hyperadrenocorticism with acquired skin fragility.

The **epidermolysis bullosa syndromes** are a group of congenital and hereditary diseases that result from defects in the dermal-epidermal attachment structures. These are known as mechanobullous diseases, because minor cutaneous trauma results in dermal-epidermal separation with formation of flaccid bullae that soon rupture, leaving glistening, flat erosions. Syndromes are classified according to the ultrastructural location of the epidermal-dermal defect: simplex, in the epidermal basal cell layer; junctional, within the basement membrane; and dystrophic, below the basement membrane in the subepidermal anchoring fibrils.

In large animals, lesions are most common on the gingivae, palate, lips, tongue, and feet. Some forms of epidermolysis bullosa are scarring, and most are fatal. In large animals, epidermolysis bullosa syndromes are known in calves (Simmental, Brangus), domestic buffalo, lambs (Suffolk, South Dorset Down, Scottish Blackface, Weisses Alpenschaf, Welsh Mountain), and Belgian foals. All three forms of epidermolysis bullosa have been characterized in dogs and cats. Epidermolysis bullosa simplex has been described in Collies and Shetland Sheepdogs. Junctional epidermolysis bullosa has been reported in a Toy Poodle, German Shorthaired Pointers, mixed-breed dogs, and Siamese cats and tentatively identified in Beaucerons. Dystrophic epidermolysis bullosa has been reported in a domestic shorthair cat and a Persian and in Golden Retrievers and Akitas. Lesions may be present at birth or develop within

the first weeks of life. The most severe lesions are on the feet, with sloughing of hooves, claws, or footpads, and oral mucous membrane and facial and perigenital skin (erosions). Except for epidermolysis bullosa simplex, these diseases are fatal.

Canine benign familial chronic pemphigus is a mechanobullous disorder that is caused by a defect in cell-to-cell adhesion in the epidermis. This disorder has been described in a family of English Setters. It develops within a few weeks of birth and causes crusting alopecic lesions on the pressure points of the skin that slowly enlarge as the puppies grow. The disease is benign, and no treatment is reported. **Familial acantholysis**, reported in New Zealand Angus calves, is a similar syndrome. This fatal syndrome is reported to be an autosomal recessive trait. Affected calves develop erosions, with collarettes and crusts, in areas subjected to trauma. Some show partial separation of the hooves. Diagnosis in both puppies and calves is established by skin biopsy of newly forming lesions.

Cutaneous mucinosis is thought to be a familial problem in some lines of Chinese Shar-Pei. Normal Shar-Pei have more cutaneous mucin than other dogs, but in some young dogs, cutaneous mucin formation in the dermis is so excessive that the skin exhibits pronounced folding and mucinous vesiculation. Diagnosis is by skin prick of the vesicles and observation of the strings of mucus that have the same appearance as normal joint fluid or, alternatively, by skin biopsy. The syndrome is partially responsive to corticosteroids, but they are contraindicated because of the young age of the affected dogs. As these dogs mature, the severity of the syndrome may abate, but it can be exaggerated by the development of allergic skin disease, which is common in the breed. The major differential diagnosis is hypothyroidism.

CUTANEOUS MANIFESTATIONS OF MULTISYSTEMIC AND METABOLIC DEFECTS

Baldy calf syndrome of female Holsteins, as the name implies, is associated with hypotrichosis. This autosomal recessive trait is lethal to male fetuses. Affected calves appear normal at birth but lose condition and patches of hair beginning 1-2 mo later. The skin then becomes thickened and wrinkled, and the tips of the ears may curl. Calves salivate profusely and become emaciated, and affected female calves die by 6-8 mo of age. The underlying metabolic

defect is not known. A similar appearing syndrome, known as **congenital anemia, dyskeratosis, and progressive alopecia**, is described in polled Hereford calves of either sex. Anemia and small size are noted at birth and become progressively more severe. Alopecia, abnormal curly hair, and hyperkeratosis begin around the muzzle and ear margins and become more extensive as the calves mature. Later, the skin becomes markedly wrinkled, and neurologic abnormalities develop. Calves have diarrhea and die before 6 mo of age.

Familial vasculopathy has been described in German Shepherds and Parson Russell Terriers. In these dogs, the skin lesions develop shortly after the first set of puppy vaccinations and seem to be exacerbated after subsequent vaccinations. The main cutaneous signs are footpad swelling and depigmentation that may progress to ulceration; all footpads are typically affected. Crusting and ulceration of the ear and tail tips and depigmentation of the planum nasale are also features. As the dogs mature, the disease may resolve, but pad lesions may be so severe that euthanasia is warranted. No known treatment is uniformly effective, although some dogs appear to respond to high dosages of corticosteroids. A severe form of **neutrophilic vasculitis** recently described in young Chinese Shar-Pei may be familial.

Familial dermatomyositis is an idiopathic inflammatory disease of the skin and muscles of young Collies and Shetland Sheepdogs. The mode of inheritance is reported to be autosomal dominant in Collies, but there is some evidence of a role for an unidentified infectious agent in the pathogenesis. A vasculopathy is associated with the early inflammatory stages of the disease in the skin and muscle; in both tissues, the eventual sequela is atrophy. The onset is typically at <6 mo of age, although

onset in adulthood has been recorded. Progression of lesions is variable, and individual pups within a litter may be affected mildly to severely. Skin lesions appear in areas of increased trauma and are seen on the face, ear tips, tail tips, and lateral surfaces of the extremities. Skin lesions, which consist of erosion, crusting, and alopecia, are exacerbated by heat and sun exposure. The muscles affected most severely are on the head and extremities. Diagnosis is established by evaluation of littermates and family history, skin biopsy, electromyography, and muscle biopsy, which must be performed early in the course of the disease. There are reports of disease amelioration with dosages of corticosteroids, vitamin E, and omega-3 fatty acids, but severely affected dogs rarely respond satisfactorily to treatment. Pentoxifylline (10 mg/kg, PO, bid) has been helpful in many dogs.

Hereditary lupoid dermatosis of German Shorthaired Pointers is first noted when the dog is ~6 mo old. It begins with scaling and crusting on the head and dorsum and quickly progresses to generalized scaling with erythema. The dermatopathy appears to be either painful or pruritic. Affected dogs become pyrexia and develop lymphadenopathy. Some develop a poorly characterized enteropathy; most lose condition. As the name implies, skin biopsy specimens reveal features of a lupus-like dermatitis. The disease is progressive and ultimately fatal. No successful treatment has been reported.

Hereditary zinc deficiency syndromes are best known in cattle and have also been described in dogs. In cattle, these syndromes include hereditary parakeratosis, lethal trait A46, edema disease, and hereditary thymic hypoplasia. Affected breeds include Friesian, Shorthorn, Angus, and Black Pied. These syndromes all become apparent within days to weeks of birth and are characterized by symmetric, mostly acral, hyperkeratosis; crusting and unthriftiness; susceptibility to infection; and early death. Affected calves exhibit conjunctivitis, ptialism, rhinitis, and diarrhea and often succumb to pneumonia. In most breeds of cattle, the trait appears to be autosomal recessive and associated with intestinal malabsorption of dietary zinc, which is more or less responsive to dietary zinc supplementation. In some breeds, the defect in absorption is absolute, and parenteral administration of zinc is needed to achieve remission. Because such treatment is rarely feasible in production animals, these are lethal traits. Diagnosis is established by excluding dermatophilosis (see p 858) and

Familial dermatomyositis in a Collie. Courtesy of Dr. Robert Dunstan.

by skin biopsy (showing mostly parakeratosis), by measuring serum zinc levels, and by necropsy findings that include hypoplasia of thymus and lymph nodes.

In dogs, there are two familial zinc deficiency syndromes. In white Bull Terriers, **lethal acrodermatitis** is characterized by retarded growth; progressive, acral, hyperkeratotic dermatitis; and pustular dermatitis around mucocutaneous junctions. These signs are apparent by 10 wk of age and are later accompanied by diarrhea, pneumonia, and death before 2 yr of age. In older dogs, footpad hyperkeratosis and paronychia contribute significantly to morbidity. The severity of the cutaneous disease can be ameliorated somewhat by control of secondary bacterial and *Malassezia* infections and, with aggressive medical treatment, the lives of affected dogs can be prolonged. These dogs do not respond to oral zinc therapy. A **familial zinc-responsive dermatopathy** that is manifest mostly by cutaneous lesions and is responsive to supplemental oral zinc is seen in Alaskan Malamutes, Huskies, and German Shorthaired Pointers. Signs develop at weaning or later in life and consist of crusting and hyperkeratosis of the extremities and mucocutaneous junctions. Often, bitches will develop signs associated with estrus or whelping and lactation. Secondary *Malassezia* infections are common. Diagnosis is established by skin biopsy and response to oral zinc supplementation.

Tyrosinemia has been described in a German Shepherd puppy. It was compared to a type of tyrosinemia in people and thus thought to be hereditary. Clinical manifestations included erosions and ulcerations of the footpads and nose and bullous lesions and pigmentation of the skin, loss of claws, and eye lesions. It must be differentiated from the familial vasculopathy of German Shepherds described above. In the puppy, serum tyrosine levels were 20–30 times above normal levels, and urine specimens contained similar high concentrations.

Porphyria is an inherited defect in the metabolism of hemoglobin and its byproducts. In cattle, accumulation of aberrant porphyrins in the skin increases sensitivity to ultraviolet light. (Porphyria has been described in cats and swine but does not result in photosensitivity.) In cattle, there are two types of inherited porphyries. Bovine protoporphyria has been reported in crossbred Limousin cattle and is inherited as an autosomal recessive trait. Signs include photodermatitis and photophobia. Affected calves may die, but mature animals may be less severely affected. Bovine

erythropoietic porphyria (see p 986) is more common and more severe. It is reported in several breeds (including Shorthorn, Holstein-Friesian, and Hereford) as an autosomal recessive trait. In addition to severe photosensitivity, signs include red-brown discoloration of teeth, bones, and urine; regenerative anemia; and stunted growth. Teeth and urine from affected animals fluoresce orange under a Wood's lamp. Skin biopsy is also useful in diagnosis.

Leukocyte adhesion deficiency in Holstein cattle is an inherited disease (autosomal recessive) with many manifestations. It is fatal before adulthood. Skin lesions are frequently seen in affected calves and include dermatitis and vasculitis. This disease can be diagnosed by molecular methods with PCR analysis of fresh or fixed tissue providing identification of affected, carrier, and normal cattle.

CONGENITAL AND HEREDITARY NEOPLASMS AND HAMARTOMAS

Congenital neoplasms are common in large animals. **Mastocytosis**, **melanocytosis**, **cutaneous lymphosarcoma**, and **vascular hamartomas** are found in calves. Melanocytomas may also arise shortly after birth in calves and may be hereditary. These are thought to be benign.

Melanomas are seen in Duroc-Jersey and Sinclair miniature pigs as familial traits. These may undergo spontaneous remission or may behave as malignant tumors. Piglets have also been described with vascular hamartomas and with congenital **fibropapillomatosis**, which is likely infectious.

Congenital tumors are rare in dogs and cats. One dog with a giant congenital pigmented nevus had a malignant melanoma develop within the lesion. In cats, familial benign mastocytosis is described in young Siamese cats.

A syndrome of multiple collagenous nevi is seen in some families of German Shepherds and is called **nodular dermatofibrosis**. Affected dogs are adults. Dozens of skin lesions may occur, and those on the feet often ulcerate or cause foot deformities and lameness. This syndrome is a cutaneous marker for renal cystadenocarcinoma and uterine leiomyoma. **Progressive dermal collagenosis** is a similar disease of postpubertal male miniature pigs. It is thought to be hereditary and is characterized by symmetric, firm plaques on the trunk that consist of thick bundles of collagen replacing the normal dermis and panniculus. A connection with internal malignancy has not been reported.

Urticaria pigmentosa is caused by mast cell hyperplasia and has been described in cats. Affected cats have multifocal, partially coalescing macular

and crusted papular eruption on the head, neck, and legs. Diagnosis is made by skin biopsy. There is evidence of a familial history.

ATOPIC DERMATITIS

Atopic dermatitis (AD) is a genetically predisposed inflammatory and pruritic allergic skin disease with characteristic clinical features. It is most commonly associated with IgE antibodies to environmental allergens. The atopic phenotype (*see* clinical signs, below) can be seen in animals with IgE-mediated skin disease, food allergy, or a condition called "atopic-like dermatitis" (ALD). ALD is defined as a pruritic skin disease in dogs with characteristic features of AD but negative tests for IgE antibodies. Feline atopic dermatitis has many similarities to canine atopic dermatitis.

Etiology and Pathogenesis: The etiology and pathogenesis of AD is complex and involves a genetic predisposition, impairment of the normal barrier function of the skin, and immunologic aberrations. Animals with AD are thought to be genetically predisposed to become sensitized to allergens in the environment. Allergens are proteins that, when inhaled or absorbed through the skin, respiratory tract, or GI tract, evoke allergen-specific IgE production. These allergen-specific IgE molecules affix themselves to tissue mast cells or basophils. When these primed cells come in contact with the specific allergen again, mast cell degranulation results in the release of proteolytic enzymes, histamine, bradykinins, and other vasoactive amines, leading to inflammation (erythema, edema, and pruritus). The skin is the primary target organ in dogs and cats, but rhinitis and asthma can also occur in ~15% of affected animals.

CANINE ATOPIC DERMATITIS

Clinical Findings: There is no sex predilection in canine AD. There are breed predilections, but the prevalence within a breed largely depends on the genetic pool and region. Breeds predisposed to development of AD include Chinese Shar-Pei, Wirehaired Fox Terrier, Golden Retriever, Dalmatian, Boxer, Boston Terrier, Labrador Retriever, Lhasa Apso, Scottish

Terrier, Shih Tzu, and West Highland White Terrier. The age of onset is generally between 6 mo and 3 yr. Clinical signs usually occur on a seasonal basis but may be seen year-round with time. Pruritus is the characteristic sign of AD. The feet, face, ears, flexural surfaces of the front legs, axillae, and abdomen are the most frequently affected areas. Primary lesions consist of erythematous macules, patches, and small papules. Lesions that develop secondary to self-trauma include alopecia, erythema, scaling, salivary staining, hemorrhagic crusts, excoriations, lichenification, hyperpigmentation, superficial staphylococcal pyoderma, *Malassezia* and bacterial overgrowth, and allergic otitis externa. Chronic or recurrent otitis is the only complaint in a small number of animals.

Diagnosis: The diagnosis is challenging and is based on signalment, clinical signs, and disease history and not on laboratory tests. Prospective studies have revealed the following clinical features compatible with a diagnosis of AD: onset of clinical signs before 3 yr of age, dogs that live mostly indoors, glucocorticoid-responsive pruritus, pruritus without skin lesions, affected front feet, affected ear pinnae, nonaffected ear margins, and nonaffected dorsolumbosacral areas. These clinical signs can overlap with other diseases, so parasites, pruritic microbial overgrowth, food allergy, and flea allergy need to be excluded. Allergy testing (intradermal or serologic) is a diagnostic aid that measures increased levels of tissue-bound or circulating IgE; alone, it is not diagnostic but rather reflects exposure. The primary reason to pursue intradermal or serologic allergy testing is to identify the offending allergens in an individual animal and to formulate specific immunotherapy. Test results are significant only if the offending allergens identified are compatible with the history or seasonality of pruritus. Animals with classic clinical signs but negative allergy tests are given the diagnosis of ALD. Immunotherapy would be difficult if not impossible in these animals.

Treatment: AD and ALD cannot be cured. Client education is important, because this is a lifelong disease that requires lifelong management and regular progress checks. Management options depend on the severity of the clinical signs and whether the pruritus is seasonal or year round.

Avoidance of allergens: This may be the best choice, but it is difficult, if not impossible, to do unless a specific allergen can be identified.

Relief from pruritus: By definition, this is a pruritic skin disease; itching may be relieved via antipruritic drugs alone or in combination with allergen-specific immunotherapy (ASIT [see below]).

Bathing and coat hygiene: Bathing dogs with AD may decrease pruritus. In dogs with a history of flares due to microbial overgrowth, routine use of antimicrobial shampoos can be of benefit. Except for the use of lipid-containing shampoos, there is no evidence of benefit from shampoos or conditioners that contain oatmeal, promoxine, antihistamines, or corticosteroids.

Recognition and control of flare factors: A relapse of clinical signs in a dog that is otherwise well controlled should prompt an investigation into what caused the exacerbation of pruritus. Recognized flare factors include, but are not limited to, fleas, food and environmental allergens, secondary microbial overgrowth, and poor coat hygiene. These need to be investigated before using systemic antipruritic drugs.

Antipruritic drugs for acute flares: In many dogs, the flare may present as allergic otitis, and topical use of otic corticosteroids may be adequate. There is good evidence for a short course of a topical triamcinolone or hydrocortisone aceponate spray for local pruritus. If the pruritus is too severe or extensive to be controlled with topical formulations, then oral steroids may be needed. Options include prednisone, prednisolone, or methylprednisolone administered PO at 0.5 mg/kg, once to twice daily, until clinical signs are in remission. Tacrolimus, cyclosporine, or essential fatty acids are unlikely to be beneficial for acute flares.

Antipruritic drugs for chronic AD: Systemic reviews of clinical trials have not shown conclusively that omega-3 and omega-6 essential fatty acids alone are likely to reduce pruritus. Use may help improve coat quality. Cyclosporine can provide relief similar to that seen with glucocorticoids. A reported 50% reduction in pruritus in 70% of dogs with AD given cyclosporine A parallels the response seen with glucocorticoids but with fewer adverse effects. Some animals can be maintained

comfortably with this drug alone. Tacrolimus ointment provides a benefit in animals with more localized lesions. However, drugs in this category tend to be more expensive than other symptomatic treatments. Another option is oclacitinib (a Janus kinase inhibitor), which has been shown to be safe and effective in control of pruritus.

Immunotherapy: Immunotherapy or ASIT is arguably the best treatment option for AD, because it is the only therapy that potentially leads to remission of signs without addition of other medications. It remains the treatment of choice of most dermatologists and allergists. ASIT attempts to increase an animal's tolerance to environmental allergens (subjectively measured when an individual is exposed to an identified allergen without developing clinical signs). Although the mode of action is not completely understood, the primary theory states that IgG increases during the first few months of hyposensitization and exerts a blocking effect on circulating allergens by binding them and preventing mast cell degranulation. Another theory states that immunotherapy causes a shift away from TH₂ toward TH₁ by enhancing γ -interferon expression. After an injection, however, allergen-specific IgE levels may also increase when immunotherapy is initiated due to a response to the additional allergen load from the immunotherapy injections. This may result in increased pruritus in some animals. Reducing the amount of allergen given often alleviates this reaction, and with time, allergen-specific IgE levels decrease. However, decreased IgE levels and clinical improvement are not always directly correlated.

ASIT can be administered via injections or allergy drops, which are equally effective. Immunotherapy is best considered for animals with problematic clinical signs that occur for several months during the year. For injections, the animal must also be cooperative enough to receive allergy injections. For allergy drops, the owner must be able to handle the animal's mouth and be able and willing to administer the drops twice a day every day. The criteria for successful hyposensitization include appropriate interpretation of test results, careful selection of allergens, adequate control of secondary infections, control of other allergies (food or flea), systematic administration of immunotherapy injections, and periodic communications between the owner and veterinarian. The long-term commitment needed from both the owner and the veterinarian for successful immunotherapy cannot be

overemphasized. The owner must be willing to follow instructions accurately, be patient, and communicate effectively with the veterinarian. The veterinarian must recognize and treat other primary or secondary causes of pruritus and manage flare factors (eg, otitis, pyoderma, *Malassezia* dermatitis, insect hypersensitivity) as they occur and guide the owner through these challenges until improvement is seen. Symptomatic therapy is required in almost every case during the induction period and at various times of the year (see above).

Allergen selection is determined by correlating the positive allergens on the test results with the prominent allergens during the time of year when the animal is symptomatic. If the test shows positive results for pollens that have no clinical relevance (eg, high pollen count during a period when the animal is not pruritic, positive reaction to an allergen not in the geographic area), then either the allergic reaction is mild (sub-threshold) or it is a false-positive reaction. Either way, the allergen is not included in the allergen mixture.

Allergen protocols vary but usually have induction and maintenance periods. During the induction period, the dosage of allergen gradually increases until an arbitrary maintenance dosage is reached. Once the maximal dosage is given, this maintenance level is continued. The interval between maintenance dosages may vary from 3–4 days to 3 wk. Adjustments in the interval are based on the animal's response. Owners are advised not to expect much response for 6 mo and are asked to commit to at least 1 yr of therapy before deciding the usefulness of immunotherapy. The best assessment of response is to compare the degree of disease or discomfort between similar seasons.

FELINE ATOPIC DERMATITIS

Feline AD is similar to canine AD. It is a pruritic disease in which affected cats have

a hypersensitivity reaction to inhaled or contacted environmental allergens. The age of onset is variable but generally is <5 yr. The signs may be seasonal or nonseasonal. Purebred cats may have a higher risk than domestic shorthaired cats. As in dogs, pruritic cats may have several clinical presentations (eg, miliary dermatitis, symmetric alopecia, eosinophilic granuloma complex, head and neck pruritus) that are consistent with a diagnosis of AD but that must be differentiated from other diseases with similar clinical signs.

Differential diagnoses include flea allergy, various mite infestations (eg, *Cheyletiella*, *Demodex*, *Notoedres*, *Sarcoptes*, *Otodectes*), mosquito bite hypersensitivity, food allergy, autoimmune disease (eg, pemphigus foliaceus), dermatophytosis, and cutaneous neoplasia. A thorough review of the cat's history and complete dermatologic and physical examination, along with the standard flea combing, skin scrapings, and fungal cultures, are mandatory first steps. The diagnosis of AD is made when the other differential diagnoses have been eliminated. Response to glucocorticoids is excellent initially but decreases over time.

Intradermal allergy testing and hyposensitization procedures in cats are similar to those used in dogs, but the intradermal test results are more difficult to read because the reactions are less dramatic and dissipate more rapidly in cats. The same avoidance recommendations made for dogs apply to cats. Symptomatic therapy includes control of secondary infections and use of antipruritic drugs. The approved formulation of cyclosporine for use in cats is liquid; the dosage is 7 mg/kg, and it can be administered PO or in food. After 30 days, the dosage can be tapered to every other day in ~70% of cats and to twice a week in ~50% of cats. Response to immunotherapy is similar to that in dogs (see above); owners are advised to commit to 1 yr of therapy before deciding its usefulness.

FOOD ALLERGY

(Adverse food reactions)

Adverse food reactions comprise allergic reactions termed food allergy as well as nonallergic reactions termed food intolerance. On a practical level, these

terms are frequently interchanged, because the precise immunologic processes of most adverse food reactions are usually not known. Immunologic reactions types I, III,

and IV are thought to be the most likely causes, but this is conjectural for most reported cases in small animals. Food allergies are very rare in herbivores. In this chapter, the more commonly used term food allergy will be used for all adverse food reactions.

Food allergy is ~10% as common as atopic dermatitis in dogs and perhaps as common as atopic dermatitis in cats. The history is that of a nonseasonal pruritus, with little variation in the intensity of pruritus from one season to another in most cases. Most reports do not suggest a breed predilection; however, one report indicated an increased relative risk in Labrador Retrievers, West Highland White Terriers, and Cocker Spaniels. Food hypersensitivities have been reported in Soft-coated Wheaten Terriers in association with protein-losing enteropathy and nephropathy. The age of onset is variable, from 2 mo to 14 yr old. One report indicated that most food allergies begin at <12 mo of age. In adult-onset food allergy, most dogs have been fed the offending allergen for >2 yr.

The distribution of pruritus and lesions varies markedly between animals. Ear canal disease that manifests as pruritus and secondary infection with bacteria (usually *Staphylococcus pseudintermedius*, *Pseudomonas* spp) or yeast (*Malassezia pachydermatis*) is common and may be the only presenting complaint. Other patterns seen include blepharitis, generalized pruritus, generalized seborrhea (scaling), a papular eruption, or a distribution pattern that may mimic that of atopic dermatitis (feet, face, and ventrum) or flea allergy dermatitis (dorsal lumbosacrum and hindlegs). The most common areas of involvement include the ears, feet, inguinal region, axillary area, proximal anterior forelegs, periorbital region, and muzzle. The degree of pruritus is usually moderate to severe. Response to glucocorticoids varies from poor to excellent.

There is no reliable diagnostic test other than a strict food elimination diet. Serologic testing and intradermal testing for food allergens have proved unreliable. The ideal food elimination diet should be balanced and nutritionally complete and not contain any ingredients that have been previously fed. Many diets contain novel protein or carbohydrate sources (eg, venison and rice). However, if a previously fed ingredient is present in the elimination diet, and the animal is allergic to that ingredient, the diet trial will be a failure. Another option is the use of hydrolyzed protein diets, in which the

protein source is hydrolyzed to small molecular weights that are not allergenic. It is estimated that hydrolyzation of the protein may still trigger an allergic response in ~10% of animals allergic to the unhydrolyzed form.

The trial diet should be fed for up to 3 mo. The key point in any food elimination diet trial is that *only* the designated food ingredients can be fed. Thus, no treats, flavored toys, medications, or toothpaste are allowed. If marked or complete resolution in the pruritus and clinical signs occurs during the elimination diet trial, food allergy can be suspected. To confirm that a food allergy exists and that the clinical improvement was not just coincidental, the animal must be challenged with the previously fed food ingredients and a relapse of clinical signs must occur. The return of clinical signs after challenge is usually between 1 hr and 14 days. Once a food allergy is confirmed, the elimination diet should be reinstituted until clinical signs resolve, which usually takes <14 days. At this point, previously fed individual ingredients should be added to the elimination diet for up to 14 days. If pruritus recurs, the individual ingredient is considered positive for having a causative role in the food allergy. If pruritus does not recur, the individual ingredient is not considered important in causing the clinical signs.

The number of offending food allergens varies from one to five ingredients. The most frequently identified causative allergens in canine food allergy include beef, chicken, eggs, corn, wheat, soy, and milk. Once the offending allergens are identified, control of the food allergy is by strict avoidance. Concurrent diseases (such as atopic dermatitis or flea allergy) may complicate the identification of underlying food allergies. Infrequently, a dog will react to new food allergens over time.

Clinical presentations of food allergy in cats include miliary dermatitis, feline symmetric alopecia, eosinophilic granuloma complex (primarily the eosinophilic plaque), and severe head and neck pruritus. No breed, sex, or age predilection is seen. Age of onset varies from 3 mo to 11 yr. In one study, however, 46% of affected cats became symptomatic at ≤2 yr of age, and Siamese cats represented 30% of the cases.

Response to glucocorticoids is variable, but about two-thirds of cats show excellent response initially. In many cats, response to glucocorticoids becomes poor with repeated treatments. As with food allergy in dogs, an elimination diet should be fed for up to

3 mo. The elimination diet should not contain any previously fed ingredients. Food elimination diets can be difficult in cats, because many cats are reluctant to change diets. Cats should not be starved or forced into eating a new elimination diet because of the serious nature of hepatic lipidosis that may be induced by prolonged anorexia.

Time until relapse of pruritus after challenge with the offending food varies from 15 min to 10 days. The most frequently identified food allergens in cats include fish, beef, milk, and chicken. Avoidance of the offending allergens will control the clinical signs associated with the food allergy.

URTICARIA

(Hives, Nettle rash)

Urticaria is characterized by multiple plaque-like eruptions that are formed by localized edema in the dermis and that often develop and disappear suddenly. It occurs in all domestic animals but most often in horses. Allergic urticaria may be exogenous or endogenous. Exogenous hives may be produced by toxic irritating products of the stinging nettle, the stings or bites of insects, topical medications, or exposure to chemicals (eg, carbolic acid, turpentine, carbon disulfide, or crude oil). Nonimmunologic factors such as pressure, sunlight, heat, exercise, psychologic stress, and genetic abnormalities may precipitate or intensify urticaria. Pruritus is not always present, particularly in horses.

Sensitive animals, particularly short-haired dogs and purebred horses, also rarely may exhibit **dermographism**, a phenomenon wherein pressure applied to the skin produces linear urticarial lesions. The clinical significance is unknown.

Endogenous urticaria may develop after exposure to topical, inhaled, or ingested allergens or administration of medications; it has been seen mostly in horses and dogs. In horses, it has been noted in the course of GI conditions, particularly severe constipation or inflammation of the intestinal mucosa. A unique form of urticaria in cattle has been described chiefly in the Channel Island breeds (Jersey, Guernsey), which become sensitized to the casein in their own milk ("milk allergy"); it occurs in cases of milk retention or unusual engorgement of the udder with milk. Urticaria has been seen in bitches during estrus. In young horses, dogs, and pigs, urticaria may be associated with intestinal parasites. **Angioneurotic edema** is a life-threatening variant of urticaria in which there is diffuse subcutaneous edema, often localized to the head,

limbs, or perineum. In horses, dermatophytosis (ringworm) and pemphigus foliaceus may present as urticaria early in the disease. In horses, vasculitis may also present with urticaria.

Clinical Findings: The wheals or plaques appear within a few minutes or hours of exposure to the causative agent. In severe cases, the cutaneous eruptions are preceded by fever, anorexia, or dullness. Horses often become excited and restless. The skin lesions are elevated, round, flat-topped, and 0.5–8 in. (1–20 cm) in diameter; they may be slightly depressed in the center. They can develop on any part of the body but are seen mainly on the back, flanks, neck, eyelids, and legs. In advanced cases, they may be found on the mucous membranes of the mouth, nose, conjunctiva, rectum, and vagina. In general, the lesions disappear as rapidly as they arise, usually within a few hours.

In sheep, lesions usually are seen only on the udder and hairless parts of the abdomen. In pigs, eruptions have been seen around the eyes, between the hindlegs, and on the snout, abdomen, and back.

In general, the prognosis is favorable. Fatalities are rare and are probably due to anaphylaxis or associated angioedema involving the respiratory passages.

Chronic urticaria is a diagnostic challenge. All allergens in an environment should be considered potential causes, and elimination of exposure instituted, if possible. Persistent urticarial lesions, particularly those that progress to thickened crusts, should be biopsied.

Treatment: Acute urticaria usually disappears spontaneously. The rapid-acting glucocorticoids, eg, hydrocortisone

sodium succinate or prednisolone sodium succinate or hemisuccinate are reported to be useful. Dexamethasone (0.1 mg/kg) has been useful in dogs, cats, and horses. Antihistamines are of questionable value and may induce urticaria if given IV. Epinephrine may be given in life-threatening situations. The lesions promptly

disappear but return rapidly if the allergen is not eliminated. Usually, local treatment of the lesions is not necessary. In chronic urticaria in horses, the antihistamine hydroxyzine at 0.4–0.8 mg/kg, bid, or the tricyclic antidepressant doxepin (which has antihistaminic properties) at 0.6 mg/kg, bid, may be useful.

DERMATOPHILOSIS

(Dermatophilus infection, Cutaneous streptothricosis, Lumpy wool, Strawberry footrot)

This infection of the epidermis, seen worldwide but more prevalent in the tropics, is also erroneously called mycotic dermatitis. The lesions are characterized by exudative dermatitis with scab formation. *Dermatophilus congolensis* has a wide host range. Among domestic animals, cattle, sheep, goats, and horses are affected most frequently, and pigs, dogs, and cats rarely. It is commonly called cutaneous streptothricosis in cattle, goats, and horses; in sheep, it is termed lumpy wool when the woolled areas of the body are affected. Infection in camel herds has been related to drought and poverty. Recent isolates from chelonids may represent a new species of *Dermatophilus*. It is also a common disease in farmed crocodiles. The few human cases reported usually have been associated with handling diseased animals.

Etiology, Transmission, and Epidemiology:

D. congolensis is a gram-positive, non-acid-fast, facultative anaerobic actinomycete. It is the only currently accepted species in the genus, but a variety of strains can be present within a group of animals during an outbreak. It has two characteristic morphologic forms: filamentous hyphae and motile zoospores. The hyphae are characterized by branching filaments (1–5 µm in diameter) that ultimately fragment by both transverse and longitudinal septation into packets of coccoid cells. The coccoid cells mature into flagellated ovoid zoospores (0.6–1 µm in diameter).

The natural habitat of *D. congolensis* is unknown. Attempts to isolate it from soil have been unsuccessful, although it is probably a saprophyte in the soil. It is believed to be spread by direct contact

between animals, through contaminated environments, or possibly via biting insects. It has been isolated only from the integument of various animals and is restricted to the living layers of the epidermis. Asymptomatic chronically infected animals are considered the primary reservoir.

Factors such as prolonged wetting by rain, high humidity, high temperature, and various ectoparasites that reduce or permeate the natural barriers of the integument influence the development, prevalence, seasonal incidence, and transmission of dermatophilosis. Ticks and lice are major predisposing factors in cattle and sheep, respectively.

The organism can exist in a quiescent form within the epidermis until infection is exacerbated by climatic conditions. Epidemics usually occur during the rainy season. Moisture facilitates release of zoospores from preexisting lesions and their subsequent penetration of the epidermis and establishment of new foci of infection. High humidity also contributes indirectly to the spread of lesions by allowing increases in the number of biting insects, particularly flies and ticks, that act as mechanical vectors. Shearing, dipping, or introducing an infected animal into a herd or flock can spread infection.

Dermatophilosis is contagious only in that any reduction in systemic or local skin resistance favors establishment of infection and subsequent disease.

Pathogenesis: To establish infection, the infective zoospores must reach a skin site where the normal protective barriers are reduced or deficient. The respiratory efflux of low concentrations of carbon dioxide from the skin attracts the motile zoospores

to susceptible areas on the skin surface. Zoospores germinate to produce hyphae, which penetrate into the living epidermis and subsequently spread in all directions from the initial focus. Hyphal penetration causes an acute inflammatory reaction. Natural resistance to the acute infection is due to phagocytosis of the infective zoospores, but once infection is established, there is little or no immunity. In most acute infections, the filamentous invasion of the epidermis ceases in 2–3 wk, and the lesions heal spontaneously. In chronic infections, the affected hair follicles and scabs are sites from which intermittent invasions of noninfected hair follicles and epidermis occur. The invaded epithelium cornifies and separates in the form of a scab. In wet scabs, moisture enhances the proliferation and release of zoospores from hyphae. The high carbon dioxide concentration produced by the dense population of zoospores accelerates their escape to the skin surface, thus completing the unique life cycle.

Clinical Findings: Dermatophilosis is seen in animals at all ages but is most prevalent in the young, in animals chronically exposed to moisture, and in immunosuppressed hosts. Lesions on a host can vary from acute to chronic. Age, sex, and breed do not seem to affect host susceptibility. Pruritus is variable. Most affected animals recover spontaneously within 3 wk of the initial infection (provided chronic maceration of the skin does not occur). In general, the onset of dry weather speeds healing. Uncomplicated skin lesions heal without scar formation. These infections usually have little effect on general health. Animals with severe generalized infections often lose condition, and movement and prehension are difficult if the feet, lips, and muzzle are severely affected; these animals are often sent to slaughter as incurable. Deaths occasionally occur, particularly in calves and lambs, because of generalized disease with or without secondary bacterial infection and secondary fly or screwworm infestation. The primary economic consequences are damaged hides in cattle, wool loss in sheep, and lameness and loss of performance in horses when severely affected around the pastern area. Cattle with lesions covering >50% of the body are likely to become seriously ill.

Lesions: Distribution of the gross lesions on cattle, sheep, and horses usually correlates with the predisposing factors that reduce or permeate the natural barriers of the integument. In cattle, the lesions can be

observed in three stages: 1) hairs matted together as paint-brush lesions, 2) crust or scab formation as the initial lesions coalesce, and 3) accumulations of cutaneous keratinized material forming wart-like lesions that are 0.5–2 cm in diameter. Typical lesions consist of raised, matted tufts of hair. Most lesions associated with prolonged wetting of the skin are distributed over the head, dorsal surfaces of the neck and body, and upper lateral surfaces of the neck and chest. Cattle that stand for long periods in deep water and mud develop lesions in areas such as skin folds of the flexor surfaces of the joints. Dairy cows may present with papular crusted lesions on the udder. Lesions initiated by biting flies (mechanical vectors) are found primarily on the back, whereas lesions induced by ticks are primarily on the head, ears, axillae, groin, and scrotum.

Chronic lumpy wool infections are characterized by pyramid-shaped masses of scab material bound to wool fibers. The crusts are primarily on the dorsal areas of the body and prevent the shearing of sheep; spiny plants often predispose to lesions on the lips, legs, and feet. Strawberry footrot is a proliferative dermatitis affecting the skin from the coronet to the carpus or hock.

Lesions on horses with long winter hair coats are similar to those of cattle, developing with matted hair and paint-brush lesions leading to crust or scab formation with yellow-green pus present under larger scabs. With short summer hair, matting and scab formation is uncommon; loss of hair with a fine paint-brush effect can be extensive. Persistent wetting of pasterns in wet yards, stables, or at pasture leads to lower limb infection; white legs and the white-skinned areas of the lips and nose are more severely affected. Generalized disease is also associated with prolonged wet weather. Outbreaks occur on farms with previously affected horses.

Histopathologic examination reveals the characteristic branching hyphae with multidimensional septations, coccoidal cells, and zoospores in the epidermis. The organisms are usually abundant in active lesions but can be sparse or absent in chronic lesions.

Diagnosis: Presumptive diagnosis depends largely on the appearance of lesions in clinically diseased animals and demonstration of *D. congolensis* in stained smears or histologic sections from scabs. A definitive diagnosis is made by demonstrating the organism in cytologic preparations, isolation via culture, and/or via skin biopsy.

An indirect fluorescent antibody technique and a single dilution ELISA test have been developed for large serologic and epidemiologic surveys. The most practical diagnostic test is cytologic examination of fresh crusts and/or impression smears of the underside of freshly avulsed lesions. Fresh crusts are minced on a glass microscope slide with a sterile scalpel blade in several drops of sterile saline. The slide is allowed to air dry and is then stained with a fast Giemsa or Romanowski stain. The organisms are seen under oil immersion as 2–6 parallel rows of gram-positive cocci that look like railroad tracks. Differential diagnoses include dermatomycoses in most species, warts and lumpy skin disease (see p 868) in cattle, contagious ecthyma (see p 866) and ulcerative dermatosis (see p 872) in sheep, and dermatophytosis (see p 872) and immune-mediated scaling diseases of horses (eg, pemphigus foliaceus).

Treatment and Control: It was previously thought that because acutely infected animals usually heal rapidly and spontaneously, treatment was indicated only for cosmetic reasons in food-producing animals. However, in certain parts of the world, the disease is associated with significant morbidity and mortality, loss of body condition, decreased milk production, and increased somatic cell counts in milk. Treatment is recommended in horses because the lesions interfere with use and are painful. Organisms are susceptible to a wide range of antimicrobials: erythromycin,

spiramycin, penicillin G, ampicillin, chloramphenicol, streptomycin, amoxicillin, tetracyclines, and novobiocin. Two doses of long-acting oxytetracycline (20 mg/kg) 1 day apart have shown to be curative in 85% of cattle and 100% of sheep, compared with cure rates of 71% in cattle and 80% in sheep for a single dose. In food-producing animals, topical applications of lime sulfur are a cost-effective adjuvant to antibacterial therapy. Insecticides applied externally are frequently used to control biting insects.

In horses, the lesions should be gently soaked and removed. Topical antibacterial shampoo therapy is effective as adjuvant therapy. Chlorhexidine is recommended. Topical treatment with povidone-iodine is superior to parenteral oxytetracycline alone (100% and 66% effective, respectively).

Isolating clinically affected animals, culling affected animals, and controlling ectoparasites are methods used to break the infective cycle. Preventing chronic maceration of the skin and keeping the animals dry are important. Zinc levels should be checked in the feed of cattle, because outbreaks have been associated with zinc deficiencies.

Zoonotic Risk: Dermatophilosis can be transmitted to people. Direct contact with an infected animal can lead to infections on the hands and arms. Affected animals should be handled with gloves, and thorough handwashing with an antibacterial soap is recommended after contact with an infected animal.

EXUDATIVE EPIDERMITIS

(Greasy pig disease)

Exudative epidermitis is a generalized dermatitis that occurs in 5- to 60-day-old pigs and is characterized by sudden onset with morbidity of 10%–90% and mortality of 5%–90%. The acute form usually affects suckling piglets, whereas a chronic form is more commonly seen in weaned pigs. It has been reported from most swine-producing areas of the world.

Lesions are caused by *Staphylococcus hyicus*, which can produce an exfoliative toxin but seems unable to penetrate intact skin. Both virulent and avirulent strains

exist. Abrasions on the face, feet, and legs or lacerations on the body precede infection. Such injuries are usually caused by fighting or by abrasive surfaces such as new concrete. Other predisposing factors that may affect the severity and progress of the disease include immunity, hygiene, nutrition, and the presence of mange mites or anything that damages the skin. Mature sows that have acquired a high level of immunity from previous exposure will provide protection to piglets via their colostrum. The incidence is often higher in

Chronic exudative epidermitis over the entire body in a 5-wk-old weaner pig. Courtesy of Dr. Ronald D. A. Cameron.

gilt litters and in newly established SPF herds in which most breeders are gilts.

Pigs develop resistance with age, but *Shyicus* may be recovered from the skin of older pigs, the vagina of sows, and the preputial diverticulum of boars. These inapparent carriers serve as a source of contamination for naive herds. Suckling pigs are usually infected by their dams, in some cases during birth from sows with vaginal infections, or from contamination in the farrowing unit. Suckling piglets are the most commonly and severely affected, but cross-infection occurs after mixing at weaning with a morbidity of as much as 80%. However, mortality is usually low in this age group. The incidence appears to have increased because of pig production units with high stocking densities and possibly earlier weaning. There are recent reports of exudative epidermitis associated with ST398 methicillin-resistant *S. aureus* (MRSA) infections, but a causal role has not been clearly demonstrated.

Clinical Findings and Lesions: The first signs are listlessness and reddening of the skin in one or more piglets in the litter. Affected pigs rapidly become depressed and refuse to eat. Body temperature may increase early in the disease but thereafter is near normal. The skin thickens, and reddish brown spots (macules) appear around the eyes, nose, lips, and ears from which serum and sebum exude. The lesions increase in size and develop a vesicular or pustular appearance.

The body is rapidly covered with a moist, greasy exudate of sebum and serum that becomes crusty. Accumulation of dirt gives

the affected area a black color. Vesicles and ulcers may also develop on the nasal disk and tongue. The feet are nearly always involved, with erosions at the coronary band and heel; the hoof may be shed in rare cases. In the acute disease, death occurs within 3–5 days. In older animals, the chronic form of the disease is seen as thick, crusty lesions over the entire body or as discrete circumscribed lesions that do not coalesce. Mortality is low except in very young suckling piglets. However, recovery is slow and growth is retarded and often associated with diarrhea, emaciation, and dehydration.

Necropsy of severely affected pigs reveals marked dehydration, congestion of the lungs, and inflammation of the peripheral lymph nodes. Distention of the kidneys and ureters with mucus, cellular casts, and debris is common in peracute and acute forms of the disease. Differential diagnoses include sarcoptic mange (see p 919), nutritional deficiencies including zinc (parakeratosis, see p 975), ringworm (see p 872), and pityriasis rosea (see p 979).

Treatment: The causative organism is inhibited by many antibiotics, including amoxicillin, ampicillin, erythromycin, lincomycin, penicillin, tylosin, trimethoprim-sulfonamide, the aminoglycosides, and cephalosporins. Successful treatment requires that the antimicrobial be given in high dosages early in the disease and for 7–10 days. Success is greatest when antimicrobial therapy is combined with daily applications of antiseptics to the entire body surface. Treatment is less effective in very young pigs and ineffective in advanced cases. In severe outbreaks, in-contact pigs should also be given antibiotics for several days. Sows due to farrow, and their housing, should be thoroughly disinfected to prevent outbreaks. Hygiene in the weaner accommodation and strategic in-water or in-feed medication for 3–5 days will help control outbreaks after weaning. Other procedures that may decrease the severity of an outbreak include clipping the needle teeth of newborn pigs, providing soft bedding, segregating infected animals, and avoiding mixing of animals to decrease the possibility of skin lesions due to fighting. Autogenous bacterins have been used with some success to reduce the incidence of disease in chronically infected herds.

INTERDIGITAL FURUNCULOSIS

Interdigital furuncles, often incorrectly referred to as interdigital cysts, are painful nodular lesions located in the interdigital webs of dogs. Histologically, these lesions represent areas of nodular pyogranulomatous inflammation—they are almost never cystic. Canine interdigital palmar and plantar comedones and follicular cysts is a recognized syndrome that may be a subtype of interdigital furuncles or a separate disease.

Etiology: The most common cause is a deep bacterial infection. Many dog breeds (eg, Chinese Shar-Pei, Labrador Retriever, English Bulldog) are predisposed to bacterial interdigital furunculosis because of the short bristly hairs located on the webbing between the toes, prominent interdigital webbing, or both. The short shafts of hairs are easily forced backward into the hair follicles during locomotion (traumatic implantation). Hair, ie, keratin, is very inflammatory in the skin, and secondary bacterial infections are common. Less commonly, foreign material is traumatically embedded in the skin. Demodicosis (see p 920) may be a primary cause of interdigital furunculosis. Canine atopic dermatitis (see p 853) is also a common cause of recurrent interdigital furunculosis.

The cause of canine interdigital palmar and plantar comedones and follicular cysts is unknown but most likely involves trauma, resulting in epidermal and follicular infundibular hyperkeratosis, acanthosis, plugging or narrowing of the follicular opening, and retention of the follicular contents.

Clinical Findings and Lesions: Early lesions of interdigital furunculosis may appear as focal or generalized areas of erythema and papules in the webbing of the feet that, if left untreated, rapidly develop into single or multiple nodules. The latter usually are 1–2 cm in diameter, reddish purple, shiny, and fluctuant; they may rupture when palpated and exude a bloody material. Interdigital furuncles are most commonly found on the dorsal aspect of the paw but may also be found ventrally. Furuncles are usually painful, and the dog may be obviously lame on the affected foot (or feet) and lick and bite at the lesions.

Lesions caused by a foreign body, eg, a grass awn, are usually solitary and are often found on a front foot; recurrence is not common in these cases. If bacteria cause the interdigital furunculosis, there may be several nodules with new lesions developing as others resolve. A common cause of recurrence is the granulomatous reaction to the presence of free keratin in the tissues.

Dogs with interdigital comedones and follicular cysts typically present with lameness and draining tracts. Skin lesions are not often seen unless the hair coat is clipped. Areas of alopecia and thickened, firm, callus-like skin with multiple comedones are typical.

Diagnosis: For furunculosis, the diagnosis is often based on clinical signs alone. The major differential diagnoses are traumatic lesions, foreign bodies, follicular comedone cysts, and neoplasia, although the latter is rare. The most useful diagnostic tests include skin scrapings for *Demodex* mites, impression smears, or fine-needle aspirates to confirm the presence of an inflammatory infiltrate. Unusual or recurrent lesions should be excised for histopathologic examination. Solitary lesions may require surgical exploration to find and remove foreign bodies such as grass awns.

Definitive diagnosis of palmar and plantar follicular cysts requires a skin biopsy. However, these cysts are suspected when clinical examination reveals draining tracts associated with callus-like lesions or obvious comedone formation. Moderate to extensive compact hyperkeratosis and acanthosis of the epidermal and follicular infundibulum is found. Follicular cysts consisting of keratin are common. Often, lesions are complicated by secondary infection and concurrent bacterial furunculosis.

Treatment: Bacterial interdigital furuncles respond best to a combination of topical and systemic therapy. Treatment is best based on culture and susceptibility, because these are deep infections and may require long-term therapy, particularly if multifocal. Pending culture, application of warm water compresses and topical triple antibiotic ointment or mupirocin antibiotic ointment are recommended. Foot soaks in

chlorhexidine solution are also helpful. Because the lesions are pyogranulomatous, it may be difficult for antibiotics to penetrate them; therefore, >8 wk of systemic antibiotic therapy may be required for lesions to completely resolve. These lesions are often complicated by concurrent *Malassezia* spp infections. Oral ketoconazole or itraconazole (5–10 mg/kg) for 30 days may be indicated. The presence of *Malassezia* can be documented by cytologic examination of nail bed debris and/or impression smears of the skin.

Chronic, recurrent interdigital furunculosis is most often caused by inappropriate antibiotic therapy (too short a course, wrong dosage, wrong drug), concurrent corticosteroid administration, demodicosis, an anatomic predisposition, or a foreign body reaction to keratin. Lesions that recur despite therapy can also be a sign of an underlying disease, eg, atopy, hypothyroidism, or concurrent *Malassezia* infection.

Lesions in confined dogs are likely to recur unless the dog is removed from wire or concrete surfaces. In some chronic cases, surgical excision or surgical correction of the webbing via fusion podoplasty may be needed. Alternatively, pulse antibiotic therapy (full dosage therapy 2–3 times/wk) or chronic low dosage antibiotic therapy (eg, 500 mg/day/dog, PO) may help maintain clinical remission and provide pain relief in dogs with chronic lesions. This therapy is recommended only when the inciting cause cannot be identified (eg, idiopathic pyoderma), treated (eg, anatomic predisposition), or resolved (eg, chronic infection caused by foreign body material or keratin).

Treatment of interdigital palmar and plantar comedones and follicular cysts can be successfully accomplished by laser therapy. Postoperative care is time intensive, with hydrotherapy and bandage changes once or twice daily.

PYODERMA

Pyoderma literally means “pus in the skin” and can be caused by infectious, inflammatory, and/or neoplastic etiologies; any condition that results in the accumulation of neutrophilic exudate can be termed a pyoderma. Most commonly, however, pyoderma refers to bacterial infections of the skin. Pyodermas are common in dogs and less common in cats.

Bacterial pyodermas are either simple infections or complex infections. Simple infections are those occurring in young animals that are triggered by one-time or simple events, eg, flea infestation. Complex infections are recurrent and are associated with underlying diseases, such as allergies (flea allergy, atopic dermatitis, food allergy), internal diseases (particularly endocrinopathies such as hypothyroidism or hyperadrenocorticism), seborrheic conditions (including follicular or sebaceous gland diseases), parasitic diseases (eg, *Demodex canis*), or anatomic predispositions (eg, skin folds). Either simple or complex infections can be superficial or deep. Bacterial pyodermas limited to the epidermis and hair follicles are referred to as superficial, whereas those that involve the dermis, deep dermis, or cause furuncu-

losis are referred to as deep. Etiologic classification refers to the pathogenic organism involved in the infection (eg, staphylococci, streptococci, etc). Infections are superficial and secondary to a variety of other conditions.

Etiology: Bacterial pyoderma is usually triggered by an overgrowth/overcolonization of normal resident or transient flora. The primary pathogen of dogs is *Staphylococcus pseudintermedius*.

Superficial pyoderma in a dog. Courtesy of Dr. Stephen White.

Normal resident bacteria in canine skin also include coagulase-negative staphylococci, streptococci, *Micrococcus* sp, and *Acinetobacter*. Transient bacteria in canine skin include *Bacillus* sp, *Corynebacterium* sp, *Escherichia coli*, *Proteus mirabilis*, and *Pseudomonas* sp. These organisms may play a role as secondary pathogens, but often *S. pseudintermedius* is required for a pathologic process to ensue. Normal resident bacteria in feline skin include *Acinetobacter* sp, *Micrococcus* sp, coagulase-negative staphylococci, and α -hemolytic streptococci. Transient bacteria in feline skin include *Alcaligenes* sp, *Bacillus* sp, *Escherichia coli*, *Proteus mirabilis*, *Pseudomonas* sp, coagulase-positive and coagulase-negative staphylococci, and α -hemolytic streptococci.

The most important factor in superficial pyodermas that allows a bacteria to colonize the skin surface is bacterial adherence, or "stickiness," to the keratinocytes. Warm, moist areas on the skin, such as lip folds, facial folds, neck folds, axillary areas, dorsal or plantar interdigital areas, vulvar folds, and tail folds, often have higher bacterial counts than other areas of skin and are at an increased risk of infection. Pressure points, such as elbows and hocks, are prone to infections, possibly because of follicular irritation and rupture due to chronic repeated pressure. Any skin disease that changes the normally dry, desert-like environment to a more humid environment can predispose the host to overcolonization of the skin with resident and transient bacteria.

Clinical Findings and Lesions: The most common clinical sign of bacterial pyoderma in both dogs and cats is excessive scaling; scales are often pierced by hairs. Pruritus is variable. In dogs, superficial pyoderma commonly appears as multifocal areas of alopecia, follicular papules or pustules, epidermal collarettes, and serous crusts. The trunk, head, and proximal extremities are most often affected. Shorthaired breeds often present with multiple superficial papules that look similar to urticaria because the inflammation in and around the follicles causes the hairs to stand more erect. These hairs are often easily epilated, an important feature that helps to distinguish superficial pyoderma from true urticaria, in which hairs do not epilate. In bacterial pyoderma, affected hairs epilate and progress to form focal areas of alopecia 0.5–2 cm in diameter. At the margins of the hair loss, mild epidermal collarette formation may be

present, but follicular pustules and erythema are often absent in shorthaired breeds, making diagnosis difficult. Collies and Shetland Sheepdogs often have diffuse areas of widespread alopecia with mild erythema and epidermal collarette formation at the leading edge of the expanding area, often mimicking an endocrinopathy. Pustules and crusts are infrequently found.

The hallmarks of deep pyoderma in dogs are pain, crusting, odor, and exudation of blood and pus. Erythema, swelling, ulcerations, hemorrhagic crusts and bullae, hair loss, and draining tracts with sero-hemorrhagic or purulent exudate may also be seen. The bridge of the muzzle, chin, elbows, hocks, interdigital areas, and lateral stifles are more prone to deep infections, but any area may be involved. Acral lick granulomas and areas of pyotraumatic dermatitis are also clinical manifestations of deep pyoderma. Interdigital furunculosis (see p 862) is another manifestation of deep pyoderma. Plant awns, naked keratin from hair shafts or ruptured hair follicles, and other foreign bodies play a significant role in the inflammatory process associated with deep pyodermas.

Superficial pyoderma in cats is usually due to *Staphylococcus* spp. It is often overlooked and underdiagnosed. The most common clinical finding is scaling, particularly over the lumbosacral area; scales pierced by hairs are a common finding. Intact pustules are almost never found. Feline pyoderma is most common in allergic skin diseases, parasitic diseases, and feline chin acne.

Miliary dermatitis can be a clinical manifestation of superficial pyoderma. Cats with deep pyodermas often present with alopecia, ulcerations, hemorrhagic crusts, and draining tracts. Eosinophilic plaques are a common clinical presentation of deep pyoderma secondary to an allergic disease. Recurrent nonhealing deep pyoderma in cats can be associated with systemic disease, such as feline immunodeficiency virus or feline leukemia virus, or atypical mycobacteria.

Diagnosis: The diagnosis of superficial pyoderma is usually based on clinical signs—hair loss, scaling, erythema, papules, pustules, and epidermal collarettes. Differential diagnoses for superficial pyoderma include demodicosis (see p 920), *Malassezia* dermatitis, dermatophytosis (see p 872), other causes of folliculitis, and uncommon crusting diseases such as pemphigus foliaceus. Diagnosis of

pyoderma should also include steps to identify any predisposing causes.

Identification of the dermatologic lesions described above allows a tentative diagnosis of superficial pyoderma. Direct impression smears of intact pustules, areas underlying crusts or epidermal collarettes, or moist erythematous areas may reveal cocci, rods, or inflammatory cell infiltrates. Impression smears of areas of hair loss and scaling may only reveal large numbers of exfoliative keratinocytes. One of the most important reasons to do impressions is to determine whether a concurrent *Malassezia* infection or overcolonization is present; there is a symbiotic relationship between *Staphylococcus* and *Malassezia*, and both are found in ~50% of cases. The infection will not resolve without concurrent systemic antimicrobial therapy. Multiple deep skin scrapings are needed to exclude parasitic infections, particularly *Demodex canis*. Dermatophyte cultures should be done to exclude dermatophytosis. Bacterial culture and susceptibility testing is highly recommended because of the increased prevalence of methicillin-resistant *Staphylococci*.

Accurate test results are most likely obtained from intact pustules or induced rupture of deep lesions. Caution should be exercised in interpreting culture results from samples submitted from crusted lesions, papules, epidermal collarettes, and fistulous tracts, because contamination of the sample is more likely than with samples obtained from a closed lesion. Pending culture and susceptibility, topical antimicrobial therapy is recommended, using chlorhexidine-based baths or solutions.

The most common underlying triggers of superficial pyoderma include fleas, flea allergy dermatitis, atopic dermatitis, food allergy, hypothyroidism, hyperadrenocorticism, and poor grooming. Appropriate diagnostic testing and treatment of underlying triggers is mandatory. The most common causes of recurrent bacterial pyoderma include failure to identify an underlying trigger, antibiotic undertreatment (dosage too low or duration of therapy too short), concurrent use of glucocorticoids, wrong antibiotic, or wrong dose.

Treatment: The primary treatment of superficial pyoderma is with appropriate antibiotics for ≥ 21 , and preferably 30, days. All clinical lesions (except for complete regrowth of alopecic areas and resolution of hyperpigmented areas) should be resolved for at least 7 days before antibiotics are discontinued. Chronic, recurrent, or deep

pyodermas typically require 8–12 wk or longer to resolve completely.

Amoxicillin, penicillin, and tetracycline are inappropriate choices to treat superficial or deep pyodermas, because they are ineffective in 90% of these cases. Fluoroquinolones should be used only if based on culture and susceptibility.

Topical antibiotics may be helpful in focal superficial pyoderma. A 2% mupirocin ointment penetrates skin well and is helpful in deep pyoderma, is not systemically absorbed, has no known contact sensitization, and is not used as a systemic antibiotic that would increase the likelihood of cross-resistance. It is not very effective against gram-negative bacteria. This ointment should not be used in cats with any known or suspected history of renal disease, because the preparation contains propylene glycol. Neomycin is more likely to cause a contact allergy than other topicals and has variable efficacy against gram-negative bacteria. Bacitracin and polymyxin B are more effective against gram-negative bacteria than other topical antibiotics but are inactivated in purulent exudates.

Attention to grooming is often overlooked in the treatment of both superficial and deep pyoderma. The hair coat should be clipped in animals with deep pyoderma, and a professional grooming is recommended in medium- to longhaired dogs with generalized superficial pyoderma. Clipping will remove excessive hair that can trap debris and bacteria and will facilitate grooming. Longhaired cats usually benefit most from having the hair coat clipped.

Dogs with superficial pyoderma should be bathed 2–3 times/wk during the first 2 wk of therapy and then 1–2 times until the infection has resolved. Dogs with deep pyoderma may require daily hydrotherapy. Medicated shampoos should be prediluted 1:2 to 1:4 before application to facilitate lathering, dispersal, and rinsing. Appropriate antibacterial shampoos include benzoyl peroxide, chlorhexidine, chlorhexidine-ketoconazole, ethyl lactate, and triclosan. Shampooing will remove bacteria, crusts, and scales, as well as reduce the pruritus, odor, and oiliness associated with the pyoderma. Clinical improvement in superficial pyodermas may not be evident for at least 14–21 days, and recovery may not be as rapid as expected.

Of increasing concern is the development of methicillin-resistant staphylococci, and narrow-spectrum antibiotics should be used in treatment of pyoderma to minimize development of resistance. Recurrent

bacterial pyoderma, deep pyoderma, and/or animals with a history of extensive antibiotic use are best treated based on culture and sensitivity. Concurrent aggressive topical antimicrobial therapy is

helpful. Avoidance of fluoroquinolones and second- and third-generation cephalosporins as empirical therapy is important to minimize the development of multistrain-resistant staphylococci.

CONTAGIOUS ECTHYMA

(Orf, Contagious pustular dermatitis, Sore mouth)

Contagious ecthyma is an infectious dermatitis of sheep and goats that affects primarily the lips of young animals. The disease is usually more severe in goats than in sheep. People are occasionally affected through direct contact.

Etiology and Epidemiology: The causal parapoxvirus is related to pseudocowpox (see p 868) and bovine papillar stomatitis (see p 215). Infection occurs by contact. The virus is highly resistant to desiccation in the environment, having been recovered from dried crusts after 12 yr. In the laboratory, it is also resistant to glycerol and to ether.

Contagious ecthyma is found worldwide and is common in young lambs reared artificially and in older lambs during late summer, fall, and winter on pasture, and during winter in feedlots.

Clinical Findings and Diagnosis: The primary lesion develops at the mucocutane-

ous junction of the lips and around erupting incisor teeth and may extend to the mucosa of the buccal cavity. Occasionally, lesions are found on the feet and around the coronet, where secondary bacterial infection with *Dermatophilus congolensis* commonly causes "strawberry footrot." Ewes nursing infected lambs may develop lesions on the teats extending onto the udder skin. The lesions develop as papules and progress through vesicular and pustular stages before encrusting. Coalescence of numerous discrete lesions often leads to the formation of large scabs, and the proliferation of dermal tissue produces a verrucose mass under them. When the lesion extends to the oral mucosa, secondary necrobacillosis (see p 1429) frequently develops.

During the course of the disease (1–4 wk), the scabs drop off and the tissues heal without scarring. During active stages of infection, more severely affected lambs do not eat normally and lose condition. Extensive lesions on the feet cause lameness. Mastitis, sometimes gangrenous, may occur in ewes with lesions on the teats.

The lesion is characteristic. The disease must be differentiated from ulcerative dermatosis (see p 872), which produces tissue destruction and crateriform ulcers. Ecthyma usually affects younger animals than does ulcerative dermatosis, although this criterion can only be used presumptively. Foot-and-mouth disease (see p 629) and bluetongue (see p 738) infection should be considered if morbidity is high and clinical signs include salivation, lameness, and fever. Staphylococcal folliculitis affects the skin of the muzzle and surrounding the eyes. Direct demonstration of virus in scab material by electron microscopy has now been replaced by PCR as the diagnostic method of choice for ecthyma. Historically, positive differentiation could be obtained by inoculating susceptible and ecthyma-immunized sheep.

Proliferative contagious ecthyma (orf) lesion extends from the mucocutaneous junction of the lips in a sheep. Courtesy of Dr. Philip Scott.

Treatment and Control: Both parenteral and topical antibiotics may help combat secondary bacterial infection of the skin lesions. In endemic areas, appropriate repellents and larvicides should be applied to the lesions to prevent myiasis. The virus is transmissible to people, and the lesions, usually confined to the hands and face, are more proliferative and occasionally very distressing. Veterinarians and sheep handlers should exercise reasonable protective precautions and wear disposable gloves. Diagnosis in people is established by transmitting the virus to sheep; a complement-fixation test may be of value.

Sheep that have recovered from natural infection are highly resistant to reinfection. Despite a multiplicity of immunogenic virus strains, the presently used commercial single-strain live vaccines have produced

fair immunity in all parts of the USA (with an occasional exception more usually seen in goats). Vaccine breaks appear to be due to the virulence of the infecting strain rather than to differences in antigenicity of the vaccine. Sheep immunized against contagious ecthyma remain susceptible to ulcerative dermatosis.

Live vaccines should be used cautiously to avoid contaminating uninfected premises, and vaccinated animals should be segregated from unprotected stock until the scabs have fallen off. A small amount of the live vaccine is brushed over light scarifications of the skin, usually on the inside of the thigh or behind the elbow or caudal fold. Lambs should be vaccinated when ~1 mo old. For best results, a second vaccination ~2–3 mo later is suggested. Nonimmunized lambs should be vaccinated ~1–2 mo before entering infected feedlots.

POX DISEASES

Pox diseases are acute viral diseases that affect many animals, including people and birds. Some poxviruses also cause zoonoses. Typically, lesions of the skin and mucosae are widespread and progress from macules to papules, vesicles, and pustules before encrusting and healing. Most lesions contain multiple intracytoplasmic inclusions, which represent sites of virus replication in infected cells. In some poxvirus infections, vesiculation is not clinically evident, but microvesicles can be seen on histologic examination and, in some, proliferative lesions are characteristic.

Infection is acquired either by inhalation or through the skin (eg, sheeppox). In certain instances (eg, fowlpox, swinepox), the virus is transmitted mechanically by biting arthropods. Infection may be followed by generalized lesions (eg, sheeppox) or remain localized (eg, pseudocowpox). Strains of poxvirus with reduced virulence are used to immunize against some infections, the classic example being the global eradication of smallpox in people by immunization with strains of live vaccinia virus.

Poxviruses can be classified according to their physicochemical and biologic properties. Immunologically, the viruses of

smallpox, cowpox, monkeypox, etc, are closely related to vaccinia virus and are classified within the genus *Orthopox*. The avian poxviruses, the myxoma viruses, and some of the other poxviruses (eg, swinepox) are species-specific. The viruses of orf, pseudocowpox, and bovine papular stomatitis are parapoxviruses. It has been recognized that several orthopoxvirus infections of domestic animals and people, notably cowpox and monkeypox, are acquired from rodent reservoir hosts. Many of these rodent hosts have not been unequivocally identified. Thus, although the use of adjectives such as "cowpox" and "monkeypox" to describe these viruses may be epidemiologically inaccurate and misnomers, their retained use reflects both historical association and, until a better nomenclature evolves, pragmatism (see p 870).

Poxvirus infections can be confirmed in the laboratory using several diagnostic techniques. The orthopoxviruses can usually be isolated in cell culture and by inoculation of embryonated eggs. Examination of clinical samples by negative-staining electron microscopy is frequently used to visualize virus particles. PCR is widely used to further characterize virus isolates.

COWPOX

In this mild, eruptive disease of dairy cows, lesions are seen on the udder and teats. Although once common, cowpox is now extremely rare and reported only in western Europe (see also p 870).

The virus of cowpox is closely related antigenically to vaccinia and smallpox viruses. Indeed, the first two can be differentiated only by sophisticated laboratory techniques. Before vaccination of the general population against smallpox was discontinued, some outbreaks of cowpox in cows in North America and Europe were due to infection with vaccinia from recently vaccinated persons. Vaccinia-related viruses continue to cause occasional outbreaks of teat infections in dairy cattle in South America and buffalo in the Indian subcontinent. These viruses often spread to people in contact with cattle. The epidemiology of these viruses is unknown, but it has been suggested that they are vaccine viruses that spread to animals during the smallpox vaccination campaigns.

The disease spreads by contact during milking. After an incubation period of 3–7 days, during which cows may be mildly febrile, papules appear on the teats and udder. Vesicles may not be evident or may rupture readily, leaving raw, ulcerated areas that form scabs. Lesions heal within 1 mo. Most cows in a milking herd may become affected. Milkers may develop fever and have lesions on the hands, arms, or face. Occasionally, cowpox in people can cause generalized disease, and fatalities have been recorded.

Cowpox or vaccinia infection may be confused with bovine herpes mammillitis (see p 1385); because the lesions of these two conditions are superficially similar, laboratory confirmation is required. The viruses of cowpox and vaccinia can be easily visualized by electron microscopy. Although they cannot be distinguished from each other, their morphology by electron microscopy is distinct from that of pseudocowpox virus and bovine herpes mammillitis virus. Both vaccinia and cowpox viruses grow readily in cell cultures.

Measures to prevent spread of cowpox within a herd must be based on segregation and hygiene. Cowpox and vaccinia viruses are important causes of zoonoses.

PSEUDOCOWPOX

(Milkier's nodes, Paravaccinia)

Pseudocowpox, a common, mild infection of the udder and teats of cows, is caused by

a parapoxvirus and is widespread worldwide. The virus of pseudocowpox is related to those of contagious ecthyma (see p 866) and bovine papillar stomatitis (see p 215). These parapoxviruses differ morphologically from vaccinia virus and other poxviruses. They have a limited host range and cannot be propagated in fertile eggs, and they will grow in some cell cultures, although relatively poorly.

Lesions begin as small, red papules on the teats or udder. These may be followed rapidly by scabbing, or small vesicles or pustules may develop before scabs form. Scabs may be abundant but can be removed without causing pain. Granulation occurs beneath the scabs, resulting in a raised lesion that heals from the center and leaves a characteristic horseshoe or circular ring of small scabs. This stage is reached in ~7–12 days. Some lesions persist for several months, giving the affected teats a rough feel and appearance, and more scabs may form. The infection spreads slowly throughout milking herds, and a variable percentage of cows shows lesions at any time. Cattle may become reinfected in subsequent lactations.

The scabbed lesions may be confused with mild traumatic injuries to the teats and udder. Scabs examined with an electron microscope frequently show characteristic virus particles.

Control of infection within a herd is difficult and depends essentially on hygienic measures, such as teat dipping, to destroy the virus and prevent transmission. Little immunity appears to develop.

People may become infected with painless but itchy purplish red nodules that are generally present on the fingers or hands. These lesions cause little disturbance and disappear after several weeks.

LUMPY SKIN DISEASE

Lumpy skin disease is an infectious, eruptive, occasionally fatal disease of cattle characterized by nodules on the skin and other parts of the body. Secondary bacterial infection often aggravates the condition. Traditionally, lumpy skin disease is found in southern and eastern Africa, but in the 1970s it extended northwest through the continent into sub-Saharan west Africa. Since 2000, it has spread to several countries of the Middle East and in 2013 was confirmed in Turkey.

Etiology and Epidemiology: The causal virus is related to that of sheep pox. The prototype strain is known as the

Neethling poxvirus. Lumpy skin disease appears epidemically or sporadically. Frequently, new foci of infection appear in areas far removed from the initial outbreak. Its incidence is highest in wet summer weather, but it may occur in winter. It is most prevalent along water courses and on low ground. Because quarantine restrictions designed to limit the spread of infection have failed, biting insects have been suspected as vectors; however, outbreaks have occurred under conditions in which insects practically could be excluded. Experimentally, three species of hard ticks found in Africa have been shown to biologically transmit the virus. Because the disease can be experimentally transmitted by infected saliva, contact infection is considered as another route of infection. African buffalo are suspected as maintenance hosts in Kenya.

Clinical Findings: A subcutaneous injection of infected material produces a painful swelling and then fever, lacrimation, nasal discharge, and hypersalivation, followed by the characteristic eruptions on the skin and other parts of the body in ~50% of susceptible cattle. The incubation period is 4–14 days.

The nodules are well circumscribed, round, slightly raised, firm, and painful and involve the entire cutis and the mucosa of the GI, respiratory, and genital tracts. Nodules may develop on the muzzle and within the nasal and buccal mucous membranes. The skin nodules contain a firm, creamy-gray or yellow mass of tissue. Regional lymph nodes are swollen, and edema develops in the udder, brisket, and legs. Secondary infection sometimes occurs and causes extensive suppurative and sloughing; as a result, the animal may become extremely emaciated, and euthanasia may be warranted. In time, the nodules either regress, or necrosis of the skin results in hard, raised areas ("sit-fasts") clearly separated from the surrounding skin. These areas slough to leave ulcers, which heal and scar.

Morbidity is 5%–50%; mortality is usually low. The greatest loss is due to reduced milk yield, loss of condition, and rejection or reduced value of the hide.

Diagnosis: The disease may be confused with pseudo-lumpy skin disease, which is caused by a herpesvirus (bovine herpesvirus 2). These diseases can be similar clinically, although in some parts of the world the herpesvirus lesions seem confined to the teats and udder of cows,

and the disease is called bovine herpes mammillitis (see p 1385).

Pseudo-lumpy skin disease is a milder disease than true lumpy skin disease, but differentiation depends essentially on isolation and identification of the virus. Histologic and ultrastructural examination of nodules may be helpful. Poxlike intracytoplasmic inclusion bodies or eosinophilic intranuclear herpesvirus inclusions may be seen in the nodules.

Dermatophilus congolensis also causes skin nodules in cattle (see p 858).

Prevention and Treatment: Quarantine restrictions are of limited use. Vaccination with attenuated virus offers the most promising method of control. The viruses of goatpox and sheepox passed in tissue culture also have been used.

Administration of antibiotics to control secondary infection and good nursing care are recommended.

SHEEPOX AND GOATPOX

Sheepox and goatpox are serious, often fatal, diseases characterized by widespread skin eruption. Both diseases are confined to parts of southeastern Europe, Africa, and Asia. The poxviruses of sheep and goats (capripoxviruses) are closely related, both antigenically and physicochemically. They are also related to the virus of lumpy skin disease (see above). Reports on the natural susceptibility of sheep to the virus of goatpox and vice versa are conflicting; at least some strains seem capable of infecting both species.

The incubation period of sheepox is 4–8 days and that of goatpox 5–14 days. The clinical picture is similar in the two diseases but is generally less severe in goats. Fever and a variable degree of systemic disturbance develop. Eyelids become swollen, and mucopurulent discharge crusts the nostrils. Widespread skin lesions develop and are most readily seen on the muzzle, ears, and areas free of wool or long hair. Palpation can detect lesions not readily seen. Lesions start as erythematous areas on the skin and progress rapidly to raised, circular plaques with congested borders caused by local inflammation, edema, and epithelial hyperplasia. Although microvesicles are present histologically, vesicles and pustules are not evident clinically. Virus is abundant in skin lesions at this stage. As lesions start to regress, necrosis of the dermis occurs and dark, hard scabs form, which are sharply separated from the surrounding skin. Regeneration of the epithelium beneath the

scabs takes several weeks. When scabs are removed, a star-shaped scar, free of hair or wool, remains. In severe cases, lesions can develop in the lungs. In some sheep and in certain breeds, the disease may be mild or the infection inapparent.

It has been suggested that transmission may be airborne, may occur by direct contact with lesions, or mechanically by biting insects.

The disease in either species must be differentiated from the milder infection, contagious ecthyma (orf, *see* p 866), which mainly causes crusty, proliferative lesions around the mouth.

Infection results in solid and enduring immunity. Live, attenuated virus vaccines induce longer immunity than inactivated virus vaccines. Live, attenuated, lumpy skin disease virus also can be used as a vaccine against sheepox and goatpox.

SWINEPOX

Swinepox is an acute, often mild, infectious disease characterized by skin eruptions that affects only pigs. It is present in the USA, particularly in the Midwest, and has been reported from all continents, although the incidence is generally low.

Historically, vaccinia virus was involved in some outbreaks; currently, swinepox virus appears to be the only cause. The disease described here is that caused by the latter. Swinepox virus is distinct from other poxviruses and does not protect against infection with vaccinia virus. It will grow on pig cell cultures but not embryonating eggs. It is relatively heat stable and survives for ~10 days at 37°C (98.6°F).

The disease is most frequently seen in young pigs, 3–6 wk old, but all ages may be affected. After an incubation period of ~1 wk, small red areas may be seen most frequently on the face, ears, inside the legs, and abdomen. These develop into papules and, within a few days, pustules or small vesicles may be seen. The centers of the pustules become dry and scabbed and are surrounded by a raised, inflamed zone so that the lesions appear umbilicated. Later, dark scabs (1–2 cm in diameter) form, giving affected piglets a spotted appearance. These eventually drop or are rubbed off without leaving a scar. Successive crops of lesions can occur so that all are not at the same stage. The early stage of the disease may be accompanied by mild fever, inappetence, and dullness. Few pigs die of uncomplicated swinepox.

Virus is abundant in the lesions and can be transferred from pig to pig by the biting

louse (*Haematopinus suis*). The disease also may be transmitted, possibly between farms, by other insects acting as mechanical carriers.

Recovered pigs are immune. There is no specific treatment. Eradication of lice is important.

COWPOX VIRUS INFECTIONS IN CATS AND OTHER SPECIES

Many orthopoxvirus infections of domestic animals and people result from “spill over” from rodent reservoir hosts. Although traditionally described as infecting cattle, infections of cattle with cowpox virus are now very rare. Domestic cats in Europe are now the most commonly recognized species clinically affected by cowpox virus. Cowpox infections are apparently restricted to Europe. The virus has not been isolated in the Americas, but there is a single report of raccoonpox virus (a related orthopoxvirus) causing a paw lesion in a cat in Canada.

Etiology and Epidemiology: All orthopox isolates from domestic cats in Europe are currently considered to be cowpox virus, although molecular characterization indicates significant heterogeneity in isolates that may be indicative of different rodent hosts. Infection due to cowpox virus has also been recorded in other domestic species (dogs, horses, and llamas) and in a wide range of captive species in various European zoos. Cowpox virus is also infectious to people, and cat-to-human transmission has been recorded. Owners should be advised accordingly.

It is assumed that because of a domestic case of raccoonpox infection in a cat in Canada with a localized infection of a paw, cats may become infected when hunting. Most affected cats come from rural environments and are known to hunt rodents; the initial lesion is often described as having originated as a small bite-like wound. Infection in cats has a marked seasonal incidence, with most cases occurring between September and November. Cat-to-cat transmission can also occur but usually results in only subclinical infection.

The significance of the disease and its relatively recent recognition in cats is an enigma. It may have always been present in the feline population but not recognized. Alternatively, the disease may be increasing in importance as a result of a change either in the epidemiology of the disease, in the reservoir host, or in the nature of the dominant biotype of the virus itself.

Pathogenesis: The most common route of entry appears to be through the skin, but oronasal infection is also possible. After local replication and development of a primary skin lesion, the virus spreads to local lymph nodes, and a leukocyte-associated viremia develops. The viremic phase may be associated with pyrexia and depression and, during this period, virus can be isolated from various tissues, including the skin, turbinates (and sometimes lungs), and lymphoid organs. Widespread secondary skin lesions appear a few days after the onset of viremia, and new lesions continue to appear for 2–3 days, at which time the viremia subsides.

Clinical Findings: Most affected cats have a history of a single primary skin lesion, usually on the head, neck, or a forelimb. The primary lesion can vary from a small, scabbed wound to a large abscess. Approximately 7–10 days after the primary lesion appears, widespread secondary lesions begin to appear. Throughout 2–4 days, these develop into discrete, circular, ulcerated papules ~0.5–1 cm in diameter. The ulcers soon become covered by scabs, and healing is usually complete by ~6 wk. Many cats show no signs other than skin lesions, but ~20% may develop mild coryza or conjunctivitis. Some cats may also be pyrexemic, depressed, and inappetent during the viremic phase just before and during the early development of secondary lesions. Concurrent bacterial infection, particularly of the primary lesions, may give rise to systemic signs. However, most domestic cats recover uneventfully. More severe pulmonary disease is uncommon in domestic cats but frequently occurs in cheetahs and is often fatal in both species. More severe disease in domestic cats is often associated with immunosuppression, either after treatment with corticosteroids or associated with infection with feline leukemia or immunodeficiency viruses.

Lesions: Because most cats survive, skin biopsies generally are the only tissue available for histologic examination. Early lesions consist of areas of epidermal hyperplasia and hypertrophy with vesiculation of the prickle cell layer. Many of the epidermal cells bordering such vesicles contain characteristic eosinophilic cytoplasmic inclusions. Later, there is ulceration and necrosis of the epidermis and replacement by an eosinophilic coagulum of necrotic cells and fibrin. A heavy, mixed inflammatory cell exudate is present in the dermis surrounding the lesion. As healing ensues, a thin layer of

epidermis covers the skin beneath the scabs, early scar tissue is present, and there is a moderate, mainly mononuclear cell infiltrate.

In rarer cases, in which the disease has generalized, lesions may also be present in the liver, lungs, trachea, bronchi, oral mucosa, and small intestine.

Diagnosis: If multiple, well-circumscribed skin lesions are present, and especially if there is a history of hunting or exposure to a rural environment, a presumptive diagnosis may be based on clinical signs. Cowpox virus infection also should be suspected when skin lesions do not respond to antibiotics. Differential diagnoses include miliary dermatitis, feline herpesvirus or calicivirus infection, eosinophilic granuloma, bite wounds, ringworm, and other chronic bacterial or fungal conditions.

Presumptive and rapid diagnosis can be made in most cases from unfixed scab, exudate, or biopsy material examined for characteristic brick-shaped orthopox virions by electron microscopy. A more accurate and sensitive method of diagnosis is by PCR, or isolation of virus in cell culture or on the chick chorioallantois. Fixed biopsy material for histologic examination and serum for antibody determination also can be sent to the laboratory.

Treatment and Control: In both domestic cats and cheetahs, it is important that cowpox be diagnosed promptly, because steroid treatment, which is often used in therapy of other skin conditions, is contraindicated. Although the disease is often severe in cheetahs, in domestic cats supportive treatment (broad-spectrum antibiotics, fluid therapy) is generally successful, and mortality is low.

Because it seems that infection in domestic cats is mainly sporadic and acquired from chance contact with an infected wildlife reservoir, it is difficult to control the exposure of outdoor cats to this virus. In wildlife parks, where big cats are at risk from contact with small wild rodents, and especially where the disease has already occurred, vaccination may be helpful. Vaccinia virus appears to be of low pathogenicity in domestic cats, and cheetahs appear to be refractive. Currently, management of outbreaks among large cats depends on prompt diagnosis and segregation of affected animals to reduce the possibility of cat-to-cat spread. Rodent control should be evaluated and premises disinfected. At ambient temperatures, poxviruses are relatively resistant and may remain infective in dried crusts for months.

ULCERATIVE DERMATOSIS OF SHEEP

(Lip and leg ulceration, Venereal balanoposthitis and vulvitis)

Ulcerative dermatosis is an infectious disease of sheep caused by a virus similar to the ecthyma virus. It manifests in two somewhat distinct forms, one characterized by formation of ulcers around the mouth and nose or on the legs (lip and leg ulceration), and the other as a venereally transmitted ulceration of the prepuce and penis or vulva.

Clinical Findings: The lesion, regardless of location, is an ulcer with a raw crater that bleeds easily, varies in depth and extent, and contains an odorless, creamy pus; it is covered from the beginning with a scab.

Face lesions occur on the upper lip, between the border of the lip and the nasal orifice, on the chin, and on the nose. In severe cases, the ulcers may perforate the lip. Foot lesions are seen anywhere between the coronet and the carpus or tarsus.

Venereal lesions partially or completely surround the preputial orifice and may become so extensive as to cause phimosis. Rarely, the ulcers may extend to the glans penis so that the ram becomes unfit for natural breeding. In ewes, edema, ulceration, and scabbing of the vulva have less serious consequences.

There are no noticeable early systemic reactions. Morbidity rates of 15%–20% are usual, although up to 60% of a flock may be infected. Often, the disease remains unrecognized until the lesions are so advanced that signs of lameness or disturbed urination become apparent.

Diagnosis: Diagnosis depends entirely on recognition of the characteristic ulcerative

lesion. Differentiation between this lesion and that of contagious ecthyma (see p 866), which is essentially proliferative in character, is fundamental. In most cases, on removal of the scabs, the lesions of ulcerative dermatosis are crateriform or ulcerative, whereas lesions of contagious ecthyma are proliferative. The question of the similarity of the agents of these two conditions is not clearly defined, but inoculation of sheep previously immunized against contagious ecthyma helps in making a diagnosis. It is also difficult, and in some instances impossible, to differentiate between ulcerative posthitis and vulvitis (see p 1372) and ulcerative dermatosis without resorting to sheep inoculation.

Prevention and Treatment: Infected sheep should be isolated, and those with genital lesions should not be bred. Recovery takes 2–8 wk and is not greatly influenced by treatment. Therapy is usually not attempted unless the animals are to be bred soon, lip lesions interfere with eating, foot lesions make the animals so lame that they are losing condition, or secondary bacterial infections become severe.

Treatment consists of removing the scabs and all necrotic tissue from the ulcers and applying any one of the following preparations: silver nitrate (styptic pencil), strong tincture of iodine, 30% copper sulfate solution, 4% formaldehyde, 5% cresol (sheep dip), or sulfa-urea powder. Foot and lower leg lesions can be treated with copper sulfate or formaldehyde solutions in footbath troughs.

DERMATOPHYTOSIS

(Ringworm)

Dermatophytosis is an infection of keratinized tissue (skin, hair, and claws) by one of the three genera of fungi collectively called dermatophytes—*Epidermophyton*, *Microsporum*, and *Trichophyton*. (See also FUNGAL INFECTIONS, p 632.) These pathogenic fungi are found worldwide, and all domestic

animals are susceptible. In developed countries, the greatest economic and human health consequences come from dermatophytosis of domestic cats and cattle. A few dermatophyte species are soil inhabitants (geophilic), eg, *M. gypseum* and *T. terrestre*, and cause disease in animals

that are exposed while digging or rooting. Other species are host-adapted to people (anthropophilic), eg. *M audouinii* and *T rubrum*, and infect other animals rarely. The most important animal pathogens worldwide are *M canis*, *M gypseum*, *T mentagrophytes*, *T equinum*, *T verrucosum*, and *M naumum*. These species are zoonotic, especially *M canis* infections of domestic cats and *T verrucosum* of cattle and lambs. The zoophilic species are transmitted primarily by contact with infected individuals and contaminated fomites such as furniture, grooming tools, or tack. Exposure to a dermatophyte does not always result in infection. The likelihood of infection depends on several factors, including the fungal species, host age, immunocompetence, condition of exposed skin surfaces, host grooming behavior, and nutritional status. Infection elicits specific immunity, both humoral and cellular, that confers incomplete and short-lived resistance to subsequent infection or disease. New information concerning dermatophytic virulence factors, notably secreted proteases involved in the invasion of keratin, aspects of host immune response against dermatophytes, and new molecular tools available for studying dermatophytes should hasten development of safe and effective vaccines against dermatophytosis in species without vaccination options.

Under most circumstances, dermatophytes grow only in keratinized tissue, and advancing infection stops when reaching living cells or inflamed tissue. Infection begins in a growing hair or in the stratum corneum, where threadlike hyphae develop from the infective arthrospores or fungal hyphal elements. Hyphae can penetrate the hair shaft and weaken it, which, together with follicular inflammation, leads to a common clinical sign of patchy hair loss. As the infection matures, clusters of arthrospores develop on the outer surface of infected hair shafts. Broken hairs infected with spores are important sources for spread of the disease. Under experimental conditions, the housefly, *Musca domestica*, can transmit *M canis* mechanically with its outer body surface for as long as 5 days. The clinical relevance is yet to be determined. As inflammation and host immunity develop, further spread of infection is inhibited, although this process may take several weeks. Thus, for most healthy adult hosts, dermatophyte infections are self-limiting. In young or debilitated animals and, to some extent, in Yorkshire Terriers and longhaired breeds of domestic cats, infection may be persistent and widespread.

Dermatophytosis is diagnosed by fungal culture, examination with a Wood's lamp, and direct microscopic examination of hair or skin scale. Fungal culture is the most accurate means of diagnosis. Dermatophyte test medium (DTM) may be used in a clinical setting. Selected lesions should have the hair clipped to a length of ~0.3 cm. The area should be gently patted with an alcohol-moistened sponge and then patted dry to reduce contamination with saprophytic fungi. Hair stubble and skin scale are collected for placement on the growth agar. The container is then loosely capped to prevent drying. Incubation at room temperature is sufficient except when culturing for *T verrucosum* from food and fiber animals, in which case incubation at 37°C is necessary. *T equinum* requires nicotinic acid if subcultured from primary growth, and some *T verrucosum* isolates require thiamine or thiamine and inositol.

Dermatophyte growth is usually apparent within 3–7 days but may require up to 3 wk on any type of DTM. Dermatophytes growing on DTM cause the medium to change to red at the time of first visible colony formation. Dermatophyte fungi have white to buff-colored, fluffy to granular mycelia. Saprophytic contaminant colonies are white or pigmented and almost never produce an initial color change on DTM. Definitive diagnosis and species identification require removal of hyphae and macroconidia from the surface of the colony with acetate tape and microscopic examination with lactophenol cotton blue stain. Dysgonic strains do exist, but lack of growth of suspected ringworm is most likely due to lack of expertise in culture technique and fungal identification or to disease processes other than ringworm that cause clinical signs.

The Wood's lamp is useful as a screening tool for *M canis* infections in cats and dogs. Infected hairs fluoresce yellow-green; however, only ≤50% of *M canis* infections fluoresce, and other fungal species in animals do not. Therefore, negative Wood's lamp examinations are not meaningful. False-positive examinations may occur and are especially likely in oily, seborrheic skin conditions. Fluorescing hairs should always be cultured to confirm the diagnosis.

Direct microscopic examination of hairs or skin scrapings may enhance clinical suspicion by demonstrating characteristic hyphae or arthrospores in the specimen. The technique is more useful in diagnosing dermatophytosis in large animals than in small animals. Hairs (preferably white ones) and scrapings from the periphery of lesions

are examined for fungal elements in a wet preparation of 20% potassium hydroxide that has been gently warmed or incubated in a humidity chamber overnight.

An ELISA for the serodiagnosis of canine dermatophytosis has been researched but is not commercially available. The sensitivity and specificity is high and similar to that of fungal culture with DTM, but positive results can be seen after elimination of the dermatophyte infection. Cross-reactivity between the various dermatophytes would not allow for species identification, which is important for identification of the source of infection.

CATTLE

Trichophyton verrucosum is the usual cause of ringworm in cattle, but *T mentagrophytes*, *T equinum*, *Microsporum gypsum*, *M nanum*, *M canis*, and others have been isolated. Dermatophytosis is most commonly recognized in calves, in which nonpruritic periocular lesions are most characteristic, although generalized skin disease may develop. Cows and heifers are reported to develop lesions on the chest and limbs most often, and bulls in the dewlap and intermaxillary skin. Lesions are characteristically discrete, scaling patches of hair loss with gray-white crust formation, but some become thickly crusted with suppuration. Ringworm as a herd health problem is more common in the winter and is more commonly recognized in temperate climates and in English rather than Zebu breeds of cattle.

Many topical treatments have been reported to be successful in cattle, but because spontaneous recovery is common, claims of efficacy are difficult to substantiate. Valuable individual animals should still be treated, because this may well limit both progression of existing lesions and spread to others in the herd. Thick crusts should be removed gently with a brush, and the material burned or disinfected with hypochlorite solution. Treatment options depend on allowed usage of some agents in animals destined for slaughter. Agents reported to be of use include washes or sprays of 4% lime sulfur, 0.5% sodium hypochlorite (1:10 household bleach), 0.5% chlorhexidine, 1% povidone-iodine, natamycin, and enilconazole. Individual lesions can be treated with miconazole or clotrimazole lotions.

A live attenuated fungal vaccine is in use in some countries other than the USA. The vaccine has been used in control and eradication programs to successfully

decrease the number of new infected herds. The duration of immunity is long lasting. The vaccine prevents development of clinical lesions, transmission to other animals, and contamination of the environment. A vaccination program combined with a cleaning and disinfection protocol can help eliminate signs of ringworm and eradicate it from the herd. Vaccination has greatly reduced the incidence of zoonotic disease in farmers, their households, veterinarians, and people working in abattoirs and tanneries. No live attenuated vaccine is available in North America.

DOGS AND CATS

In dogs, ~70% of cases are caused by *Microsporum canis*, 20% by *M gypsum*, and 10% by *Trichophyton mentagrophytes*; in cats, 98% are caused by *M canis*. The Wood's lamp is useful in establishing a tentative diagnosis of dermatophytosis in dogs and cats but cannot be used to exclude this type of infection. Definitive diagnosis is established by DTM culture (see p 872). Detection of infection in asymptomatic carrier animals is facilitated by brushing the coat with a new toothbrush and then inoculating a culture plate with the collected hair and scale by pressing the bristles to the surface of the medium.

The clinical appearance of ringworm in cats is quite variable. Kittens are affected most commonly. Typical lesions consist of focal alopecia, scaling, and crusting; most are located around the ears and face or on the extremities. Cats with clinically inapparent infections can serve as a source of infection to other cats or people. Occasionally, dermatophytosis in cats causes feline miliary dermatitis and is pruritic. Cats with generalized dermatophytosis occasionally develop cutaneous ulcerated nodules, known as dermatophyte granulomas or pseudomycetomas. Devon Rex cats can have a maculopapular hyperpigmented, crusted disease that histopathologically is an eosinophilic/mastocytic dermatitis.

Lesions in dogs are classically alopecic, scaly patches with broken hairs. Dogs may also develop regional or generalized folliculitis and furunculosis with papules and pustules. A focal nodular form of dermatophytosis in dogs is the kerion reaction. Generalized ringworm in adult dogs is uncommon and is usually accompanied by immunodeficiency, especially endogenous or iatrogenic hyperadrenocorticism. Differential diagnoses for classic ringworm lesions

in dogs include demodicosis, bacterial folliculitis, and seborrheic dermatitis.

Dermatophytosis in dogs and shorthaired cats may be self-limiting, but resolution can be hastened by treatment. Another primary objective of therapy is to decrease environmental contamination and prevent spread of infection to other animals and people. Although no controlled studies exist that prove clipping of the hair coat shortens the duration of infection, clinical studies support this recommendation, at least for cats with long hair and/or generalized dermatophytosis, even if it initially worsens or spreads the lesions. Environmental decontamination with bleach (1:10 dilution) or enilconazole solution (0.2%) is effective.

Whole-body topical therapy may hasten a clinical cure (if not a mycologic cure) and decrease environmental contamination. Based on in vitro and in vivo studies, whole-body lime sulfur dips (1:16), 0.2% enilconazole rinses, 2% miconazole, and a combined 2% miconazole/chlorhexidine shampoo were found to be antifungal. These may be appropriate for adjunctive therapy. Enilconazole rinse is not currently available in the USA in a formulation approved for dogs and cats. Topical use of enilconazole may have been the cause of hypersalivation, idiopathic muscle weakness, and slightly increased serum ALT concentration in one study. Local lesions can be treated effectively with topical miconazole or clotrimazole.

For chronic or severe cases and for ringworm in longhaired breeds of cats and Yorkshire Terriers, systemic treatment is indicated. Itraconazole, fluconazole, terbinafine, ketoconazole, and griseofulvin have all been used successfully. The microsize formulation of griseofulvin can be used in dogs (25–100 mg/kg, daily or in divided doses) and in cats (25–50 mg/kg, daily in divided doses) and is best absorbed when given with a fatty meal. The ultramicrosize formulations should be used at lower dosages (10–15 mg/kg/day). There is no veterinary-labeled griseofulvin currently approved for use in dogs and cats in the USA. Cats may develop bone marrow suppression, especially neutropenia, at higher doses as idiosyncratic reactions. This is more common in feline immunodeficiency virus-positive cats. In both dogs and cats, GI upset is a fairly common sequela of griseofulvin administration.

Other effective treatments include itraconazole (5–10 mg/kg/day, or pulse therapy 5–10 mg/kg/day for 28 days then on an alternate-week regimen [1 week on, 1 week off]), ketoconazole (5–10 mg/kg/day),

terbinafine (30–40 mg/kg/day), and fluconazole (5–10 mg/kg/day). Fluconazole may be the least effective of these drugs. Terbinafine was found to be at levels higher than the minimum inhibitory concentration on the hair of treated animals for 5.3 wk after 2 wk of daily therapy. This may indicate its potential for use as a pulse therapy drug after 2 wk of daily administration. None of these drugs is approved for use in domestic animals in the USA. In addition, ketoconazole is often a cause of anorexia in cats and is not used as often in this species. Systemic and topical treatments for dermatophytosis should be continued until a negative brush culture is obtained. A brush culture is usually submitted after a minimum of 1 mo of therapy or when clinical lesions are minimal to resolved. In chronic disease and/or challenging environments, the endpoint of treatment may more appropriately be two or three consecutive negative fungal cultures obtained at weekly or biweekly intervals. Efficacy of lufenuron either to treat or prevent *M. canis* infection has not been confirmed in controlled studies.

HORSES

Trichophyton equinum and *T. mentagrophytes* are the primary causes of ringworm in horses, although *Microsporum gypseum*, *M. canis*, and *T. verrucosum* have also been isolated. Clinical signs consist of one or more patches of alopecia and erythema, scaling, and crusting, which are present to varying degrees. Early lesions may resemble papular urticaria but progress with crusting and hair loss within a few days. Diagnosis is confirmed by culture. Differential diagnoses include dermatophilosis, pemphigus foliaceus, and bacterial folliculitis. Transmission is by direct contact or by grooming implements and tack. Most lesions are seen in the saddle and girth areas ("girth itch").

Treatment is generally topical because systemic therapy is expensive and of unproven efficacy. Whole-body rinses as described earlier for cattle may be recommended, and individual lesions treated with clotrimazole or miconazole preparations. Grooming implements and tack should be disinfected, and affected horses should be isolated.

PIGS, SHEEP, AND GOATS

Dermatophytosis in pigs is usually caused by *Microsporum nanum*. Lesions are rings of inflammation or brown discoloration

that spread centrifugally up to a diameter of 6 cm. Lesions are fairly asymptomatic in adults, and ringworm in swine is generally of little economic consequence. Zoonotic infections in farm workers are not common.

Ringworm is a common, troublesome problem in show lambs but is otherwise uncommon in production flocks of sheep and goats. The infecting species include *M canis*, *M gypseum*, and *Trichophyton verrucosum*. Lesions in lambs are most often noticed on the head, but widespread lesions under the wool may be apparent

when lambs are sheared for show, or may develop later as a consequence of contamination from clippers at shearing. Infected lambs should not be issued certificates for transport to show until the infection is cleared. Because there is little evidence that lambs with a functional rumen absorb griseofulvin to effective levels, treatment is best accomplished with sodium hypochlorite solutions or enilconazole rinses (where available). In healthy lambs, as in other species, these infections are self-limiting, but resolution may not be evident in time for show purposes.

CATTLE GRUBS

Hypodermosis of cattle in the northern hemisphere is caused by bot fly larvae (cattle grubs or ox warbles) of *Hypoderma* spp (order Diptera, family Oestridae). In Central and South America, larvae (tropical warbles) of *Dermatobia hominis* (order Diptera, family Cuterebridae) are important pests of cattle.

HYPODERMA SPP

Two species of *Hypoderma*, *H bovis* (common cattle grub) and *H lineatum* (northern cattle grub), are economically important and primary pests of cattle. They are found between 25° and 60° latitude in the northern hemisphere in >50 countries of North America, Europe, Africa, and Asia. In North America, *H lineatum* is found in Canada, the USA, and northern Mexico, whereas *H bovis* is generally found north of the 35th parallel. Occurrence in cattle and American bison was historically common. However, widespread use of macrocyclic lactones have decreased the prevalences of *H lineatum* and *H bovis* in cattle in North America. *H tarandi* parasitizes native Cervidae and reindeer in arctic and subarctic regions. Larvae of *Hypoderma* spp also have been reported in horses, sheep, goats, and people.

Life Cycle: Adult *Hypoderma*, known also as heel flies or gad flies, are ~15 mm long, hairy, and bee-like in appearance. In late spring or early summer, they attach their eggs on the hair of cattle, particularly on the legs and lower body regions. The

eggs hatch in 3–7 days, and first-stage larvae travel to the base of the hair shaft and penetrate the skin. Normally, the first-stage larvae travel through the fascial planes between muscles, along connective tissue, or along nerve pathways. They secrete proteolytic enzymes that facilitate their movement. During fall and winter, larvae migrate toward two different regions, depending on the species. *H lineatum* larvae migrate to the submucosal connective tissue of the esophageal wall, where they accumulate for 2–4 mo. *H bovis* larvae migrate to the region of the spinal canal, where they are found in the epidural fat between the dura mater and the periosteum for a similar period.

Beginning in early winter, the larvae arrive in the subdermal tissue of the back of the host, where they make breathing holes (central punctum) through the skin. Cysts or warbles form around the larvae, which undergo two molts (second and third stage). The warble stage lasts 4–8 wk. Finally, third-stage larvae emerge through the breathing holes, drop to the ground, and pupate. Flies emerge from the pupae in 1–3 mo, depending on weather conditions. Adult flies, which do not feed, live <1 wk. The life cycle is complete in 1 yr.

For the two species, seasonal events are similar except that those for *H lineatum* occur ~6–8 wk earlier than those of *H bovis*. These events vary from year to year but correlate with local and regional climatic conditions. Larvae first appear in backs of cattle about mid September in southern USA but not until late January or later in

northern USA. Grubs first emerge from the back during the last half of November in Texas and during the first half of March in Montana. When both species are present, third-stage larvae may appear in the back for ~5–6 mo; when only one species is present, the larvae may appear for ~3–4 mo. The activity of ovipositing (by female flies) is at its height from January to March in southern USA and from May to July in northern USA.

Clinical Findings and Pathogenesis:

During periods of sunshine on warm days, cattle may run with their tails high in the air when chased by female heel flies, particularly *H. bovis*. This behavior in cattle is referred to as “gadding” and is a strategy to avoid female flies and their attempt to deposit eggs. Not all stampeding or gadding of this kind is the result of heel fly attacks, because this activity has been seen in the absence of heel flies. Gadding in cattle may result in loss of production, altered reproduction, self-injury, or death.

In otherwise healthy cattle, *H. bovis* larvae and their secretions in the epidural fat of the spinal canal are associated with dissolved connective tissue, fat necrosis, and inflammation. Sometimes, the inflammation extends to the periosteum and bone, producing a localized area of periostitis and osteomyelitis. Occasionally, the epineurium and perineurium may become involved. In rare severe cases, paralysis or other nervous disorders may occur. Similarly, *H. lineatum* in the submucosa of the esophagus may cause sufficient inflammation and edema in the surrounding tissues to hinder swallowing or eructation. It is unusual, however, for clinical signs of parasitism to be evident during the migratory phase.

Penetration of the skin by newly hatched larvae may produce a hypodermal rash, most often in older, previously infested cattle. The points of penetration are painful and inflamed and usually exude a yellowish serum. Warbles may be found in the back from tailhead to shoulders, and from topline to about one-third the distance down the sides. Usually, the warbles are firm and raised considerably above the normal contour of the skin. In each warble, there is a breathing hole, ranging in size from a small slit to a round hole (3–4 mm in diameter) for more mature larvae. Generally, secondary infection is depressed; however, warbles may occasionally develop in large, suppurating abscesses. The emergence of the third-stage larvae, their forced expulsion, or their death within the cysts

usually results in healing of the lesions without complications. Carcasses and hides of cattle infested with cattle grubs show marked evidence of the infestation and are reduced in value.

An infested animal may have 1 to ≥ 300 warbles but generally < 100 ; infested herds often have individual animals with no larvae. Young animals are most heavily infested.

If migrating *Hypoderma* die in esophageal tissue (*H. lineatum*) or near the spinal cord (*H. bovis*), they can cause severe, sometimes fatal, reactions. These reactions appear to be related to the numbers of larvae but are rare in any case.

Death of first-stage larvae of *H. lineatum* in the submucosal connective tissue of the esophagus causes inflammation of the esophageal wall, dysphagia, drooling, and bloat. Again, recovery is usually rapid and complete (48–72 hr after treatment), but in severe cases, the bloat may be fatal. Rupture of the esophagus may be caused by attempted passage of a stomach tube in an affected animal.

Death of first-stage larvae of *H. bovis* in the spinal canal of cattle after systemic insecticide treatment has resulted in stiffness, ataxia, muscular weakness, and paralysis of hindlimbs. Recovery is usually rapid and complete, but occasionally, paralysis may be permanent.

Concurrent with the decrease in the prevalences of *H. lineatum* and *H. bovis* in cattle, widespread use of macrocyclic lactones has also led to a decline in the clinical relevances of these parasites in North America. However, serologic surveys have demonstrated that cattle are still exposed to *Hypoderma* spp. Should treatment programs stop or move away from products that have efficacy against *Hypoderma* spp, clinical signs due to infestation will likely reappear.

Diagnosis: Third-stage larvae of *Hypoderma* spp are found in warbles, the furuncle-like nodules or cysts along the back of cattle. On recovery from a warble, third-stage larvae can be easily differentiated. *H. bovis* is longer (27–28 mm) and has no spines on the tenth segment and a funnel-shaped spiracular plate. *H. lineatum* is slightly shorter (25 mm) and has spines on the tenth segment and typically a flat spiracular plate. In cases of bloat or paralysis, the presence of disintegrating grubs and the associated hemorrhage and tissue damage distinguishes animals that are parasitized from those that are not. ELISA-based tests have been developed to

Hypoderma spp, third-stage larva. Courtesy of Dr. Raffaele Roncalli.

detect anti-*Hypoderma* antibodies in sera and milk. These ELISA tests are often used to measure risk of exposure and do not correlate well with observation of clinical hypodermosis in cattle.

Treatment and Control: Systemic insecticides in various formulations are available for treatment. Pour-on products containing macrocyclic lactones (doramectin, eprinomectin, ivermectin, or moxidectin) are poured evenly along the midline of the back. Some products must not be applied when the skin or hair coat are wet or when rain is expected to wet cattle within 6 hr. The application site should be free of skin lesions, mud, or manure. Cattle stressed by castration, overheating, vaccination, or shipping should not be treated.

In the USA, registrations of most, if not all, systemic organophosphate insecticides for cattle grub control have been cancelled, and the practices of dipping or spraying cattle for cattle grub control have been replaced by pour-on and/or injectable treatments.

Doramectin and ivermectin are systemically active against *Hypoderma* larvae when injected SC. Ivermectin is also available as an oral paste. The injectable and pour-on systemic treatments are approved for control of *Hypoderma* and other myiasis-causing flies in many countries.

Eprinomectin and moxidectin pour-on formulations are approved for treatment of both beef and dairy cattle. Otherwise, use of drugs for cattle grub control is prohibited in dairy animals of breeding age. Because residues may be present in cattle for varying periods after treatment, withdrawal times for all treatments must be observed.

In areas where *Hypoderma* spp are prevalent, cattle, especially calves, should be treated as soon as possible after the end

of the heel fly season. They should not be treated later than 8–12 wk before the anticipated first appearance of grubs in the backs, because adverse reactions may occur when migrating larvae are killed.

Where systemic insecticides cannot be used, *Hypoderma* spp larvae can be controlled by applying tetrachlorvinphos dust to the warbles in the back. The dust should be applied to the animal's back and worked into the grub holes. Because new grubs continue to appear in the back, treatment must be repeated every 30–45 days during the warble season.

On small groups of tractable animals, mechanical extraction by instrument or hand expulsion (ie, squeezing) of the individual larva is effective. Larvae can also be removed by carefully injecting 1 mL of 3% hydrogen peroxide with a blunt cannula through the central punctum. However, care must be used to not rupture or pierce the larvae during removal. Rarely, when these procedures are performed carelessly, larvae are crushed or pierced, inducing an anaphylaxis-type reaction. This anaphylaxis is believed to result from the overwhelming and sudden release of *Hypoderma* spp antigens. Experimental studies have also demonstrated that this anaphylaxis-type reaction is due to the release of toxins from *Hypoderma* larvae.

Research to develop vaccines against *Hypoderma* spp infestations was conducted as early as the 1950s. Even though some natural and recombinant antigens were demonstrated to have efficacy against *Hypoderma* spp infestations, the high efficacy and ease of use of macrocyclic lactones have precluded modern vaccine development.

DERMATOBIA HOMINIS

The tropical warble fly or torsalo, one of the most important parasites of cattle in Latin America, is distributed between southern Mexico and northern Argentina. Larval stages are found in many hosts, including cattle, sheep, goats, pigs, buffalo, dogs, cats, rabbits, and people. Cattle and dogs are infected most commonly. *D hominis* is thought to initiate the lesion that gives rise to lechiguana, a disease of cattle (see below).

Life Cycle: The adult fly is 12–15 mm long and has a short life span (1–9 days). The adult fly fastens its eggs to different types of insects (49 have been described as vectors of *D hominis* in Latin America; most are mosquitoes or muscoid flies) that

then transport them to warm-blooded hosts, where they hatch as the insects feed. The larvae penetrate the skin of the animal within a few minutes of hatching and remain in the subcutaneous tissue for 4–18 wk. During this period, the larvae grow within warbles with breathing holes. When mature, the larvae leave the host and drop to the ground, burrow, and pupate. After the pupal period, which lasts 4–11 wk, the flies emerge as adults. The complete life cycle takes 11–17 wk.

Clinical Findings and Pathogenesis:

Larval penetration of the skin is accompanied by pain and local inflammation, and pus gradually forms. Infested hides are condemned at slaughter, and production of milk and meat is reduced. In 1982, it was estimated that cattle infested with *D hominis* resulted in a yearly reduction in weight of 40.6 g/larva. In 2014, combining losses due to reduced weight gain and hide damage, infestation by *D hominis* in cattle raised in Brazil was estimated to cost producers \$383 million USD annually. Efforts to characterize and produce antigenic proteins that confer immunity against *D hominis* have resulted in identification of a candidate vaccine, with 90% efficacy in immunized cattle.

Treatment and Control: Different contact and systemic insecticides in various formulations are available for treatment. Generally, *D hominis* infestations in cattle are susceptible to systemic organophosphates and macrocyclic lactone endectocides, which may be approved and available locally.

Lechiguana

Lechiguana is a sporadic, chronic disease of cattle that, thus far, has been reported only from southern and southeastern Brazil, in areas where infection by *Dermatobia hominis* is common. It is characterized by large, hard, subcutaneous swellings that develop rapidly, mainly in the scapular and

adjacent areas (chest, neck, shoulders, and ribs). Most cattle affected have only one swelling, but two swellings are occasionally seen. The regional lymph nodes are enlarged and without treatment may become enormous.

Mannheimia granulomatis has been recovered from lesions and is considered causal. The lesion that gives rise to lechiguana is initiated by *D hominis* larvae. *M granulomatis* is consistently recovered from lesions of the clinical disease, and it is thought to be mainly responsible for the characteristic tissue changes. The involvement of a myofibroblast-like cell population that expresses mRNA for type I collagen is suggested to be associated with the increase of collagen deposition. It has also been demonstrated that macrophages activated by *M granulomatis* induce fibroblast proliferation. The habitat or source of *M granulomatis* is not known. It has not been recovered from cattle without lechiguana.

Histologically, lesions consist of focal proliferation of fibrous tissue infiltrated by plasma cells, eosinophils, lymphocytes, and sometimes neutrophils. The primary lesion is an eosinophilic lymphangitis, which results in eosinophilic abscesses, with occasional rosettes containing bacteria in their centers. The subcutaneous, tumorous mass produced may attain a size as large as 40 × 50 cm in 2 mo. Without treatment, death occurs after 3–11 mo, probably due to inanition resulting from the enormous swellings.

When well established, the disease is clinically obvious. Diagnosis is confirmed by recovery of *M granulomatis* and observation of the characteristic histopathologic lesions.

Treatment with chloramphenicol (3 g/day for 5 days) or danofloxacin mesylate (1.25 mg/kg/day for 3 days) results in rapid reduction of swellings, with almost complete regression in 30 days. Conducting susceptibility tests is advisable before using other antimicrobials.

CUTEREBRA INFESTATION IN SMALL ANIMALS

This opportunistic, parasitic infestation of dogs, cats, and ferrets is caused by the rodent or rabbit bot fly, *Cuterebra* spp (order Diptera, family Cuterebridae). Flies are usually host- and site-specific relative to their life cycle. However, rabbit *Cuterebra*

are less host-specific and are usually associated with dog and cat infestations. Rarely, cats and dogs may be infested with *Hypoderma* spp or *Dermatobia hominis*. Ferrets housed outside may be infested by *Hypoderma* or *Cuterebra* spp.

Etiology: Adult *Cuterebra* flies are large and bee-like and do not feed or bite. Females deposit eggs around the openings of animal nests, burrows, along runways of the normal hosts, or on stones or vegetation in these areas. A female fly may deposit 5–15 eggs per site and >2,000 eggs in her lifetime. Animals become infested as they pass through contaminated areas; the eggs hatch in response to heat from a nearby host. In the target host, the larvae enter the body through the mouth or nares during grooming or, less commonly, through open wounds. After penetration, the larvae migrate to various species-specific subcutaneous locations on the body, where they develop and communicate with the air through a breathing pore. After ~30 days, the larvae exit the skin, fall to the soil, and pupate. The duration of pupation varies depending on the environmental factors and winter diapause.

Clinical Findings and Diagnosis:

Cuterebra lesions are most common in the summer and fall when the larvae enlarge and produce a fistulous swelling ~1 cm in diameter. Dogs, cats, and ferrets are abnormal hosts for this parasite; aberrant migrations can involve the head, brain, nasal passages, pharynx, and eyelids. In the skin, typical lesions are seen around the head, neck, and trunk. The hair is often matted, and a subcutaneous swelling is present beneath the lesions. Cats often groom the area aggressively. Pain at the site is variable and usually associated with secondary infections. Purulent material may exude from the lesion; the most common differential diagnosis is an abscess or foreign body.

Free-roaming cats are more likely to develop lesions than indoor cats. Clinical signs are often associated with the CNS and typically occur between July and September. Cats may have depression, lethargy, or seizures; upper respiratory infections; or

abnormal body temperatures (either hyperthermia or hypothermia). One key historical finding in cats with neurologic signs caused by *Cuterebra* infestations is an acute episode of violent sneezing weeks to months before clinical presentation. Common neurologic findings include blindness, abnormal mentation, and signs of unilateral prosencephalic disease. Idiopathic vestibular signs in cats may be due to aberrant migration of the parasite.

Definitive diagnosis is made by finding and identifying a larva. In cats, CT scans may help identify larvae. Second instar larvae are 5–10 mm long and are gray to cream in color. Third instar larvae are dark, thick, heavily spined and are the stage most commonly seen by veterinarians.

Treatment: Suspect lesions should be explored by carefully enlarging and probing the breathing pore or fistula with mosquito forceps. It is not unusual for the parasite to retreat into the opened pore, making it difficult to grasp. Covering the breathing pore with white petroleum jelly for 10–15 minutes before grasping the parasite can make it easier to remove. The lesion should not be squeezed, because this may rupture the larva and lead to a chronic foreign body reaction and secondary infection. There are anecdotal reports of larval rupture causing anaphylaxis. If possible, the larva should be removed in one piece; recurrent abscesses at the site of previous *Cuterebra* infestation suggest residual infection or remaining pieces of larva. The area should be thoroughly flushed with sterile saline, debrided (if necessary), and allowed to heal by granulation. Healing may be slow. Ivermectin has been described as a treatment for cats with CNS cuterebriasis. Diphenhydramine (4 mg/kg, IM) is administered 1–2 hr before ivermectin (400 mcg/kg, SC) and dexamethasone (0.1 mg/kg, IV). Ivermectin is not approved for use in cats.

FLEAS AND FLEA ALLERGY DERMATITIS

There are >2,200 species of fleas recognized worldwide. In North America, only a few species commonly infest dogs and cats: *Ctenocephalides felis* (the cat flea), *Ctenocephalides canis* (the dog flea), *Pulex simulans* (a flea of small mammals), and

Echidnophaga gallinacea (the poultry sticktight flea). However, by far the most prevalent flea on dogs and cats is *C. felis*. Cat fleas cause severe irritation in animals and people and are responsible for flea allergy dermatitis. They also serve as the vector of

typhus-like rickettsiae and *Bartonella* sp and are the intermediate host for filarid and cestode parasites. Cat fleas have been found to infest >50 different mammalian and avian hosts throughout the world. In North America, the most commonly infested hosts are domestic and wild canids, domestic and wild felids, raccoons, opossums, ferrets, and domestic rabbits.

Transmission, Epidemiology, and Pathogenesis:

Cat fleas deposit their eggs in the pelage of their host. The eggs are pearly white, oval with rounded ends, and 0.5 mm long. They readily fall from the pelage and drop onto bedding, carpet, or soil, where hatching occurs in ~1–6 days. Newly hatched flea larvae are 1–5 mm long, slender, white, segmented, and sparsely covered with short hairs. Larvae are free-living, feeding on organic debris found in their environment and on adult flea feces, which are essential for successful development. Flea larvae avoid direct light and actively move deep in carpet fibers or under organic debris (grass, branches, leaves, or soil).

Larvae are susceptible to desiccation, with prolonged exposures to relative humidity <50% being lethal. The areas within a home with the necessary humidity are limited, and suitable outdoor sites are even rarer. Flea development occurs outdoors only where the ground is shaded and moist (1%–20% soil moisture content) and where the flea-infested animal spends a significant amount of time so that adult flea feces will be deposited into the larval environment. In the indoor environment, flea larvae probably survive only in the protected microenvironment deep within carpet fibers, in cracks between hardwood floors in humid climates, and on unfinished concrete floors in damp basements. The larval stage usually lasts 5–11 days but may be prolonged for 2–3 wk, depending on availability of food and climatic conditions.

After completing its development, the mature larva produces a silk-like cocoon in which it pupates. The cocoon is ovoid, ~0.5 cm long, whitish, and loosely spun. Flea cocoons can be found in soil, under vegetation, in carpets, under furniture, and on animal bedding. Once the pupa has fully developed (1–2 wk), the adult flea can emerge from the cocoon when properly stimulated by physical pressure, carbon dioxide, substrate movement, or heat.

The preemerged adult (which is a fully formed adult flea) residing in the cocoon is the stage that can extend the longevity of the flea. If the preemerged adult does not

receive the proper stimulus to emerge, it can remain quiescent in the cocoon for several weeks until a suitable host arrives. Emergence can be delayed up to 350 days if preemerged adults are protected from desiccation. Newly emerging fleas move to the top of the carpet pile or vegetation, where they are more likely to encounter a passing host. Under ideal conditions of temperature (27°C [80.6°F]) and relative humidity (90%), a newly emerged cat flea can survive ~12 days before requiring a blood meal; at 50% relative humidity, this interval drops to ~3 days. It is these newly emerged unfed fleas that infest animals and bite people. There is generally minimal inter-host movement of cat fleas. However, it has been documented that before *C. felis* reaches reproductive status, there can be some limited movement on and off hosts. Cat fleas that have found a preferred host (eg, dog, cat, opossum, etc) and have initiated reproduction generally do not leave their host unless forced off by grooming or insecticides.

Depending on temperature and humidity, the entire life cycle of the cat flea can be completed in as little as 12–14 days or can be prolonged for up to 350 days. However, under typical household conditions with normal pet and human activity, cat fleas complete their life cycle in 3–8 wk.

Adults begin feeding almost immediately once they find a host. Female cat fleas can consume 13.6 µL of blood daily, which is 15 times their body weight. After rapid transit through the flea, the excreted blood dries within minutes into reddish black fecal pellets or long tubular coils (flea dirt). Fleas mate after feeding, and egg production begins within 24–48 hr of females taking their first blood meal. Female cat fleas can produce up to 40–50 eggs/day during peak egg production, averaging 27 eggs/day through 50 days. Individual females may continue to produce eggs for >100 days.

Cat fleas are susceptible to cold. No stage of the life cycle (egg, larva, pupa, or adult) can survive exposure to <3°C (37.4°F) for several days. Therefore, cat fleas survive winters in north temperate climates as adults on untreated dogs and cats or on small wild mammals (eg, raccoons or opossums) in the urban environment. As these animals pass through yards in the spring or set up nesting sites in crawl spaces or attics, the eggs laid by surviving female fleas drop off and subsequently develop to adults. Cat fleas may also survive the winter as preemerged adults in microenvironments protected from the cold.

Fleas can cause iron-deficiency anemia in heavily infested hosts, particularly in young animals. Fleas in the genus *Ctenocephalides* have been reported to produce anemia in poultry, dogs, cats, goats, calves, and sheep.
